ENCYCLOPÆDIA BRITANNICA.

MILAN.

MILAN (the ancient *Mediolanum*, Italian *Milano*, and German *Mailand*), a city of Austrian Italy, and capital of the Lombardo-Venetian kingdom, is situated on the small river Olona, in N. Lat. 45. 27. 35., and E. Long. 9. 5. 45. It stands nearly in the centre of the extensive fertile plain of Northern Italy, at an almost equal distance from the lower range of the Alps and from the Po, and about midway between the rivers Ticino (*Ticinus*) and Adda (*Addua*), with the former of which it is connected by means of the canal called Naviglio Grande, and with the latter by the canal of the Martesana. (For an account of the foundation and early history of Milan, see **MEDIOLANUM**.)

During the Gothic wars, Milan having espoused the Greek cause, was besieged and taken by the Goths under Uraia, a nephew of Vitiges, who, according to Procopius, put to the sword 300,000 of its male inhabitants, and reduced the women to slavery. From this great blow it did not recover for centuries. The metropolitan see was the only thing that it preserved of its former power and splendour. Under the Longobard kings it was the residence of one of the dukes appointed by Alboin, but it remained without any importance. Towards the end of the ninth century Archbishop Anspertus partially repaired its ancient walls. As late, however, as the tenth century much of the space inclosed within them was occupied by cultivated fields; the squares were used as meadows; most of the houses were of thatched wood; and, according to the quaint expression of its old historian, Landulphus senior, there was no good form of government, *ob nimiam hominum raritatem*.

In the year 924, however, Pavia having been captured and plundered by the followers of King Berengarius, many of its inhabitants repaired to Milan, which from that time began again to rise rapidly to prosperity. In 945 a diet was held in the city for the first time, by which Lotharius was elected king of Italy; and in 961 the Emperor Otho the Great was crowned as king of Italy in its old church of Santo Ambrogio. At the beginning of the 11th century (1042) a feud between the lower classes and the nobles, with the archbishop at their head, ended in the expulsion

of the latter from the town for two years. In 1066 the introduction of the celibacy of the clergy by Gregory VII. (Hildebrand) gave rise to great discords; yet Milan went on increasing in population and importance. It appointed *Consoli* for its government; and in the following century had so far asserted its independence, that the Emperor Frederic Barbarossa determined to reduce it to obedience. He descended into Italy in 1158, and soon obliged the Milanese to acknowledge his authority, on a stipulation from him that they should be allowed to elect their own consuls. Frederic, however, did not keep the terms which had been agreed to, but claimed by his agents the appointment of a *Podestà*, who should govern Milan in his name and under his authority. As those agents were driven out of the town, on the 16th April 1159, he passed a sentence by which the Milanese were condemned to slavery and their property to plunder. In 1161 he surrounded the town, and after a seven months' siege, compelled the inhabitants to surrender, and razed the city to the ground. Frederic was so proud of this achievement, that many of his diplomas were dated "*Post destructionem Mediolani*."

The fate of Milan awoke the sympathy and excited the indignation of the Lombard towns. Prompted by Pope Alexander III., who was at war with the Emperor, and aided by the agency of the friars, who were the unsuspected means of communication, they resolved to combine together for mutual protection. Deputies from the principal towns secretly assembled in the monastery of Pontida, near Bergamo, on the 7th of April 1167, and laid the foundation of a celebrated confederation known in the history of Italy as the *Lega Lombarda*. By the first article of the league they bound themselves to the restoration of Milan. Accordingly, whilst the Emperor was in the Romagna, the citizens of Cremona, Brescia, Bergamo, Mantua, and Verona marched towards Milan, and on the 27th April 1167, headed by a friar who carried the ensigns, escorted the Milanese home who had been dispersed among the neighbouring villages, and aided them in repairing the houses and raising the walls of their ruined town. On the first news of what

Milan. had happened, the Emperor hastened back to Lombardy, but the allied forces were so numerous that he found himself obliged to retire to Germany through Savoy, the only road that remained open to him. At the instigation of the town of Pavia, the Count of Savoy and the Marquis of Monserrat, Frederic again descended into Italy with a large army in 1174; but after a fruitless siege of the new town of Alexandria, he was met by the army of the League near Legnano, and completely defeated on the 29th of May 1176. At length the peace of Constance, June 25, 1183, secured the liberties of the Lombard towns.

The internal constitution of Milan at this time was framed of elements so discordant, that they must soon have led to the gradual centralization of power in a single person. The nobles were divided into two classes: the upper class had a council of 300, called *Credenza de' Consoli*, for out of them the consuls were chosen; the lower had their own council of 100 members, called *La Motta*. The rest of the people in 1198 constituted themselves into a body, and appointed a council of 500, which was called *Credenza di Santo Ambrogio*. As the supreme power resided in the union of these three councils, and their proceedings were not directed by any settled rules, it was so difficult to carry on the machinery of government, that they had recourse at length to a *Podestà*, or dictator, generally a native of another town, whose office was annual, and who had full power over the life and property of all the inhabitants. The first dictator was appointed in 1186.

The Emperor Frederic II., following the steps of his grandfather Frederic I., tried to subdue Milan. In 1237 he defeated the Milanese near Cortenova; and again, in 1239, invaded their territory with a large army, which was completely routed. In 1245 he renewed his attacks, but was unsuccessful.

Milan might now have enjoyed freedom and prosperity, but the civil dissensions between the people and the aristocracy, which had been kept in check by fear of the common enemy, were soon renewed, and led eventually to the complete extinction of their liberties. Out of gratitude to Pagano della Torre, Lord of Valsassina, who, after the defeat of Cortenova, had saved the remains of the army, the people chose him as *Podestà*, to protect them against the nobles; and at his death in 1241 they appointed in his place his nephew Martino della Torre, to whom they gave the title of *Anziano* (elder) *della Credenza di Santo Ambrogio*, with power to impose taxes. Martino formed a registry of all the lands and their owners; and in 1248 for the first time introduced the land-tax into the Milanese territory. Before his death he obtained a decree that his brother Philip should be named *Podestà* for life; but as Philip died after a short time, Napoleone, or Napo della Torre, a son of Pagano, was appointed *Anziano* for life. Under this humble name Napo was the despot of Milan; and in 1273 he obtained the dignity of Imperial Vicar from the Emperor Rudolph of Hapsburg, the founder of the House of Austria. Whilst in the full enjoyment of his power, many nobles whom he had persecuted and driven from Milan, led by an exile, Ottone Visconti, the Archbishop of Milan, surprised him, and made him prisoner at Desio on the 21st January 1277. Ottone was proclaimed lord of Milan, and with him originated the subsequent power of his house. Napo ended his days in an iron cage on the 16th August 1278.

With the exception of nine years, from 1302 to 1311, during which Mosca and Guido della Torre succeeded in restoring their family influence, the Viscontis, without having the name, were actually the sovereigns of Milan from 1277 to 1447, the year of the death of Filippo Maria, the last of that house. Their power was marked by tyranny and great cruelties. Azone and Giovanni were the only members of the house who showed any virtues. Many of them came to a violent end. Galeazzo I. died of an

illness contracted whilst in prison; Stefano died of poison; Marco was thrown out of a window; Luchino was poisoned by his own wife; Matteo II. was murdered by his brothers; Barnabo died of poison whilst imprisoned at Trezzo; and Giovanni Maria was murdered at the age of twenty-four. Giovan Galeazzo, called Count of Virtù, from a fief in France which his wife Isabella brought as dower, having obtained in 1395 the creation of his estates into a dukedom by the Emperor Wenzel, was the first of the family who bore the title of duke. Filippo Maria having died without legitimate offspring, the Milanese tried to restore the republican form of government; but after three years they were compelled by famine to surrender to Francesco Sforza, who had married Bianca Maria, a natural daughter of Filippo. Sforza entered Milan on the 26th February 1450, and was proclaimed duke. He transmitted his power to his descendants, who held it till 1535, the year in which the last of them, Francesco II., died without issue. At the extinction of this line, Milan and its duchy were a subject of contention between King Francis I. and the Emperor Charles V. In 1455 the Emperor agreed to give his daughter Maria in marriage to the Duke of Orleans, second son of Francis, with the duchy of Milan as her dower; but the untimely death of this prince having left the succession again open, Charles V., on the 5th July 1546, gave the duchy to his son Philip, afterwards Philip II. of Spain.

The history of Milan and its duchy, after it became a Spanish province, has already been sketched in this work under ITALY, and more especially under LOMBARDO-VENETIAN KINGDOM. An account of the events of which Milan was the scene in 1847-50 will be given under the head SARDINIA.

Milan was desolated several times by the plague, but never so severely as in 1630, when it lost 140,000 of its inhabitants. A powerful and heart-rending description of that fearful visitation may be found in Manzoni's well-known novel, *The Promessi Sposi*.

The modern town is nearly of a circular figure; it is walled and protected by a citadel built by Francesco Sforza, enlarged by Philip II., and much strengthened by the Austrians since 1849. The whole compass of the wall is nearly $7\frac{1}{2}$ English miles; and just outside of it runs a road called *Strada de Circonvallazione*. The town has an area of 8,182,389 square metres, one-half of which is occupied by 5114 houses; one-fourth by 348 streets, lanes, &c., and 64 squares; and one-fourth by gardens. Its average height above the sea is 450 feet. The longest part, from the Porta Romana to the Porta Sempione, is about 3600 yards; and the broadest part, from the Porta Ticinese to the Porta Orientale, is 3200 yards. The wall is furnished with ten gates, some of which are the most striking objects of the city. The most remarkable of these is the Porta Ticinese, which resembles the entrance to a Roman temple. It is built of granite, and consists of colossal columns of the Ionic order, with an appropriate entablature; and in connection with it is the fine bridge over the Naviglio Grande. The *Arco della Pace*, begun by Eugene Beauharnais in 1807, from a design of the Marquis Cagnola, was called originally *Arco del Sempione*, and was intended to celebrate Napoleon's victories in Germany and Italy. At the fall of Napoleon in 1814 it had scarcely risen to the impost of the smaller arches. In 1816 the works were resumed by the Austrians, who gave it its present name to commemorate the return of the peace, and changed the destination of the sculptures that ornament it. It was finally completed and inaugurated in 1838, at the time of the coronation of the Emperor Ferdinand II. The columns, of 6 feet in circumference and 40 feet in height, formed out of a single block of marble, are its most distinguishing ornaments. The arch resting on them, of a breadth nearly equal to that of Constantine, is

Milan.

{ Milan. ornamented with a car of bronze, to which six horses are harnessed, and in which the goddess of victory is seated. The whole building is of white marble, with the figures and bas-reliefs of bronze. The total cost was L.142,840.

There are in Milan few piazzas or squares, and none either large, fine, or even regular. The Piazza del Duomo is long, but narrow and disfigured by the booth-like shops and buildings that surround it. The Piazza de' Mercanti, though small, is remarkable as containing some remains of ancient Milan, and has in its centre a portico where the traders assemble. The Piazza Fontana has a fine fountain, with two excellent figures in marble. The Piazza d'Armi, formerly the Foro Bonaparte, is the best promenade in Milan. It is planted with trees, and is about 600 yards long and 540 broad. The streets of Milan are generally narrow and crooked, and rather gloomy from the height of the buildings. The Corso, or High Street, is an exception. It runs through the whole city, is nearly $2\frac{1}{2}$ miles in length, is of great breadth, and on both sides has magnificent and lofty houses. The streets are kept clean, and the pavement, which is composed of small pieces of marble or of granite, is far better than is usually seen in towns on the Continent.

Amongst the public buildings the *Duomo* or cathedral is the most remarkable. Next to St Peter's at Rome, it is the largest church in Italy. It is 486 feet in length, 288 feet in breadth between the transepts, and 252 in the body; the height of the crown of the vaulting of the nave is 153 feet, and of the highest pinnacle 355 feet. This vast edifice, dedicated to St Charles, was commenced so long ago as the year 1386. Under Napoleon large sums were drawn from the public revenue and applied to this structure; and since the restoration of the Austrian government 12,000 francs, or about L.500, have been paid monthly till the completion of the edifice. It is now almost completed. The outside of the church, which is wholly of white marble, and which in several places had become black from the weather, has been well rubbed, and now appears quite as white as the newer parts. There is no place from which a good view of this cathedral can be obtained. On three sides it is shut in by narrow streets, and only the majestic front, with its five colossal entrances, can be seen from the Piazza del Duomo. The general style of the building is Gothic; but in many of its details it is mixed with incongruous ornaments that detract from its beauty. A vast collection of figures from the hands of the most eminent statuary, to the number of more than 5000, are placed upon the walls, Gothic turrets, and pinnacles. They are images of various saints, all as large as life. Richly-ornamented galleries, with finely-carved volutes and roses, extend from the one tower to the other. The roof, which is a remarkable work of art, is reached by a winding staircase of two hundred steps, from which the labyrinth of pillars surrounding the spectator has a most singular effect. In the centre of the roof rises the majestic dome, on which is placed a bronze statue of the Virgin Mary. The church has five entrances, leading to a like number of divisions, which are formed by fifty-two octagonal marble pillars 86 feet in height, and bound together at the top by Gothic arches. The altars are numerous and richly ornamented, and along the floor a meridian line was drawn in 1786. The floor is composed of pieces of marble of different colours formed into various ornamental figures. The entrance to this edifice is very imposing, and the panorama from the top is one of the finest in Italy.

The other ecclesiastical edifices are numerous, and most of them of great interest. The Basilica of *St Ambrogio* is the most ancient mediæval structure in Milan. It was founded by St Ambrose in the year 387, and dedicated to SS. Gervasius and Protasius, and afterwards rebuilt in its present form by Archbishop Anspertus in the ninth century. Though repaired in 1631, its original features were pre-

served unaltered. It is a kind of museum for the history of the arts; and the gold and silver facing of the high altar is one of the most remarkable monuments of goldsmith's art in the ninth century. The church of *St Eustorgio*, near the Porta Ticinese, rebuilt in the thirteenth century, is the most interesting repository of family monuments in Milan, though many of them were greatly defaced by the French at the end of the last century. *St Lorenzo*, rebuilt in the sixteenth century upon the plan of St Vitale at Ravenna, contains several fine pictures. *Sta. Maria presso San Celso*, or *La Madonna*, is a magnificent building, and one of the richest churches in Milan. *St Fedele* unites simplicity with great extent. *St Carlo Borromeo* was built in 1838 by contribution raised amongst the inhabitants after the first invasion of the cholera.

The celebrated fresco-painting of the "Last Supper," by Leonardo da Vinci, remains in what was formerly the refectory of the Dominican convent annexed to the church of *Sta. Maria delle Grazie*. It has been ruined by neglect and repainting; while the saline efflorescence which has extended itself over the wall on which it is painted has destroyed the glow of the colours, and in many places the paint has peeled off, whilst in others it is covered with mould.

Several of the civic buildings are deserving of notice. The royal palace, though the residence of the viceroy, has by no means an imposing exterior. It contains the magnificent throne apartment and the fresco-paintings of Appiani. The palace of the archbishop is a fine piece of architecture, with an admirable collection of paintings. The *Broletto*, or town-hall, is an extensive building with two courts and colonnades, erected by Filippo Maria Visconti for the Count of Carmagnola. Besides these edifices, the palaces of the families Litta, Melzi, Borromeo, Trivulzi, Vismara, Pozzi, and numerous others, are of great extent as well as of various kinds of architecture, and contain many valuable paintings.

The institutions devoted to science, literature, and the fine arts are the most distinguishing objects on which the Milanese can pride themselves. The Ambrosian Library, founded by Cardinal Borromeo, contains about 100,000 printed books, great part of which are arranged in a lofty hall, and about 18,000 MSS. bound into 5500 vols. Many of the MSS. were brought from the suppressed monastery of Bobbio, and are celebrated for the *palimpsests* discovered among them by Angelo Mai. In connection with the library are apartments containing collections of pictures and of statuary, both of great merit. The Brera, formerly the college of the Jesuits, and, still earlier, of a brotherhood called *Umiliati*, is devoted to science, and is connected with the university of Pavia. The interior square of the building is surrounded with colonnades—on the ground floor composed of Doric, and on the upper floor with Ionic pillars, forming open halls. The tower of this edifice is employed as an astronomical observatory, and the garden is made use of for the purposes of botany. The ground floor is adapted for lecture-rooms, and the upper floor contains a library of more than 125,000 volumes and numerous valuable manuscripts. Adjoining it is the picture gallery, containing many excellent productions, especially some most valuable fresco-paintings, which have been preserved and removed from the churches and monasteries in and around the city. On the upper storey are apartments containing numerous casts of ancient and modern sculpture in plaster of Paris, and also a collection of coins and medals. Besides these public institutions, there are many collections of old and valuable works in the libraries Fagnani, Melzi, Reina, Litta, Archinto, Trivulzi, &c.

In this large city, where the destitute, the aged, and the infirm are very numerous, the institutions for their relief are upon a commensurate scale, and possess property to the

{ Milan.

Milazzo. amount of nearly L.7,000,000. The Ospedale Maggiore, begun by Francesco Sforza in 1456, is a prodigious range of building, with a beautiful front of 450 feet in length, entered by magnificent portals. The usual number of patients contained in it is about 1600, but it can contain as many as 2000. The annual average number of patients admitted is 20,000; of deaths, 2700. With this is connected the Foundling Hospital, in which nearly 1000 children are maintained within the walls, and about 2000 are sent to board in the villages around the city. There is also a large lying-in hospital; a lunatic asylum, in which are kept generally 420 insane persons; the lazaretto, containing many small houses without the gates, as a precaution against the plague; the Trivulzi, which contains 600 poor of both sexes, above seventy years of age, who are maintained by property bequeathed to it by the noble family of that name; an orphan-house, which supports 350 young persons; and several smaller institutions. Besides these, the monks and the nuns of the order of mercy have each their benevolent establishments.

The places of amusement are both numerous and extensive. The opera-house, *La Scala*, built in 1776 on the site of an ancient church of that name, is, next to St Carlo at Naples, the largest theatre in Europe. It contains 240 boxes in six tiers, one above the other, and has seats for 800 persons in the pit, besides standing room in the centre and both sides of it, so that it is calculated to contain nearly 5000 spectators. There is also the imperial theatre of the Canobbiana, which can hold 2500 spectators; and three or four small private theatres.

The city, including the suburbs, contained in 1854 168,596 inhabitants (exclusive of the Austrian garrison), of whom 84,039 were men and 84,557 were women. They formed 37,300 families, and were classified as follows:—

Married.	Unmarried.	Do. under 18.	Widowers.	Celibacy by vow.	Total.
58,161	60,504	32,158	16,112	1661	168,596

There were among them 16,640, or 1 in 10, proprietors; 6984 employés, in actual service or pensioned off; 59,392 tradesmen, merchants, and artists; 4078 who followed liberal professions; and 10,560, or 1 in 15, were supported in the charitable institutions. 31,674 inhabitants above seven years of age, and 2893 under seven, frequented public, private, or charitable schools; giving 1 student for 5 inhabitants. The average mortality was 1 in 35. One-third of the population died under 19; one-fifth from 19 to 25; one-fifth from 26 to 40; one-eighth from 40 to 60; one-tenth from 61 to 89; only 5 died above 90 years of age.

Milan has often been called the Paris of the south. It has an appearance of wealth and industry not generally met with in Italian towns. Its chief wholesale trade consists in silk, either raw or spun, and in cheese; for the particulars of which see **LOMBARDY**. As Milan is a kind of metropolis to the north of Italy, and resorted to in the winter by the rich, the tradesmen are at that time of the year in full occupation; but at other seasons they find little employment, except what arises from the foreign visitors. A railway connects Milan and Venice, with the exception of a temporary break of some 15 miles between Treviglio and Bergamo; while the Turin railroad extends as far as Novara, 27 miles west of Milan.

MILAZZO, or **MELAZZO** (the ancient *Mylæ*), a fortified seaport-town of Sicily, intendency of Messina, on a narrow rocky promontory on the northern coast of the island, 15 miles W. of Messina. It consists of an upper and a lower town, both irregularly built, and containing no public buildings of note. It is principally distinguished for its fortifications, its citadel, and other military works, being so strong by nature and art as to be reckoned almost impregnable. The harbour is good, and a large export trade is carried on in wine, silk, tunny, fruit, corn, and oil. The

inhabitants are chiefly employed in the tunny fishery and as sailors. Pop. 8000.

MILBORNE PORT, a decayed market-town and borough of England, county of Somerset, on the Ivel, 28 miles E. by S. of Taunton. It sent two members to Parliament in the reign of Edward I.; and from Charles I. till disfranchised by the Reform Act. An ancient guildhall stands in the High Street, and the parish church is a large cruciform edifice, surmounted by a massive square tower. Leather-dressing and glove-making are the principal trades carried on. Pop. of parish (1851) 1746.

MILDENHALL, a market-town of England, county of Suffolk, on the Lark, 70 miles N.N.E. from London. The town is irregularly laid out, but the houses are generally well built. The parish church is a large and handsome edifice, with a richly carved roof and a lofty tower. The inhabitants are chiefly engaged in agriculture, and by means of the Lark, which is here navigable, there is some trade. Pop. of parish (1851) 4374.

MILETUS, a Greek city of Ionia, in Asia Minor, was situated on the northern side of the peninsula of Mt. Grion, at the entrance of the Gulf of Latmus, nearly opposite the mouth of the Mæander, from which it was 80 stadia, or 10 miles distant. At the time of the Ionian emigration to Asia Minor, Miletus was a town peopled by Carians, in whose territory it stood. It is said to have belonged originally to the Leleges, and to have been afterwards occupied by a band of Cretans, under Sarpedon the brother of Minos. When the Ionians arrived in Asia, Neleus and a company of his followers seized Miletus, put to death all the men, and took the women for their wives. Miletus thus became one of the twelve cities of the Ionian league, and was the farthest S. of their number. The town possessed four separate harbours, large and commodious, one of which was capable of containing a large fleet; and Miletus was remarkable for naval and commercial activity, and for the number of its colonies in the most distant parts of the then known world. These are said to have been in number between seventy and eighty; and the most important of them were—Abydus, Lampsacus, Parium, Proconnesus, Cyzicus, Heraclea, Sinope, Amisus, Phasis, Panticapæum, on the Cimmerian Bosphorus; Obbia, at the mouth of the Borysthenes; Istria, at the mouth of the Danube; and Naucratis, in Egypt. And though their attention was chiefly turned towards the E. and N., their ships also navigated the Mediterranean, and even passed the Pillars of Hercules. Of the internal history of Miletus in early times but little is known. According to Herodotus, it seems to have been much distracted by factions, which rose to such a height, that after a contest which had lasted for two generations, the intervention of the Persians was necessary to allay the discord. The Milesians were frequently engaged in wars with other states, both in Greece and in Asia. They assisted Eretria against Chalcis, in the contest for the sovereignty of Eubœa; and they engaged in a war between Chios and Erythræ, on the side of the former. But their most important war was that against the Lydians, from 623 to 612 B.C., when Miletus was governed by Thrasybulus, a friend of Periander of Corinth, and during the reigns of Sadyattes and Alyattes, two successive kings of Lydia. A peace was at last concluded, which left Miletus independent; although in the reign of Cræsus, the successor of Alyattes, the Milesians seem to have consented to pay tribute to Lydia; a concession which they transferred to Cyrus when he conquered that country. Miletus was afterwards governed in succession by Histigeus and Aristagoras, who contributed greatly to excite the Ionians to cast off the Persian yoke. In this revolt, which began in 500 B.C., Miletus took part; but it was taken by the Persians in 494 B.C., and its inhabitants transported to the banks of the Tigris. The town was given to the

Frontier.

Carians; and although it recovered its liberty after the battle of Mycale in 479 B.C., it never regained its former greatness and prosperity. The fall of Miletus gave so much concern to the Greeks, that when the poet Phrynichus made it the subject of a tragedy, the Athenians were affected to tears, forbade the piece to be represented, and imposed a heavy fine on the author. Miletus is celebrated as the birth-place of Thales, Anaximander, and Anaximenes, the principal philosophers of the Ionic school; and of Cadmus and Hecataeus, two of the earliest chroniclers of Greece.

MILFORD, a seaport and market-town of Wales, county of Pembroke, on the N. side of Milford Haven, 12 miles W.N.W. of Pembroke. The town is pleasantly situated, and well and regularly built of stone; the principal streets, three in number, run along the shore from E. to W., and other shorter ones cross them at right angles. The parish church, which is remarkable for its high tower and painted windows, is situated at the E. end of the town. The town has also a market-house and custom-house. In the neighbourhood of Milford are to be seen the remains of an old religious establishment, known by the name of Pill Priory. The town of Milford is of very recent origin, having been founded in 1790; but it rose very rapidly to be a large and prosperous town. It had a royal dockyard for building men-of-war, and an arsenal; and it was a station in the mail route to Ireland. But these sources of its prosperity did not long continue; the dockyard was transferred to the other side of the Haven, and soon after, the starting-place of the packets was also removed to the S. The town, however, still shows some activity in ship-building; and the excellent roadstead contributes much to the prosperity and importance of the town. The shipping has been largely increased by the South Wales railway, which connects this port with the principal towns in the kingdom. Milford has a considerable trade, chiefly in timber. The oysters got on this coast are excellent, and they are dredged to a considerable extent. Pop. (1851) 2837.

MILFORD HAVEN, an arm of the sea in the county of Pembroke, Wales, has its entrance towards the S., but soon turns, and stretches E. for 12 miles, from Dale near its mouth to Pembroke Ferry, with a breadth varying from 1 to 3 miles. It is one of the best harbours in Europe, being sufficiently large to accommodate the whole British navy in good anchorage, and in a sheltered position. On account, however, of its distance from the Channel, and the inconvenience of its position, it is not of so much importance, either as a harbour for men-of-war or as a commercial port, as it would otherwise be. It has numerous smaller creeks running into the land, and the scenery is in some places very beautiful; the shores being lined with gently sloping hills. There is a lighthouse at the entrance called St Anne's light, near the village of Dale. In the reign of Henry IV. a French fleet anchored in Milford Haven, with a body of 1200 men, to assist Owen Glendwr; and here also Henry VII. landed, shortly before the battle of Bosworth Field.

MILHAU, (the ancient *Æmilianum*), a town of France, department of Aveyron, and capital of a cognominal arrondissement, is situated on the right bank of the river Tarn, 30 miles S.E. of Rodez. It is generally well built, though its streets, with the exception of the principal one, are narrow. It has tribunals of primary instance and commerce, a communal college, society of agriculture, &c.; and was one of the strongholds of the Protestants during the French religious wars. The chief manufactures are silk-twist, woollen cloth, leather, and leather gloves. It carries on a considerable trade in cheese, cattle, wool, timber, wine, fruits, &c. Pop. (1851) 9869.

MILITARY FRONTIER (*Militargrenze*), a tract of country in the Austrian dominions, extending along the

borders of Turkey from the Adriatic to Transylvania, is bounded on the N. by Croatia, Slavonia, Hungary, and Transylvania, and S. by Bosnia, Servia, and Wallachia, having a length of nearly 1000 miles, and an area of about 16,000 square miles. This district derives its name from the military government by which it is ruled, and it serves to defend the Austrian empire against the sudden inroads of the Turks. The inhabitants are at once peasants and soldiers, and they compose a force of 45,000 men, constantly under arms in the time of peace. In 1815 there was a body of 62,000. They hold their land on condition of military service, and while at home receive no further remuneration; but when they are led to other parts they are entitled to the usual pay of the Austrian army. They are divided into 17 regiments of infantry and 1 of hussars, besides a battalion of boatmen, called *Tschaikisten*, who cruise on the large rivers of the district in boats armed with guns. Each regiment consists of two battalions that serve in turn, and the colonel of the regiment exercises civil as well as military authority. The supreme government is in the hands of the Aulic council of war (*Hofkriegsrath*) at Vienna. Under this there are four general commandos, which have their seats at Agram, Temesvar, Peterwardein, and Hermannstadt. Every male between the ages of 18 and 60 is liable to military service, and is occupied with such duties for about eight months in the year. During the remainder of their time they are employed in agriculture and pastoral occupations; but, owing to the little time which they can spare from military duty, the agriculture of the district is in a very backward state. They live together in families, which possess land in common; and all the members are obliged to perform their share in the cultivation of the soil. The produce is divided equally among all the labourers; but the heads of the family receive a double share. Many of the families contain as many as eighty members. The people are for the most part Slavonian origin; but there are also Croatians, Servians, Wallachians, and other tribes. They are intelligent and clever, patriotic, and strongly attached to the imperial family. The first establishment of this military government was in the sixteenth century, in the reign of Ferdinand I., who settled military colonists in a part of Croatia. The system was afterwards extended and perfected, especially by Prince Eugene of Savoy towards the end of the seventeenth, and by Field Marshal Lascy in the eighteenth century. The present system of government was established in 1807. The whole country is divided into four parts,—the Croatian, Slavonian, Hungarian, and Transylvanian Military Frontier. Pop. (1851) 1,009,109.

MILITARY or MARTIAL LAW, is that branch of the laws of war which respects military discipline, or the government and control of persons employed in the operations or for the purposes of war. Military law is not exclusive of the common law; for a man by becoming a soldier does not cease to be a citizen or a member of the British commonwealth. He is a citizen still, capable of performing the duties of a subject, and answerable in the ordinary course of law for his conduct in that capacity. Martial law is therefore a system of rule superadded to the common law, for regulating the citizen in his additional character of soldier; a temporary character assumed for a special end, and to be laid aside when that end has been attained, and when the disturbance which gave occasion to it has subsided. For, as the law knows nothing of a mere soldier, or one bred up to no other profession than that of arms, so a perpetual standing army is against the principles of the constitution, and if without consent of parliament, is clearly against law.

Throughout all Europe, in the feudal times, property was commonly held upon condition of military service; and the possessors of land were, by virtue of their right, at once its

Military or
Martial
Law.

Military or
Martial
Law.

cultivators in peace and its defenders in war. But the fetters of land under the feudal system were incompatible with a state of commerce, and the arbitrary power of lords over their vassals was adverse to civil liberty; its strictness declined; the services of tenants were commuted for money, and with money were purchased the services of mercenaries, who were ready to make war a trade. The disorders incident to the disbanding of these troops, the changes which had taken place in the mode of warfare, and the necessity of attending to the balance of power in Europe, all concurred to suggest the idea of a disciplined standing army, which was formed first in France, and then in the other states of Europe. The military despotism, however, which ensued on the continent was in this country happily prevented by the spirit of a free people; and at the Revolution it was asserted and declared, that the raising or keeping up a standing army within the kingdom, in time of peace, without consent of parliament, is contrary to law. The expediency of a standing army is admitted, and at the same time the liberties of the people are maintained. A standing army therefore exists, but primarily for the benefit, because only with the consent, of the people.

In early times the king's justiciar was *caput legis et militiae*; at the head not only of the law, but also of the military force of the kingdom. But in England, on the division of the *aula regis*, the constable and marischal presided over a court of chivalry for the determination of matters of honour and arms. From time to time, however, other tribunals were subsequently instituted for the administration of martial law; and at length, after the Revolution, when, in addition to the militia and other local troops of the kingdom, a regular standing army was judged necessary for the safety of the realm, for the defence of the possessions of the crown, and for the preservation of the balance of power in Europe, acts were passed for the maintenance of military order and discipline. Scotland differed from England in this respect, that there was here no distribution of the powers of the lord justiciar, such as took place in England, nor was there ever any court of chivalry. In other respects the two countries were, in as far as concerns martial law, very much alike.

The first of the military acts passed after the Revolution was occasioned by a mutiny in a body of English and Scotch troops (amongst whom were the regiment of dragoons now called the Scotch Greys, and the Royal Scotch regiment of foot), on being ordered to Holland to replace some of the troops of that country which King William had brought over with him. The circumstance was communicated to parliament, and on the 3d April 1689 an act was passed for punishing mutiny, desertion, &c., which has been renewed annually by parliament down to the present day. It authorized the king to grant commissions to certain officers to hold courts-martial for the trial of crimes committed by officers and soldiers; and this act, which has been renewed from time to time, has since the Union been extended to Scotland.

An act of the same nature was passed in the parliament of England, 13 Cha. II. stat. i. c. 9, authorizing the lord high admiral to grant commission to inferior vice-admirals, &c., to assemble courts-martial for the trial of offences committed at sea by officers, marines, or others in the king's naval service. But this statute was in many points altered by subsequent enactments, till at last all the laws relating to courts-martial for the sea service were reduced into one act, applying equally to the whole United Kingdom, namely, 22 Geo. II. c. 33, explained and amended by 19 Geo. III. c. 17.

The more recent statutes for the government of the forces, naval and military, are 1 Will. IV. c. 14, 15; 2 and 3 Will. IV. c. 23, 28; 3 and 4 Will. IV. c. 5, 6; 4 and 5 Will. IV. c. 4, 5, &c. During the reign of Victoria they

Militia.

have been as follows:—2 and 3 Vict. c. 5; 3 and 4 Vict. c. 6 and 37; 4 and 5 Vict. c. 2; 5 and 6 Vict. c. 12; 6 and 7 Vict. c. 3; 7 and 8 Vict. c. 9; 8 and 9 Vict. c. 8; 9 and 10 Vict. c. 11; 10 and 11 Vict. c. 12; 11 and 12 Vict. c. 11; 12 and 13 Vict. c. 10; 13 and 14 Vict. c. 5; 14 and 15 Vict. c. 6; 15 and 16 Vict. c. 7; 16 and 17 Vict. c. 9; 17 and 18 Vict. c. 4; 19 and 20 Vict. c. 10; 20 Vict. c. 13; which brings down the statutes respecting military law to March 21, 1857. The judgments of courts-martial, like those of other courts, are liable to be taken cognisance of in the superior courts of common law, and the members punished for illegal proceedings, and for all wilful and corrupt abuse of authority against the known, obvious, and common principles of justice. (See Grose's *Military Antiquities*; Tytler on *Courts-Martial*; Adye on *Courts-Martial*; M'Arthur on *Courts-Martial*; and Napier's *Remarks on Military Law*.)

MILITIA, from the Latin *miles*, a soldier, in its original signification, means warfare, the qualification of soldiership, or the military body. In this last signification it became incorporated with the English language. It is now used to distinguish, from the regular forces, the body of citizens who may be annually called out for a limited time, and embodied on occasions of emergency. As the system out of which the present militia has arisen existed previously to the establishment of a mercenary army, and frequently constituted the sole military organization of its time, a historical sketch of the institution will involve to a certain extent a general view of the military state of Britain during the earlier periods of our history.

Any account of the military system of the Saxons, especially when we approach the era of the Norman Conquest, becomes involved in the great question as to the extent to which feudal practices had been adopted in England previous to that event. It has, however, been distinctly ascertained, that land, amongst the Anglo-Saxons, became not only the reward of military services performed, but the stipulated wages of their continuation. Thus there came to be a connection between the performance of services to a chief and the holding of land under him; the soldier or thane possessing the land on the condition of performing military duties, but not, as by the mature usages of the feudal system, rendering the service as an incident of the tenure of the land. The grants so made were generally for a contingent period, and were revocable from a vassal unfit to perform his military engagements; and we find amongst them a species of transaction so complicated as grants to churchmen, on the condition of their making provision for the performance of the military duties they were personally disqualified from undertaking. (Sir Francis Palgrave's *Rise and Progress of the English Commonwealth; Proofs and Illustrations*, ccxx.) The oath of the vassal was personal and conditional, and had no reference to the land as a bond of union. (Allen *On the Rise and Growth of the Royal Prerogative*, Ap. xxii.) It was the duty of the superior to protect his follower, and when he ceased to do so, the vassal was relieved from obedience; but desertion was viewed as a crime of great magnitude. Those freemen who had undertaken to perform military service in return for lands were entitled, like the clients of the Romans, to select their own "Hlafords" or patrons; but this class of followers seems to have gradually decreased towards the era of the Conquest, when it would appear from Domesday-book that all land was, or was presumed to be, held of a superior. It was perhaps for the furtherance of such a principle, without the invasion of existing free rights in property, that an exception sometimes appears in favour of the tenant:—*Et poterat ire cum ea (terra) ad quem vellet Dominum*; intimating that he might hold his land of whatsoever lord he chose.

Whatever right the patron may have had to the exclu-

Militia. sive military services of his dependent, it undoubtedly yielded to the claim of the state to the assistance of every freeman in cases of invasion or rebellion. It is probable that when the national force, denominated the *Fyrd*, was brought into existence, the right of patronage gave the superior no further power than that of leading his dependents when they joined the general host. The approach to any decision on this point is impeded by many difficulties, arising from the incongruities in the practice of different periods and of different parts of the country, and the absence of any contemporary treatise explanatory of the general rules and the reason of the apparent exceptions. It is thus that on some occasions the right of the Hlaford to command his followers is spoken of without any reference to the paramount claims of the public, whilst elsewhere we find the community arrayed by command of the sovereign, without reference to the circumstance that two distinct classes are to appear in the field, in the respective position of patrons and vassals. "From the earliest period," says Sir Francis Palgrave, "to which our documents can reach, we find the *Fyrd* appearing as a general armament of the people, comprehending every rank, though under different obligations and penalties. If the *Sithcund-man*, being a landholder, remained at home, he forfeited all his land; sixty shillings was his fine; whilst thirty shillings was the *Fyrd-wite* of the churl, and to the last it continued a levy of all the population of the country." (*Proofs and Illustrations*, ut supra, ccclxviii.) Sir William Blackstone and others include the national militia amongst the improvements attributed to the inventive genius of the great Alfred. The *Fyrd*, however, is of earlier origin. In the laws attributed to Edward the Confessor, the authenticity of which is justly doubted, though they are certainly the work of some one well acquainted with the Anglo-Saxon constitution, there are regulations for the organization and discipline of the *Fyrd*, probably embodying those improvements of Alfred which procured him the credit of having planned the system. These regulations adapt the arms to be provided by each freeman to a scale of wealth; forbid their being sold or pledged under penalties; provide for their descending to heirs; and appoint annual exhibitions, which, in order to baffle attempts to display the same weapons in different districts, were to take place simultaneously all over the country. (*Leges Edwardi*, apud Wilkins, sect. 35.) The command was given to district leaders called "Heretochs," who, it is stated, were like the *vice-comites* or sheriffs, elected by their respective districts in full folk-mote. Sir William Blackstone observes, that the power thus vested in the people proved dangerous to the community, by erecting a rival to the royal prerogative; and he refers to this source of influence the treachery of Eric Streone, and the usurpation of Harold. Whatever the theory of the Anglo-Saxon constitution may have admitted, however, it does not appear, from the history of the period, that the voice of the people regularly influenced the command of the natural force; and undoubtedly, in the instances cited, the power unduly used had been otherwise obtained.

The Norman Conquest did not produce so much effect by altering the system so established, as by bringing the new engine of feudalism to act in concert with it. The king was then the commander of two separate forces. His feudal army was furnished by the tenants of his knights' fees, for each of which he could demand the service of one knight or of two esquires for forty days. These were his personal followers during their period of service, and were liable to be employed either at home or abroad. But the absolute demand on his services was inconvenient to the vassal, and the limitation of the period was often no less so to the king. Hence those who were partial to the occupation of war frequently remained with the army beyond their assigned period for a stipulated remuneration, whilst

others got their services commuted into a money-payment, which afterwards merged into the oppressive exaction of scutage. Whilst this new species of force came into operation, the *Fyrd* of the Saxons still remained in existence. It afterwards was the source whence arose two distinct institutions; the *posse comitatus*, liable to be called out by the sheriff to keep the king's peace; and the militia force of the present day.

In the celebrated "assize of arms" of 1181, we find the *Fyrd* of the Anglo-Saxons in its original purity. All freemen are appointed to have arms in their possession, according to a scale of ranks, which consists, first, of the holders of a knight's fee; secondly, of the possessors of chattels or rents to the extent of sixteen merks; thirdly, of the holders of similar property to the value of ten merks; and, lastly, of all other burgesses and freemen (Wilkins, 296). The *Fyrd*, with its periodical exhibitions of arms, was recognised as late as the year 1285, when, by the statute of Winchester (13 Ed. I., st. ii., c. 6), the scale of arms assigned to the respective ranks was revised. The part of the act which enforces the keeping of arms was adjusted to the progress of the art of war in 1558 (4th and 5th Ph. and M. c. 2), and finally abolished in 1604 (1st Jac. I., c. 25, sect. 46).

Meanwhile practices commenced which gave rise to much subsequent dispute respecting the question, how far the right of the monarch to demand the military assistance of his subjects in such wars as he chose to prosecute was restricted. Many apparent anomalies in the constitution of this early period may be explained by reflecting that the Anglo-Saxon people continued to cherish certain privileges and customs which the Norman monarchs were often unable openly to abolish, whilst they were frequently powerful enough to infringe them. The annual array was an institution with which they naturally tampered, finding it their interest to amalgamate it with their feudal prerogatives. On the other hand, there were no definite limits to the prerogative, which insinuated itself wherever it was not practically checked. Accordingly we find parliament avoiding for some time any distinct recognition of the prerogative of the crown, or the privileges of the subject, and acting on the defensive against the former. Thus, by statute 1st Ed. III., c. 5, "The king wills, that no man from henceforth shall be charged to arm himself, otherwise than he was wont in the times of his progenitors kings of England; and that no man be compelled to go out of his shire but where necessity requireth, and sudden coming of strange enemies into the realm; and that it shall be done as hath been used in times past for the defence of the realm." The seventh chapter of the same statute gives redress on complaints that commissioners appointed to raise soldiers had been chargeable to the shires; and by the instructions to the sheriffs in the 10th Ed. III., stat. ii., money so exacted is directed to be returned. More decided attempts to amalgamate the assize of arms with the feudal force appear to have been opposed in 1351, when by 25th Ed. III., stat. v., c. 8, it was enacted that "no man shall be constrained to find men of arms, hobelers nor archers, other than those who shall hold by such services, if it be not by common assent and grant made in parliament."

At an early period, the crown gradually enlarged its military authority by issuing commissions of array. These writs, which were at first probably mere authorities to individuals to use the royal name and influence in collecting troops, came from practice to be viewed as emanating from the prerogative. In that anxiety to avoid collision with the crown which distinguishes many of the old acts of parliament, they are frequently alluded to without being either sanctioned or condemned. A singular instance of apparently intentional ambiguity occurs in 1st Ed. III., stat. ii., c. 15, which was avowedly passed for the relief of indivi-

Militia.

Militia.

duals who, at the suggestion of "false and evil counselors" had been prevailed on by "duress" to come under burdensome obligations to perform military duties. The contracts are cancelled with a sort of oracular qualification, evidently inserted as the nominal price of a real concession: "Considering that such writings were made to the king's dishonour, sithens that every man is bound to do to the king as his liege lord all that pertaineth to him, without any manner of writing." In the fifth year of Henry IV. a statute was passed limiting the form and authority of commissions of array. It involves the anticipation of foreign invasion, empowers the commissioners in such circumstances to array and train all men-at-arms, to cause all able-bodied men to arm themselves according to their substance, to amerce those unable to bear arms in a similarly adjusted ratio, and to require the services of persons so armed on the sea-shore, or elsewhere, at the moment of danger. It is singular that this statute, which forms the only legislative authority to which Charles I. finally appealed in the celebrated struggle for the command of the militia, has never been conceived of sufficient importance to be printed in any collection of the statutes, and seems to have been accidentally discovered in manuscript by some of the crown officers (Rush. *Hist. Col.*, part iii., vol. i. 661-9). It was indeed, like the last cited statute, an act of grace, having been passed for the protection of the persons nominated as commissioners, who, according to the preamble, were liable to many penalties and forfeitures in the performance of their assigned duties. It is worthy of note, as bearing on the extent of the authority intended to be conferred by this act, that during the previous year (by 4th Hen. IV., c. 13) the enactments above referred to, checking the encroachments of the royal authority, were all jealously confirmed; the holders of lands in Wales and of military fiefs, and persons who had bound themselves by contract to perform military services, being specially excepted. During the Tudor dynasty, the declaratory limitations attempted by the old statutes were undoubtedly little respected by the crown, and forced levies were made on many occasions, when the necessities contemplated by the acts could be brought forward as a nominal justification, without being minutely questioned. A statute of the year 1558 (4th and 5th Phil. and M. c. 3) appears at first sight to give full sanction to the right of impressment; but an observation of the circumstances in which the act was to be enforced, and reference to a previous act which it professed to amend, show that it was intended for the discipline of those who had become soldiers, and to prevent their desertion. During the Long Parliament, by an act granting the temporary power of impressing as many men as the king and both houses of parliament might appoint (16th Car. I., c. 28), the limitations were again confirmed; and it was declared, that by the law of the realm the subject ought not to be impressed or compelled to go beyond his county, &c., in the same terms as the statute of the first of Edward III.

Such was the state of matters when, in the celebrated dispute between Charles I. and the parliament regarding the right to command the militia, it was maintained on the one hand that the preservation of the peace of the country, and its protection from foreign invaders, were the unalienable privileges of the crown, and involved the right to command all armies, and to demand on all occasions the military service of the lieges; and, on the other, that such privileges existed in no individual without the consent of both houses of parliament; whilst it was urged, first in the form of an ordinance, and next in that of a bill, that the king should consent to the militia being placed in the hands of commissioners named by parliament. Although the statutes above referred to show that in moments of danger the king was so far the guardian of the peace, that he was entitled to put himself at the head of the persons bound to keep them-

selves in readiness for such occasions, and the practice had been undoubtedly still more favourable to the prerogative, neither an act of the legislature, nor any uninterrupted train of precedents, had given the monarch the unlimited military command which he arrogated. At an unfortunate time for the adjustment of such a question, it had to be settled between the conflicting branches of the legislature; and Whitelocke at least approached the truth when he said, he apprehended "that the power of the militia is neither in the king only, nor in the parliament; and if the law hath placed it anywhere, it is both in the king and parliament, when they join together;" though the state of matters equivocally illustrated his remark in continuation, that "it is a wise institution of our law not to settle this power anywhere, but rather to leave it *in dubio*, or *in nubibus*, that the people might be kept in ignorance thereof, as a thing not fit to be known nor to be pried into." Arguments founded on precedent and the nature of the constitution were at that juncture, however, merely like the diplomatic manœuvres preceding an international war. Each party was calculating its strength for the approaching conflict; and if their respective rights were so earnestly insisted on by either side, with any other view than that of colouring the real grounds of the rupture, it was that of securing the wavering by a show of adherence to constitutional principles. In a short time each party mustered its own forces in its own way.

In the parliament which was summoned after the Restoration, effectual means were taken by two statutes (13th Car. II., c. 6, and 13th and 14th Car. II., c. 3), which probably would not have been passed by the convention parliament, to put an end to any doubts as to the prerogative on this point. It was declared, that "the sole supreme government, command, and disposition of the militia, and of all forces by sea and land, and of all forts and places of strength, is, and by the laws of England ever was, the undoubted right of his majesty and his royal predecessors;" and lieutenants and their deputies were empowered to charge their counties to provide horse and foot soldiers, according to a fixed scale of property. The system thus constructed was slightly amended in the years 1699, 1714, and 1743.

In 1756, when the large standing force, which the position of Britain rendered it expedient to keep up, was made more unpopular by the introduction of the Hanoverian mercenaries, a bill to reconstruct the militia passed through the House of Commons under the auspices of Mr Charles Townshend and his friends, but was rejected in the House of Lords by 59 to 23. With some difficulty the measure was carried in 1757; but, though approved of by a large party, its practical enforcement frequently produced discontent and local disturbance. In 1762 the system was improved, and several acts were afterwards passed amending particular departments. In 1802 the militia laws of England and Scotland were consolidated by 42d Geo. III., c. 90 and 91; and these statutes, with that of 49th Geo. III., c. 120, applicable to Ireland, and the later acts of 15th and 16th Vict., c. 50; 17th and 18th Vict., c. 13, 105 and 106; and 18th and 19th Vict., c. 1, 57, 100, and 106—contain the law applicable to the militia of the United Kingdom. Before giving such a brief selection from the many minute regulations prescribed by these statutes, as a work of general reference is expected to contain, we may be permitted to glance at the origin of the militias of Scotland and Ireland.

In Scotland there seems never to have been, except in burghs, a national force for the defence of the citizens, like the Fyrd of the Saxons. The earliest acts of parliament, however, enforce practice in the bow, of which the efficiency had been so dearly learned in the English wars; whilst periodical "wapenshawings" are directed to be held, in which each individual should be armed upon a scale

Militia.

Militia. vaguely proportioned to his property. (Acts, 1424, c. 18 and 44; 1425, c. 60; 1457, c. 64; 1491, c. 31; and 1540, c. 85-91.) In time of war or rebellion proclamations were issued, charging all sheriffs and magistrates of burghs, to direct the attendants of the respective wapenshawings to join the king's host (1482, c. 90); and the criminal records contain many prosecutions for "abiding from" the various "raids," which are generally settled by composition with the lord treasurer. During the civil wars of the seventeenth century, the army which had been brought into existence by the enthusiasm of the Covenanters was supported by levies and assessments apportioned by district committees of war appointed by parliament, whose duties and powers were modelled on those of the commissioners of array in England. In 1662 (1st Car. II. 3, 27), the parliament made offer of 20,000 foot and 2000 horse to be at his majesty's sole disposal, and to be marched to any part of Scotland, England, or Ireland. This body constituted a regular standing army, the organization of which underwent some alterations in the years 1669, 1672, 1693, and 1695. From this last period no legislative improvements were made in the militia of Scotland until the year 1797, when the system established in England was partially extended to that part of the empire, though not without considerable local disturbance.

In Ireland the predatory army of *gallowglasses*, which, even in times of comparative tranquillity, it was found necessary to keep constantly armed for the preservation or the enlargement of the pale, was supported to a small extent by supplies from England; but it chiefly depended on exactions from the Anglo-Irish, made by a dexterous application of the many fines and petty tributes originally exigible by the native chiefs. To these the English added the formidable exactions of coign and livery, which embracing free quarters, and all that is generally taken under the sanction of that licence, were the frequent subject of bitter complaint, though not much heeded by a government which expected that the conquest would at least support itself. (See *Irish State Papers*, published by authority of government, ii. 477, &c.) In 1715, on occasion of the rebellion in Scotland, an act was passed by the Irish parliament (2d Geo. I., c. 9) for raising a militia to consist of Protestants. Roman Catholics were subject to double rates; and all serviceable horses belonging to them might be seized and made use of, provided that within ten days the sum of L.5 (deducting the expense of seizure and keeping) was tendered to the owner of each as full payment. After several partial alterations, the militia laws were consolidated by the Irish parliament in 1793 (33d Geo. III., c. 22), and 1795 (35th Geo. III., c. 8), and accommodated to those of England in 1809.

By the present constitution of the militia in the United Kingdom the sovereign appoints lords-lieutenant in Britain, and governors in Ireland, to each county or province, with power to call out and train the militia annually, and to appoint deputy-lieutenants or deputy-governors, and other officers, subject to the royal approval. The higher officers in the militia, unless they enjoy an exemption on account of their rank in the army, require to be qualified by the possession of property. The amount varied greatly in the different departments of the United Kingdom, and being of the character of real or landed estate, was farther complicated by the different kinds of feudal tenure. From time to time there were partial legislative innovations on the purely territorial character of the qualification, and by an act passed in 1855, a uniform qualification throughout the empire, which might be in landed estate or any other property, was adopted. The qualification thus fixed is a yearly rent or value of,—for a colonel, L.600; for a lieutenant-colonel, L.400; for a major, L.300; and for a captain, L.200.

The business of balloting for and calling out the militia,

commences with the annual general meeting of the lieutenancy of each county, when the next subdivision meeting is appointed, to which chief constables, or other officers, are required to direct constables or schoolmasters to return lists of all males between the ages of eighteen and thirty-five in their respective parishes. Within fourteen days after requisition, the constable or schoolmaster leaves a schedule in each dwelling-house, to be filled up within fourteen days, with the names and designations of persons within the ages, and their claims of exemption, if there be any, under a penalty of L.5. Within a month after serving the notices, the constables or schoolmasters make up, and affix to the church doors, lists mentioning exemptions and incapacities, and notifying the times and places for the discussion of appeals. These are decided by two or more deputies at the subdivision meetings, and their decisions are final. The clerks of general meetings then transmit lists to the privy council, distinguishing those liable to serve from those exempt. The men to be enrolled are chosen by ballot from each parish; all who are not above four feet and five inches in height, or are not approved of on examination by a surgeon, being discharged, and others balloted for in their room. Those who do not personally appear, or send an approved substitute to take the oath, are liable in a penalty of L.10. There are arrangements by which, with the consent of the inhabitants, volunteers, remunerated by parish assessments, may be substituted for balloted men.

The persons exempted are,—peers; commissioned officers of the other forces, whether on full or half-pay; non-commissioned officers and private men in the other forces; persons serving, or who have served for four years, as commissioned officers in the militia; persons serving in the yeomanry or volunteers; persons serving, or who have served at any time within a year past in the local militia; resident members of the several universities; clergymen of the establishments, and registered dissenting clergymen; parish schoolmasters; articled clerks; apprentices; seafaring men; persons employed in the royal docks, the Tower, Woolwich Warren, the gun-wharfs of Portsmouth, and the stores under the direction of the Board of Ordnance; persons free of the company of watermen of the Thames; any poor man with more than one child born in wedlock, in England; any man with more than two lawful children, and not possessing property to the value of L.50, in Scotland; and in Ireland, any poor man not worth L.10, or who does not pay L.5 a year of rent, and has more than three lawful children under the age of fourteen.

The mutiny act and the articles of war apply to the militia, when called out, with the ordinary constitutional limitation, that no punishment can extend to life or limb. There are separate provisions for recovering deserters, &c. Until lately the conditions on which the militia could be called into service were, in Britain, invasion, or imminent danger of invasion, or actual rebellion or insurrection; in Ireland, actual invasion, rebellion, or insurrection. An act of 1854 so far altered this constitutional principle as to authorize the sovereign to call out the militia "whenever a state of war exists between her majesty and any foreign power." The old principle, that the militia cannot be compelled to serve out of the kingdom is still adhered to; and it has been thought necessary to pass special laws to enable them to volunteer for foreign service. In 1813 (54 Geo. III., c. 1) provision was made for accepting the service of militiamen and officers, to be formed into provisional regiments, and to co-operate with the regular forces. At previous periods, considerable numbers of militiamen had been drafted into the line, the losses of the militia regiments being made up by temporary acts, which slightly increased their original quotas. In 1855 a special act was passed "to enable Her Majesty to accept the services of the militia out of the United Kingdom, for the vigorous prosecution of the war."

Milizia.

By 48 Geo. III., c. 111 and 150, the celebrated local militia was, in 1808, appointed in England and Scotland, being limited in each county to "six times the original quota, or proportion of the original quota of militia." In 1812 two new acts were passed (52 Geo. III., c. 38 and 68), which apportioned the numbers of men to the respective shires in England and Scotland, but contained regulating provisions which tended to make the local militia and volunteers together amount to six times the number of the original militia contingents. When these forces were added to the 200,000 men allowed to be trained by Mr Windham's act (46 Geo. III., c. 90), the citizen army at the disposal of government in Great Britain amounted, independently of the militia, &c., of Ireland, and of temporary augmentations, to very nearly 500,000 men. In 1811 the effective strength of the regular militia was 77,424 private men, whilst that of the local militia was 213,609. In 1819 the disembodied militia of Britain and Ireland, calculated from the estimates of the year, amounted in round numbers to 71,200; and in 1829 it amounted to 70,082 private men and drummers.

The balloting, enrolling, and exercising of the militia has of late taken place only at occasional periods, an act being generally passed during each session suspending their annual recurrence. The militia were called out during the late war with Russia; and by a parliamentary return, the numbers in the three kingdoms on the 14th March were,—England, 44,198; Scotland, 4461; and Ireland, 13,095; making a total of 61,754. Within a month the numbers had decreased to 51,183, but during that period 19,450 had volunteered from the militia into the line. At the close of the session of 1857, the great Indian mutinies rendered it necessary again to take measures for calling out the militia. (J. H. B.)

MILIZIA, FRANCESCO, an eminent Italian architect, was born in 1725. He gives the following account of himself in his autobiography:—"My native place is Oria, a small town in Terra d'Otranto, in the kingdom of Naples. I am the only son of one of the noblest and richest families in that small community. At nine years I was taken to Padua, where one of my uncles on my father's side had established himself in the practice of medicine. There I studied rhetoric with very indifferent success until at the end of seven years I ran away from Padua, in consequence of having been scolded by my uncle, and wandered until I found myself at Bobbio, near Placentia. Thence I sent news of myself to my parents, and went to Rome, where my father met me, took me to Naples, and left me there to study. I learned a little logic and metaphysics under the celebrated Abbé Genovesi, and studied physical science and geometry under Father Orlando, a Celestian monk. From Naples I also ran away, having a strong desire to see the world, more especially France; but having arrived at Leghorn, I was forced to go back from want of money. I returned to Oria; and after having spent several years in idleness, I shut myself up in a country-house, and studied science. Finally, when I was twenty-five years old, I married a noble lady from Gallipoli, of amiable disposition; and having fixed my abode in her native town, I paid some attention to books, but more to amusements. Having obtained from my father a larger provision, I went with my wife to visit Rome, and after a year and a half returned to Gallipoli, whence, in 1761, in my thirty-sixth year, I went back again to Rome. There I continued to study, and took some pleasure in architecture, although I knew nothing of drawing. Enamoured with this art, which I still regard as the noblest and most useful, I wrote the *Vite degli Architetti più celebri*, which was well received by the public, although my criticism was too severe, and my style but little cultivated."

This extract from Milizia's autobiography does not extend farther than the year 1775. About this time he was appointed superintendent-architect of the royal Farnesian palaces, which the king of Naples possesses in the Papal

States, but resigned the office in 1786. He lived in the closest intimacy with all the artistic and literary celebrities at Rome, especially with Raphael Mengs, whose views he adopted with such enthusiasm, and diffused with so much pertinacity, as frequently to be unjust to other artists who did not share in his opinions. His critical partiality and bluntness of manner also gained him many personal enemies. He died at Rome, March 1798, of pulmonic disease.

The first work of importance published by Milizia was the *Vite de' più celebri Architetti d'ogni Nazione e d'ogni tempo Antichi e Moderni, preceduti da un saggio sopra l'Architettura* (Rome, 1768), which, in the last edition, he more modestly entitled, *Memorie degli Architetti Antichi e Moderni*; Parma, 1781. He denounces faults in severe and strong language, while he praises good qualities with a few sober words. This work was translated into English by Edward Cressy, London, 1826. His next work (*Del Teatro*, Rome, 1772) is a curious sign of the times. The frivolity, and even immorality of the drama at Rome, suggested to Milizia the thought of denouncing the abuses of the stage. He accordingly wrote a book, in which he insisted on the reform of the theatre. A storm was raised against him by the Roman public, headed by the priesthood, who compelled the master of the sacred palace to withdraw all the copies of the obnoxious book. More just criticism, however, subsequently placed the work in its proper light. The best of Milizia's works is the *Principi di Architettura Civile*, published in 1785. He treats, first, of "Beauty;" secondly, of "Fitness;" thirdly, of "Solidity." This work roused many antagonists. His language, his principles, and his judgments were all violently attacked by the older artists, while the young followed him enthusiastically. His next work (*Arte di Vedere*, Venezia, 1781) raised against him even a fiercer storm, by the free manner in which he examines the greatest works of the greatest men. In his *Roma delle belle Arti del Disegno*, Bassano, 1781, the principal monuments and buildings of Rome were so severely handled, that the book was proscribed and the author persecuted. This caused him to leave his work unfinished, and to turn his attention to totally different labours. To the last part of his life belong the *Dizionario delle Arti del Disegno*, Bassano, 1787, which is worth very little; the *Introduzione alla Storia ed alla Geografia fisica della Spagna*, Parma, 1783; the *Storia dell'Astronomia*; the *Elementi delle Matematiche Pure*; and, finally, his work on the *Economia Politica*, which was published after his death, Rome, 1798. (E. F.)

MILK, a well-known fluid, constituting the sole food of mammals during a certain period after birth, is an opaque, white, emulsive liquid, with a bland, sweetish taste, and a faint peculiar odour. When examined by the microscope it is found to consist of myriads of remarkably minute globular particles suspended in a serous liquid. These particles are termed *butter*, and are readily separated from the surrounding liquor, on being allowed to stand, owing to their relative specific lightness. On rising to the surface they carry with them a portion of caseine, one of the main constituents of milk, retain some of the serum or whey in which they float, and thus form *cream*. The upper stratum of cream is richer in butter, while the lower abounds more in the albuminous substance, caseine. The milk from which the cream has been separated is termed *skimmed milk*, and that from which the butter has been extracted is termed *butter-milk*. The butter or fatty matter is obtained from the milk by the process of agitation called *churning*, and the curd or cheese, or caseine, as the technical phrase is, is separated from the milk by the infusion of *rennet*, a liquid obtained by macerating the stomach of a sucking animal (as of the calf) preserved by means of salt. The whey of milk from which the curd and butter have been completely separated, yields on evaporation a colourless, sweet sub-

Milk.

Milk.

stance, known by the name of *sugar of milk*, as well as one or more nitrogenous composition. The relative proportion of the constituents of milk vary considerably in all animals with the quality of the food, the age of the animal, and the period after parturition. Among the most elaborate experiments on the composition of several kinds of milk are those of MM. O. Henri and Chevallier, published in the *Journal de Pharmacie*, vol. xxv, and which are as follows:—

	Milk of the				
	Cow.	Ass.	Woman.	Goat.	Ewe.
Caseine	4.48	1.82	1.52	4.02	4.50
Butter.....	3.13	0.11	3.55	3.32	4.20
Sugar of milk..	4.77	6.08	6.50	5.28	5.00
Various salts...	0.60	0.34	0.45	0.58	0.68
Water	87.02	91.65	87.98	86.80	85.62
Total.....	100.00	100.00	100.00	100.00	100.00
Solid substances	12.98	8.35	12.02	13.20	14.38

Of the various saline constituents which enter into the composition of milk, Schwartz gives the following as the composition of the ashes of 100 parts of cow's milk. (See Gmelin, *Handbuch der Theoret. Chemie*, vol. ii.)

Soda (in milk combined with lactic acid)	0.0115
Chloride of potassium.....	0.1350
Phosphate of soda.....	0.0225
Phosphate of lime.....	0.1805
Phosphate of magnesia.....	0.0170
Phosphate of iron.....	0.0032
	0.3697

The quality of the milk is also affected by the state of health of the female supplying it. Tubercular disease of the lungs of an animal has been found to increase the quantity of phosphate of lime in the milk. Labillardière states (*Dict. Mat. Méd.* iv.) that the milk of a cow affected by a species of tubercular phthisis contained seven times more phosphate of lime than usual; and Dupuy, according to Pereira, has also noticed the large quantity of calcareous matter in the milk of cows, in whose lungs the same substance was found in abundance. The morbid changes produced in the quality of the milk by the disease called *cocote*, so prevalent among the cows of Paris some years ago, attracted considerable attention among scientific men. The principal morbid changes recognised in the milk were a want of homogeneousness, imperfect liquidity, a tendency to become viscid on the addition of ammonia, and on microscopic examination the presence of certain globules not found in healthy milk. And not only is this subject of great importance in reference to the frequency of disease in cows, and the consequent morbid character of their milk; it also requires very special attention in connection with the milk of the human subject. The deleterious effect to a child of being suckled by a female labouring under tuberculous disease must be too obvious to require exemplification. According to Dr Jon. Pereira (*Treatise on Food and Diet*), it is possible by adding certain ingredients to the food to modify the *colour, odour, taste, and medicinal effect* of the milk of a female; and the influence which medicines taken by the parent exert over the child is known to every nurse. As the natural food of the young mammal of every species is the milk of its mother, we may accordingly regard milk not only as containing all the elements necessary for the nutrition and growth of the body during a certain period, but also as a kind of model food for the species to which the animal belongs. Milk appears to partake of the nature of both animal and vegetable food. The large proportion of caseine and butter which it contains represent the fibrin and fat of beef, while the equally large proportion of sugar represents the starch of wheaten bread. The curd of milk goes to form the albumen and fibrin of the blood. The

Milk.

butter serves to form fat, and with the sugar contributes, by yielding carbon and hydrogen to be burnt in the lungs, to support the animal heat of the body. The salts develop the osseous system; the iron is required by the blood and the hair, while its chloride salt goes to form the hydrochloric acid of the gastric juice.

Milk, as an article of food, is of great use and value, as well for the adult as for the child, and for healthy persons as well as for invalids. The chief objection often to its employment is the difficulty of digestion of its fatty matter. Whey, as an excellent diluent and nutritive, is often used in febrile and inflammatory complaints. It owes its slightly nutritive qualities to the sugar of milk which it contains. It gently promotes the action of the secreting organs, and thus proves useful in congestion of the liver. According to Pereira there are various establishments in Switzerland and Germany for the cure of chronic disorders by the use of pure or aromatized whey (*Molkenuren; Cures de Petit-Lait*). The whey is obtained from the milk of the cow, the goat, or the ass; and is used as a drink, as a lavement, or as a bath, associated often with the employment of mineral waters. Butter-milk also forms a very agreeable cooling beverage in febrile and inflammatory diseases; and its nutritive qualities are owing to the caseine, the sugar, and the salts of milk which it possesses.

With respect to the distinctive properties of the different milks in most frequent use, valuable information will be obtained by referring to the table already given. While *ewe's* milk contains the largest proportion of nutritive matter, it is on that account less easy of digestion, and not suited for dyspeptics. The same holds of *goat's* milk, which ranks next in nutritive power. *Ass's* milk is the least nutritive, but the most easy of digestion. With the exception of woman's milk it is the richest in sugar. It is considered a most valuable aliment in consumptive cases, in chronic diseases of the digestive organs, and in convalescence from acute maladies. This seems to depend on the small quantity of butter and the large quantity of sugar of milk which it contains. *Cow's* milk holds a middle place in nutritive and digestible properties between goat's and ass's milk. According to Donné (*Comptes Rendus*, 1841), it is the only milk which is either very feebly alkaline, often neutral, or sometimes slightly acid. The milk of the ass and the woman are always obviously alkaline. The milk of women from fifteen to twenty years of age is said to contain more solid constituents than that of women between thirty and forty. Women with dark hair also are said to give a richer milk than women with light hair. (See Pereira's *Treatise on Food and Diet*, also Johnston's *Chemistry of Common Life*). For further information respecting the milk of cows see DAIRY.

MILL, JAMES, was born on the 6th of April 1773, in the parish of Logie Pert, near Montrose, where his father united the occupations of shoemaker and small farmer. After receiving his elementary education at the parochial school of Logie Pert, and at the grammar-school of Montrose, he was sent by Sir John Stuart, Bart. of Fettercairn, to the University of Edinburgh, to study for the church. After completing his theological course, he received license as a preacher, but as accident rather than choice had led him into the profession, he never contracted any particular liking for it, and was not promoted to a charge. The study which chiefly delighted him, and exercised his thoughts during the period of his academical course, was that of metaphysical and ethical philosophy. The class of moral philosophy was then taught by Mr Dugald Stewart, to whose noble eloquence and animated exhortations to mental study Mill always listened with profound attention and enthusiastic admiration. In a letter to a friend in 1821, Mill, speaking of Stewart, from whose system of speculation he was then widely separated, remarked, "The

Mill

taste for the studies which have formed my favourite pursuits, and which will be so to the end of my life, I owe to him."

After having officiated for a considerable time as a private tutor, Mill removed to London in 1800, where he became editor of the *Literary Journal*, which did not, however, long survive. From the period of his arrival in the metropolis till the year 1819, when he received a valuable appointment in the India House, he supported himself and his increasing family entirely by his pen. Much of his time was employed in writing for periodical publications. For several years he was an occasional contributor to the *Edinburgh, British, Eclectic, and Monthly Reviews*. He early made the acquaintance of Jeremy Bentham, and actively co-operated with the supporters of the *Philanthropist* in those exertions to which the Lancastrian and Infant Schools owed their origin; and at a later period he was one of the founders of the London University.

His principal work, the *History of British India*, had been commenced as far back as the year 1806, but the greatness of the work itself, and the variety and weight of his other avocations, prevented its completion for upwards of ten years. It was at last published in five volumes, 8vo, in the winter of 1817-18. It was the smallest merit of this book, that it was the only single work calculated to convey to the general reader any intelligible notion whatever of India, or Indian affairs as a whole, and which rendered it, therefore, indispensable to all Englishmen who would possess even the most general knowledge of one great department of their country's interest. But it achieved far more. It gave a new turn to the thoughts of all the most eminent leading men engaged in the administration of Indian affairs; and the measures of government in that country for many years bore testimony to the high merit of this valuable history.

Although he had very freely censured the conduct of the East India Company, yet the powers of mind and knowledge of the subject which he displayed induced the Court of Directors, in the spring of 1819, when they were desirous of strengthening their home establishment, to introduce him into it (though personally unknown to most of them, and having little or no interest), and to intrust to him the chief conduct of their correspondence with India, in the revenue branch of administration. He was subsequently made head of the department of correspondence with India in the India House, or, in other words, chief minister for Indian affairs to the East India Company; and he lived to see almost all the great principles which he had advocated, not merely recognised, but practically employed in the government of India.

Mill's official duties might well have furnished him with an excuse for relinquishing his pen as an author. But his mind was not of a cast to stop short in the career of inquiry, or to allow the calls of business to suppress the fruits of his reflections. He became a contributor to the *Supplement* to the former editions of the present work about three years before his appointment to the India House; and his contributions were continued nearly till the completion of that publication in the year 1824. His most striking articles were those on *Colonies, Education, Government, Jurisprudence, Law of Nations, Liberty of the Press, and Prison Discipline*. These essays were also widely disseminated by separate republications of them, at a very cheap rate, and proved not the least effective of his writings in stirring the thoughts of his contemporaries.

In 1821-22 he published his *Elements of Political Economy*, a treatise in which the science, as remodelled by Ricardo, was for the first time, and without any pretensions to originality, brought into a systematic form, and arranged in strict scientific order.

Mill

Mill's originality and acuteness as a metaphysician were abundantly displayed in his *Analysis of the Phenomena of the Human Mind*, published in 1829. He belongs to the sensational school of philosophy, and there is perhaps no English writer since Locke who has employed so much energy and acuteness in analyzing our mental phenomena upon purely sensational principles. As a sensationist he stands midway between Locke and the French ideologists. The latter held that all mental phenomena were but different forms of sensation; while the former, although maintaining that the material of our knowledge was derivable from sensation, nevertheless asserted the existence of certain powers of reflection by which this primitive material is moulded. While differing essentially from both, Mill resembled Locke in tracing our mental phenomena to two primitive elements, viz., *sensations* and *ideas*; but under the latter term he included much less than did the English philosopher under the word reflection. By *sensations* he understands "that which exists when the object of sense is present;" and by *ideas*, "that which exists after the object of the sense has ceased to be present." (*Analysis, &c.*, vol. i., p. 41.) These two classes of "feelings," as forming the whole material of our thoughts and emotions, are the basis of all our mental operations. But these phenomena do not recur arbitrarily; on the contrary, they are under the regulation of a law called the association of ideas, which marshals them in synchronous or successive order, giving rise to "complex notions" and "trains of thought." Again, in order to be able to communicate our sensations and ideas to others, we require to assign to them certain "names." These elementary processes, then, of "sensation, ideation, association, and naming," form the groundwork of Mill's analysis. The rest of his work is occupied in showing how, out of these elements, all the complex phenomena of the mind can be formed. The subtle ingenuity of the writer is here strikingly brought out, but no amount of dexterity can make a false system true. Accordingly, the reader, while continually constrained to admire the manly independence of thought, and clear forcible style of the author, is nevertheless compelled to dissent from the most important results of his system. To take a single specimen of the shifts to which Mill is frequently and unconsciously driven. Memory and judgment are not of course with him original faculties; they are generated according to the fourfold process already indicated. But how is it possible to derive judgment and memory from such processes, seeing that these very powers are involved in the formation of those sensations and ideas which lie at the basis of the whole system? Mill's definition of an idea necessarily involves the recognition and distinction of a present and a past object; but it is the judgment which distinguishes, and it is the memory which renders a past possible. Here, then, at the very threshold of the system, the faculties which he afterwards tries so ingeniously to account for are found in full operation. Such specimens of analysis are not peculiar to Mill, however; they belong to the entire sensational school; and it was the radical vice of the system, rather than an intellectual defect in the analyst, which led this philosopher astray.

Mill's last work was a fragment published anonymously in 1835, containing a criticism of a very severe kind upon the *Dissertation on the History of Ethical Philosophy*, contributed by Sir James Mackintosh to the present publication. Most even of those who agree in the general opinions expressed by Mr Mill have admitted that the degree of bitterness which he manifested towards this eminent and singularly candid writer was in a great measure uncalled for.

Mr Mill wrote several of the principal articles in the early numbers of the *Westminster Review*, among which may be specially mentioned the one on the *Formation*

Mill
||
Millen-
nium.

of *Opinions*, and, after an interval of some years, the celebrated article on the *Ballot*. After the union of the *Westminster* with the *London Review*, he wrote, among other racy and characteristic articles, one entitled *Aristocracy*, which was the last of his literary labours.

For some winters previously to his death he had an obstinate cough, which, by ending in pulmonary consumption, carried him off on the 23d of June 1836. His remains were buried in Kensington church, he having lived at Kensington during the last five years of his life.

The high reputation of Mill is honourably sustained in the person of his son, the present John Stuart Mill, author of the *System of Logic, Ratiocinative and Inductive*, who is one of the profoundest thinkers of the age.

MILL, John, was the son of Thomas Mill of Bampton, and was born about the year 1645, at Shapp, in Westmoreland. He studied at Queen's College, Oxford, which he entered as servitor in 1661; and took his degree of M.A. in 1669. Mill was soon after made a fellow of his college; and having subsequently entered the church, he obtained great reputation as a preacher. In 1681 he became rector of Blechingdon in Oxfordshire; and during the same year he was made Doctor of Divinity and chaplain to Charles II. The work by which Mill is best known is his edition of the Greek Testament, a performance of great labour and erudition, on which he spent the last thirty years of his life. He had the benefit of the counsel and encouragement, in this work, of Dr Fell, Bishop of Oxford, at whose expense the publication of it was begun; but this divine having died, Mill not only continued the work at his own cost, but repaid to the executors the sum furnished by the bishop. In 1685 he became principal of St Edmund's Hall in Oxford; and in 1704 he was appointed by Queen Anne a prebend of Canterbury. Mill died in 1707, just a fortnight after the publication of his Greek Testament. This edition, which is the best proof of the industry, learning, and scholarship of its author, is based on those of Robert Stephens, 1550, and of Bishop Fell, 1675; and contains a collection of more than 30,000 various readings, from MSS., versions, quotations from the fathers, &c. The number of these variations excited the alarm of many, and especially of Dr Whitby, who, imagining that they would destroy the validity of the text, wrote a work in order to reduce their number and importance. The same subject was taken up by Antony Collins, for a different purpose, in his *Discourse on Free-Thinking*, in which he contends that "these numerous variations destroy the authority of the New Testament." But this book was answered by Whiston and Bentley with great ability and success; showing that the variety of readings is no objection to the authority of the Scriptures, being only a necessary result of the number and variety of the MSS. Their arguments are briefly summed up in the irony of Swift; that the multitude of readings renders the Bible quite useless; and of course the works of Livy, Horace, and other ancient authors, are all likewise worthless, for a similar reason.

MILLEDGEVILLE, a town in the United States of North America, capital of the state of Georgia, is situated on the W. bank of the Oconee River, 80 miles W.S.W. of Augusta. It stands in a beautiful and fertile cotton country, and contains a number of handsome residences. The river supplies excellent water power; and was once navigated below by small steamers, but these are now superseded by railroads. A branch railroad, 17 miles long, extends S. to Gordon on the central railroad, and another extends in the opposite direction to Eatonton. Pop. (1850) 3500.

MILLENNIUM, a period of a thousand years, generally used with reference to the thousand years during which, according to the statement of the Apostle John in

the 4th verse of the 20th chapter of the Apocalypse, Christ is to reign with his saints upon earth.

As almost all nations are possessed of some traditional information respecting the existence of a happy and a holy age at the commencement of the world's history, so among most of them do we find traces, more or less distinct, of an expectation that a period of still greater excellence will immediately precede its close. In several of the oriental religious systems this expectation occupies a prominent place;¹ nor will the classical reader need to be reminded of the well-known Eclogue of Virgil, in which he describes the glories of "the last age," and the return of the Saturnian reign, in strains which so strikingly accord with those of the Jewish Scriptures, that this poem seems to have been commonly regarded by the early church as prophetic of the birth and reign of Christ.² A still more remarkable, because more explicit, allusion to a millennium occurs in the writings of Plato, in the statement which he repeatedly makes, that a period of a thousand years (χιλιετης πορεία, χιλιετον ερος, περιδος χιλιετης) must intervene between death and our "arrival at the inheritance and possession of the second life."³

Among the Jews this expectation assumed a more definite form, and was expressed in less hesitating language. Their prophets distinctly revealed to them the certainty of a period of future felicity under the reign of the Messiah;⁴ and they had, from a comparatively early age, the tradition, that that period would extend through a thousand years. This tradition seems to have had its rise in the notion, that as the work of creation was divided among six ordinary days, so the world would have to pass through six divine days of toil and suffering (each of which days they imagined to be a millennium, from a misinterpretation of Ps. xc. 4); and that as God rested on the seventh day, so should the seventh millennium be a period of universal rest and quiet under the reign of the Messiah. In the rabbinical writings frequent allusions to this opinion are to be found, the most important of which have been collected by Wetstein in his notes on Apoc. xx. Of these allusions the following may be taken as a specimen: "There is a tradition in the house of Elias, that the righteous whom the holy blessed God shall raise from the dead, shall not return again to the dust, but for the space of a *thousand years*, in which the holy blessed God shall renew the world, they shall have wings like the wings of eagles, and shall fly above the waters."⁵

From the Jews this notion of a personal reign of the Messiah with his saints on earth, was adopted by several in the early church, by whom the passage in the Apocalypse above referred to was confidently quoted in support of the opinion. By some of these the blessings anticipated during the millennium were regarded as entirely of a temporal and sensual kind, while others looked forward to that period as a season of spiritual enjoyment and religious harmony. In neither of these forms, however, does the opinion ever seem to have become general in the church. Indeed, we are expressly informed by Origen, that it was confined to those "of the simpler sort," and to such as "refusing the labour of intelligence, followed the superficial mode of literal interpretation."⁶ Great obscurity, however, attends the history of this dogma in the early church, as the documents we possess are too few, and too partial in their information, to justify our expressing any definite opinion on

nium.

the subject. From the testimony of Eusebius, we learn that the first who taught it in the church was Papias, a bishop of Phrygia, in the earlier part of the second century, who professed to have received a traditional revelation on the subject from the apostles. Influenced by a regard to the piety and antiquity of the man (την ἀρχαιοτητα τῶνδρος προβεβλημένοι), several ecclesiastics, and among the rest Irenæus and Justin Martyr, adopted his opinion. Adherents were also found in the Latin church, especially from among the Montanist party. It is justly remarked, however, by Professor Neander, that the defensive attitude which the advocates of the doctrine perpetually assume in regard to it, affords a strong presumption that it was not the doctrine of the church in general.¹

In the third century it was vehemently assailed by Origen, and as eagerly defended by Nepos, a bishop of the district of Arsinoë, in Egypt. The latter, however, was but a feeble antagonist for so redoubtable a controversialist as Origen, whom his scholars delighted to style the Adamantine; and consequently his interference served only to quicken the downfall of the cause he had espoused. The assault of Origen was followed by that of Dionysius, bishop of Alexandria, and one of Origen's most able scholars, which seems, in the Eastern church at least, completely to have driven the opinion into obscurity.² From this time forward we find few traces of it in ecclesiastical history, until we arrive at the tenth century, when it was revived, though in a very altered form, and used for the purpose of terrifying the ignorant populace into larger concessions to the ambition and avarice of the papal power. They were taught that the millennium, during which Satan was to be bound, was to be calculated from the birth of Christ, and consequently was then rapidly drawing to a close; that at its termination Satan would be again set free, and the reign of Antichrist would commence; and that, after a short season of triumph to the enemies of the church, the last judgment would take place, and the world be consumed by the final conflagration. So powerful was the effect produced by the teaching of this doctrine, that multitudes, as the eventful year that was to close the last century of the millennium approached, forsook their homes, "and hastened to the shores of Palestine, with the pious persuasion that Mount Zion would be the throne of Christ when he should descend to judge the world; and these, in order to secure a more partial sentence from the God of mercy and charity, usually made over their property, before they departed, to some adjacent church or monastery."³ The much-dreaded year, however, having passed away without any of the expected convulsions, the minds of the people recovered their equilibrium. Those who had fled returned to their homes, and resumed their wonted occupations; and the only lasting effect of this stupendous panic was the augmentation of the temporal prosperity of the church."⁴

Since the Reformation, the opinion of the early millenarians has been revived in the church; and the doctrine of a personal reign of Christ on earth with his saints has been maintained by many excellent persons, as one of the truths clearly revealed in the Scriptures. The tenets of those who avow this opinion are chiefly the following:—That Jerusalem is to be rebuilt, the temple restored, and sacrifice again offered on the altar; that this city is to form the residence of Christ, who is to reign there in glory with all his saints for a thousand years; that for this purpose there shall be a resurrection of all the pious dead, that none

of the Saviour's followers may be absent during his triumph; that at the close of the thousand years they shall all return to heaven, and the world be left to Satan and his followers for a season; and that then the general resurrection and last judgment shall take place, and the history of the world be brought to a close. In support of these tenets, they appeal to numerous passages in the prophetic writings of the Old Testament, to some sayings of Christ himself recorded in the Evangelists, to one or two detached passages in the writings of the apostles, and principally to the declarations of St John in the Apocalypse. The passages in the Prophecies on which most stress is laid by them are those in which the latter-day glory seems to be described in connection with the return of the Lord of Hosts unto Zion, the establishment of his sanctuary with men for ever, and the coming of the nations to Jerusalem to receive instruction, and offer their homage to Him.¹ The declarations of our Lord referred to are those in which he speaks of the destruction of Jerusalem in connection with his second advent;² from which it is inferred that Jerusalem shall remain in its present state, and that seasons of tribulation and sorrow shall befall the church, until Christ come to restore the one to its former glory, and to exalt the other over all its enemies.³ The passages quoted from the apostles are chiefly two: the one the address of St Peter to the Jews,—"Repent and be converted, that your sins may be blotted out, when the times of refreshing shall come from the presence of the Lord; when he shall send Jesus Christ, which before was preached unto you;"⁴ which is held to prove that Christ shall come again, and that this event shall be attended with times of refreshing to the Jews; the other the declaration of St Paul to the Thessalonians,⁵ that "the dead in Christ shall rise first;" from which it is inferred that there will be a resurrection of the just antecedent to the general resurrection. The main prop of the doctrine, however, is the passage in the twentieth chapter of the Apocalypse, already referred to, and which is as follows: "And I saw thrones, and they sat on them, and judgment was given unto them; and I saw the souls of them that were beheaded for the witness of Jesus, and for the word of God, and which had not worshipped the beast, neither his image, neither had received his mark upon their foreheads or in their hands; and they lived and reigned with Christ a thousand years. But the rest of the dead lived not again till the thousand years were finished. This is the first resurrection" (verses 4, 5). Here it is contended that we have a distinct testimony in favour of a millennial reign of Christ and his people, and of a resurrection of those who had been faithful to him, as well as of those who had suffered for his sake, antecedent to that of the rest of the dead, and hence called "the first resurrection."

By those who oppose this system, it is generally admitted that the expectation of a long season of uninterrupted triumph to the cause of Christ, is one which is fully authorized by the declarations of Scripture. It is denied, however, that these declarations, when properly interpreted, support the notion of a personal reign, and a twofold resurrection. With regard to the passages from the Old Testament prophecies, it is maintained, that many of those adduced by Millenarians, as favouring their system, have been already fulfilled in the temporal history of the Jewish nation; and that in others which seem to have a still future reference, Jerusalem is used as typically representative of

nium.

the Christian church in its triumphant state; the temple is spoken of in reference to the ministrations of the gospel; and the coming of the people to Jerusalem is set forth as indicative of the universal prevalence of the Christian faith. The inference deduced by Millennarians from the words of our Lord above referred to, is regarded by their opponents as at best very obscure and far-fetched; while, on the other hand, it is contended, that the obvious comparison which our Lord draws between the destruction of Jerusalem and his second coming, as well as the circumstances of appalling and unexpected suddenness with which his appearance will be made, seem much better to accord with the notion that the coming spoken of is his coming to judgment, than with the opinion that it is an advent for which his church shall be longing, and the world prepared. In the statement of St Peter to the Jews, it is admitted that there are some expressions which would seem at first sight to favour the Millennarian scheme; but it is argued that every such inference is precluded by the words which follow, and in which the apostle declares, that the heavens must retain Christ "until the restitution (or accomplishment) of all things, which God hath spoken by the mouth of all his holy prophets since the world began." As, therefore, by the showing of Millennarians themselves, the glories of the millennium form part of the "all things" that are revealed in inspired prophecy, and which must be fulfilled *before* Christ shall re-appear on earth, it is plainly impossible that he can come to our world in person at the *commencement* of that period; and consequently the times of refreshing spoken of by St Peter must be interpreted of other blessings than those which would flow from the personal reign of Christ at Jerusalem. As to the statement of St Paul, that "the dead in Christ shall rise first," it is affirmed that a single glance at the context is sufficient to convince us that the apostle is not establishing a difference between the righteous and the wicked as to the time of their respective resurrections, but is simply showing that those believers who are alive at the season of Christ's second advent shall not enjoy any advantage over those who are dead, for the latter shall be raised first, *i.e.*, previous to the common ascent of the whole to meet the Lord in the air. In reference to the passage from the Apocalypse, it is contended, *1st*, That the expression "*first* resurrection" no more necessitates a twofold *corporeal* resurrection, than the phrases "*first* and *second* death," so frequently employed by the same writer, necessitate the supposition of a twofold *corporeal* dissolution; but that in both cases we have an instance of the same intermingling of the spiritual with the material, as in our Lord's declaration, "Let the dead bury their dead," where, as is generally admitted, the first adjective is used in a spiritual or metaphorical, the second in a literal and corporeal sense; *2dly*, That the phrase, "the rest of the dead," refers to the "remnant" spoken of in the 21st verse of the 19th chapter (the words in the original are the same in both verses, *οι λοιποι*), by whose resurrection is intended the temporary restoration of the reign of evil after the millennium; *3dly*, That it is not a legitimate interpretation to regard the expression, "I saw the *souls* of them that were beheaded," &c., as intimating their *corporeal* resuscitation; for though we may properly enough speak of a *soul* when we mean a *person*, yet it would outrage all propriety of language for any one to say that he saw the *souls* of certain individuals, when he meant that he saw these individuals themselves; *4thly*, That by the return to the earth of the souls of the martyrs and confessors, nothing more is intimated than the universal prevalence of that holy and determined spirit by which they were distinguished; in the same way as the ancient prophecy, that Elias should return to the earth before the appearance of the Messiah, is allowed to have received its accomplishment when John the Baptist came "in the *spirit*

Miller,
Hugh.

and *power* of Elias;" *5thly*, That it is as contrary to sound principles of interpretation to expound a book professedly symbolical literally, as it would be to expound a professed narrative symbolically; *6thly*, That it is imperative on those who insist on the literal interpretation of this passage to be consistent, and interpret literally the whole book, in which case we should have literal vials, and trumpets, and mill-stones, and chains, and burning lakes, &c.; an extent of literality for which few will be hardy enough to contend; and, *lastly*, That by interpreting the whole passage symbolically, and understanding by it a prediction of a season of joyful triumph to the church, during which the whole world shall be under the religion of Christ, and the zeal and piety of its holiest members in its purest days shall be universally diffused, no violence is done to any part of it, while a meaning is elicited in entire accordance with the general tenor of Scripture.

It is further objected by those who are opposed to Millennarianism, in the *first* place, that the hypothesis is in itself exceedingly improbable; for since Scripture assures us that the departed saints are already with Christ in heaven, in the enjoyment of unspeakable felicity, it is hardly conceivable that they would leave such a state to dwell for a thousand years on earth, in a state which at best must be one of imperfect enjoyment, and then return to heaven to permit their enemies for a season to reign in their stead; *2dly*, That the Millennarian notion of a resurrection of the righteous antecedent to that of the wicked, is directly opposed to the testimony of Scripture, which represents the two as simultaneous; see, *e.g.* John, v. 28-29, &c.; *3dly*, That the idea of a long interval elapsing between the advent of Christ and the last judgment, is inconsistent with those passages which represent the one as immediately consequent upon the other; such as 2 Thess. i. 7-10; 2 Tim. iv. 1, &c.; *4thly*, That, on the Millennarian hypothesis, there can be no judgment of the righteous whatever, for they having been once admitted to *reign* with Christ, can never after that be placed for trial at his bar—a hypothesis clearly at variance with innumerable passages of Scripture; such, *e.g.* as Rom. xiv. 10-12, Matt. xxv. 31-46, &c.; *5thly*, That to represent the millennium as a state of immortality on earth is to confound it with the New Jerusalem, though the two are distinctly revealed as separate states, the one previous and the other subsequent to the final judgment; and, *lastly*, That the theory of Millennarianism is in two points at least self-contradictory; for it not only represents Christ as reigning until the *last* enemy has been destroyed, and yet supposes the existence of a whole host of enemies, who, at the close of that reign, are to be gathered together; but also represents them as contending with the saints, until they are consumed by fire from God (Rev. xx. 7-10), though, according to another part of their hypothesis, the saints shall before this have returned with Christ to heaven. For these reasons, among others of less weight, this hypothesis of a personal reign of Christ on earth has been rejected by the majority of divines, and the period of the millennium regarded as a season of great spiritual blessedness, consequent on the complete triumph of Christianity throughout the earth. (W. L. A.)

MILLER, HUGH, a popular miscellaneous writer and geologist, was born in Cromarty on the 10th of October 1802. He may be said emphatically to have sprung from the bosom of the people, and to have inherited, along with his higher intellectual qualities, the virtues, habits, and feelings of the old middle-class country population of Scotland. His father was a seaman, owner of a small coasting vessel that plied along the shores of the Moray Firth, and who unfortunately perished at sea when his son was only about five years of age. But Hugh had kindly, sagacious relatives, who attended to his education, and would have struggled hard to send him to college had he not himself

Miller,
Hugh.

resolved on being a stone mason. He was proud to appear as a working man; proud of his rough coat and leather apron; and resolved to force his way upwards by solitary study, self-denial, and perseverance. As a boy he was somewhat intractable—lonely, observant, fond of books, and delighting in rambles by the sea-side, exploring the rocks, caves, and woods of his native shore. He wrought fifteen years as a mason; and his early labours in a quarry gave him his first lessons in geology. Those studies in the open air he has beautifully described—"Sweet are the uses of adversity;" and along with his love of natural science he had the feeling and fancy of a poet. His first publication was *Poems Written in the Leisure Hours of a Journeyman Mason*, which appeared in 1829; and the same year he wrote a series of *Letters on the Herring Fishing*. These were recognised as remarkable productions. Their author had evidently read and studied the best English authors, and possessed extraordinary powers of description and illustration. His prose style was succinct, clear, and elegant—formed on the model of our best essayists, Cowley, Addison, and Goldsmith. His verses were less essentially poetical than his prose; and it was soon obvious to himself, as to others, that poetry was not to be his peculiar vocation. For two or three years after his advent as an author Mr Miller continued to labour as a mason; but a branch of the Commercial Bank of Scotland being opened in his native town, he was appointed accountant of the new establishment. About the same time he published *Scenes and Legends of the North of Scotland, or the Traditional History of Cromarty*,—the result of many years' oral collections among the old inhabitants of the town and neighbourhood, and of a wide and curious range of reading and reflection. His next appearance was as a polemical controversialist. The Scottish Church question as to the rights of patronage then agitated the country, and Miller wrote two able pamphlets,—a *Letter to Lord Brougham*, and *Whiggism of the Old School*, supporting the principles and opinions afterwards embodied in vigorous action in the Free Church. These popular little treatises led to Mr Miller's appointment as editor of *The Witness*, a twice-a-week newspaper established in Edinburgh in 1840, of which he afterwards became the principal proprietor. He was now fairly launched into the world of politics and literature—a stout Presbyterian, determined to give no quarter to the opponents of spiritual independence or to the supporters of the Established Church, which he conceived to be degraded, dismantled, and obsolete. There was much bitterness and personality in this contest, but Miller gradually emerged from it, and sought distinction in a wider field. In the sixteen years of his Edinburgh life he wrote those works which now constitute his fame:—*The Old Red Sandstone, or New Walks in an Old Field*; *First Impressions of England and its People*; *Footprints of the Creator, or the Asterolepis of Stromness*; and *My Schools and Schoolmasters, or the Story of my Education* (the last a delightful and instructive autobiography). No geologist had ever before evinced the same art or talent in popularizing the truths of his science—in investing it with poetical beauty and interest, and at the same time extending its facts and principles by close and accurate research. In the formation known as the Old Red Sandstone he is entitled to the honours of a discoverer, having shown that it is not, as was supposed, barren of fossils, but in reality rich in organic remains. In the Palæontological history of plants and animals, and in tracing the fossil floras of Scotland, Mr Miller also did good service to science; while he laboured with untiring zeal and Christian devotedness to disprove the development hypothesis and to harmonize the phenomena of geology with the text of Scripture. His latest efforts were directed to the illustration of the first chapter of Genesis, to prove that the days of creation were not natural but prophetic days—unmeasured eras of time.

Passages of great eloquence and of rich and solemn imagination abound in these semi-theological disquisitions. The fossil remains seem, in his glowing pages, to live and flourish, to fly, swim, or gambol, or to shoot up in vegetative profusion and splendour, as in the primal dawn of creation. Such power belongs only to high genius—the power to reanimate and vivify the past, and to clothe the scattered hints and discoveries of science with living beauty and radiance. What Burns did for the old songs of Scotland, Miller did for the facts of geology. His friends, however, saw with regret that the indefatigable and inspired student was overtaxing his brain and hand. For some years before his death he suffered from ill-health and hypochondria. Always averse to general society (for he never conquered his natural shyness and awkwardness of address), his love of solitude became a disease. He had not attained by practice to facility in composition; and latterly he complained that with double labour he could only do half work; extraordinary visions or delusions overmastered at times his clear intellect; his egotism (always his greatest weakness) magnified everything affecting his fame or his writings, and he surrounded himself with weapons of defence, sword, dagger, and pistols, to guard his person and geological museum. Manifestations of this kind had been long conspicuous; yet when he took up his pen and elaborated his original conceptions and fine descriptions, no trace of mental disease was apparent. His last work, *The Testimony of the Rocks*, is one of the ablest and most argumentative of his compositions. He had laboured night and day at this final "testimony," and corrected its last page the day preceding his death. The excessive application, and perhaps a feeling of triumphant exultation at the successful completion of his task, overturned his already shattered intellect, and he died by his own hand on the night of the 23d or morning of the 24th of December 1856. This melancholy termination to the life of so noble a worker produced a sensation of grief and astonishment over the whole kingdom. His indomitable energy and masculine intellect, his enthusiasm and nationality, his fine English style and brilliant imagination, the purity of his life and his devotion to Christian duty and principle—all these were well-known traits of his character and writings that hallowed and endeared his name. Scotland had lost one of her worthiest sons, and geology one of its most eloquent exponents and illustrators. (R. C—S.)

MILLER, *Johann Martin*, was born in 1750, at Ulm, where his father was a preacher and professor. He studied for the church at Göttingen; where he became one of the *Hainbund*, or society of poets, which included among its members Boie, Bürger, Höty, and others. In 1783 Miller was appointed preacher in the cathedral of Ulm; and in 1810 he was made dean of Ulm. He wrote poetry, chiefly lyrical and elegiac; and many of his pieces have become extremely popular. He also wrote several novels and romances, in the sentimental style, of which the principal is *Siegwart*, a work which excited great interest, and met with much success. His novels and romances are now forgotten, and little read; but his poems have lost none of their popularity. He died in 1814.

MILLET. Under this name the fruits of several plants belonging to the order *Graminaceæ* are known in commerce. All of them are used as food, either for domestic animals or man. That to which the term is most generally applied is the "common millet," *Panicum miliaceum*, Linn., originally a native of India, but now naturalized even as far north as England. It is thought that this and some of its allied species constituted one of the earliest of the grain products used in making bread, and that its generic name is derived from *panis*, bread, and not, as has been frequently assumed, from its panicle inflorescence. It is mentioned by Pliny as being one of the ordinary cereals of his time. He says, "Campania is particularly prolific in millet, and a

Miller
Millet.

Millin.

fine white porridge is made from it; it makes a bread, too, of remarkable sweetness. The nations of Sarmatia live principally on this porridge, and even the raw meal." "The Ethiopians know of no other grain but millet and barley."

This species of millet is still sold in London shops called Italian warehouses, for the purpose of being used as a substitute for rice or semolina in making puddings, the demand being confined to professional cooks and others who cater for the luxurious. Its principal use, however, is in feeding cage-birds. Occasionally a crop of this very beautiful grain is seen in Kent, but its culture is almost discontinued, and the little which is used in this country is imported from Italy or France.

Another species, *Panicum italicum*, is also said to have been used by the ancients; but there is much confusion respecting the millet plants mentioned by Pliny; we believe he usually meant the species of *Sorghum*, and not those of *Panicum*, as he spoke of "white, black, red, and even purple" millet, and his translators have generally assumed that he meant *P. miliaceum* or *P. italicum*. His descriptions, however, apply strictly only to the species and varieties of durra or Turkish millet, the commonest of which, *Sorghum vulgare*, is now becoming an article of considerable importance in the commerce of this country. It is imported in large quantities, particularly into Liverpool, under the names of "great millet," "durra," "darra," and "Turkish millet;" and there is no doubt that although ostensibly imported as food for cattle and poultry, it is chiefly ground into flour, with wheat, and used for human food. It is this grain, we believe, of which Pliny says, "there is no grain known that weighs heavier than millet, and which swells more in baking." *Sorghum vulgare*, Persoon, is a native of India, but is extensively cultivated throughout Asia, Africa, Southern Europe, and the West Indies. In the last locality it is called negro corn, and is largely consumed by the coloured population when made into bread. It is similarly used in other countries, though not so exclusively; the bread made from it is very white and agreeable. The two-coloured millet, *Sorghum bicolor*, W., is often mixed with it, but the grains are inferior in size, and being marked with a large black spot, the colour when ground is not so good. The imports of these grains have hitherto been very irregular, and owing to the various names under which they have been offered, the quantity cannot be correctly ascertained. In 1856, however, it exceeded 600 quarters.

Pliny says, "A kind of millet has been introduced from India into Italy within the last ten years, of a swarthy colour, large grain, and a stalk like that of a reed. This stalk springs up to the height of 7 feet, and has tufts of a remarkable size, known by the name of 'phobe.' This is the most prolific of all the cereals; for from a single grain no less than 3 sextarii are produced; it requires, however, to be sown in a humid soil." Strangely enough, during the year 1856, this grain, the black millet, *Sorghum nigrum*, of Römer and Schultz, was introduced as a new cereal into the Liverpool corn market, under the name of "sorgho," an evident corruption of its generic name; it came from Italy, and was very strongly recommended for cattle feeding; for which purpose, no doubt, it would succeed admirably. The red millet, *Sorghum rubens*, W., is also occasionally brought from Africa and used for poultry feeding. One of the great millets, *Sorghum saccharatum*, has lately been proposed as a substitute for the sugar-cane, but with very little prospect of success; its hard twiggy panicle has, however, been for a considerable time extensively employed in the United States (where it is called broom-corn) in making those brushes called whisks, and for carpet brooms. Several other species of millet are used in various parts of the world, but they are of comparatively little importance. (T. C. A.)

MILLIN DE GRAND-MAISON, AUBIN-LOUIS, an

VOL. XV.

Millingen
||
Millot.

eminent antiquary, was born at Paris in 1759. He was originally intended for the church, but he afterwards left this sphere, and devoted himself to literary pursuits. In 1785 he published a collection of translations from foreign languages; and becoming acquainted with Willemet the botanist, and having his attention thus directed to natural science, he published in 1790 a work on the Rise and Progress of Natural History in France. On the outbreak of the French revolution, Millin was favourably disposed to the first movements of the friends of liberty; but the excesses and atrocities of the Reign of Terror seriously disconcerted him; and he did not hesitate to express the utmost horror and indignation at these actions. He was in consequence imprisoned, and did not regain his liberty till the fall of Robespierre, in 1794. In the same year he succeeded Barthélemy as keeper of the cabinet of medals, and about the same time he edited, at first along with other distinguished men, and afterwards alone, the *Magasin Encyclopédique*. He also lectured on the history of antiquities; but finding that his labours were injuring his health, he travelled to the south of France, examining the antiquities to be found there. On a second journey thither, which he carried afterwards into Italy, the effects of his exertions were such as to cause his death in 1818. He was a voluminous writer, and his principal works are as follows:—*Dictionnaire des Beaux Arts*, 1806; *Histoire Métallique de la Révolution Française* 1806; *Voyage dans le Midi de la France*, 1807-11; *Voyage en Savoie, en Piémont, à Nice, et dans l'Etat de Gènes*, 1816; *Voyage dans le Milanais, à Plaisance, Parme, Modène, Mantoue, et Crémone*, 1817; and *Histoire Métallique de Napoleon*, 1819-20.

MILLINGEN, JAMES, an antiquary of considerable eminence, was born in London in 1774, and educated at Westminster School, where he became a good classical scholar, and displayed a great taste for antiquities. He wished at one time to enter the army, but was prevented by the state of his health; and when about to go to one of the English universities, his future course was entirely changed by his father's repairing with his family to France, under the influence of the bright hopes inspired by the French revolution. Millingen resided in Paris for some time, where he was imprisoned as a British subject by order of the Convention. When released he became partner in a banking establishment, and continued his study of numismatics. Millingen having undertaken a journey to Italy, died at Florence in 1845. His principal works are:—*Recueil de Médailles Grecques Inédites*, Rome, 1812; *Peintures Antiques Inédites de vases Grecques*, Rome, 1813; *Ancient Unedited Monuments of Grecian Art*, London, 1823; and *Ancient Coins of Greek Cities and Kings*, London, 1831.

MILLOT, CLAUDE-FRANÇOIS-XAVIER, a distinguished historian, was born in 1726 at Ornans, a small town of Franche-Comté, and was descended from an old family connected with the profession of the law. When his studies were completed he was admitted among the Jesuits; and after having taught classics in several towns, he was appointed professor of rhetoric in the college of Lyons, one of the most celebrated institutions of the society in France. In a discourse, crowned by the Academy of Dijon, he ventured to pronounce a eulogium on Montesquieu, an act of boldness which offended his superiors, and led to his leaving the society. He next tried the pulpit, but not meeting with much success in that profession, he turned his attention to literature, and began by composing abridgments of the history of France and England, which met with great success. Having about this time received the appointment of professor of history at Parma from the Marquess of Felino, Millot soon found himself highly unpopular in his Italian residence, from his stanch adherence.

Milner
||
Milner.

to the minister his patron, then an object of popular hatred in that state. On the retirement of the Marquess of Felino, the Abbé Millot returned to France, where his courageous conduct procured him many friends. The court of Versailles, in the name of that of Parma, granted him a pension of 4000 francs; and in 1778 he was appointed preceptor to the Duc d'Enghien. He died on the 21st of March 1785, the same day on which, nine years afterwards, his august pupil was shot in the fosse of Vincennes. The Abbé Millot had been received into the French Academy in 1777, in the room of Gresset. He was also a member of the Academies of Lyons, Nancy, and Châlons-sur-Marne. D'Alembert used to cite him as the man in whom he had found the fewest prejudices and the least pretensions. The following are his principal works, viz.:—*Deux Discours*, Lyons, 1750, in 8vo; *Essai sur l'Homme*, translated from Pope with notes, and a discourse on English philosophy, Lyons, 1761; *Harangues choisies des Historiens Latins*, Lyons, 1764, in two volumes, 12mo; *Elémens de l'Histoire de la France*, Paris, 1769, in 3 vols.; *Elémens de l'Histoire d'Angleterre*, Paris, 1769, 3 vols.; *Elémens d'Histoire Générale Ancienne et Moderne*, Paris, 1783, 9 vols., a work which has been translated into the German, Danish, Dutch, English, Swedish, Italian, Spanish, and Portuguese languages; *Histoire Littéraire des Troubadours*, Paris, 1774, 3 vols.; *Mémoires Politiques et Militaires pour servir à l'Histoire de Louis XIV. et de Louis XV.*, Paris, 1777, in 6 vols. 12mo; and *Extraits de l'Histoire Ancienne, de l'Histoire Romaine, et de l'Histoire de France*, Paris, 1796.

MILNE, JOSHUA, the author of the famous Treatise on Annuities which goes by his name, was born in 1776, and pursued the calling of an actuary. His *Treatise on Annuities*, which was published in 1815, is still regarded as one of the standard works on the subject. At his death, in 1851, he left behind him a large library containing a complete and valuable collection of works on the statistics of vitality; and on the science of botany.

MILNER, JOSEPH, a divine and historian, was born in 1744, near Leeds in Yorkshire. He received his elementary education at the Leeds grammar school; but having the misfortune early to lose his father, he was deprived of the means of prosecuting his studies at a university. Milner, however, from his diligence and talent, obtained the employment of chapel-clerk of Catherine Hall, Cambridge, which enabled him to study at that university. After graduating in 1766, he entered the church, and divided his time between teaching and lecturing in Hull. He was made vicar of North Ferriby; and although he met with much neglect and opposition on account of his evangelical views, which subjected him to the charge of Methodism, yet his preaching was exceedingly popular. He was appointed vicar of Hull in 1797, but only enjoyed the preferment a few weeks, when he was removed by death. His principal works are the *History of the Church of Christ*, which was completed by his brother, and two volumes of posthumous *Sermons*.

MILNER, Isaac, a learned divine, brother of the preceding, was born at Leeds in 1751. He was educated at the grammar school of his native town, and subsequently at Queen's College, Cambridge, which he entered in 1770. He attained to the honour of a senior wrangler in 1774, and gained a fellowship the following year. In 1785 he was appointed Jacksonian professor of experimental philosophy, received the degree of D.D. in 1788, became dean of Carlisle in 1791, and in 1798 was made Lucasian professor of mathematics. Milner was an intimate friend of Wilberforce, and in 1787 he accompanied him and Pitt to the continent. He died in 1820, after writing a continuation of his brother's *Church History*, besides *Animadversions on Dr Harvie's History of the Church of Christ*,

Milner

Milo.

MILNER, John, a Roman Catholic divine, was born at London in 1752, and educated at the college of Douai. After being ordained in 1777, he came to Winchester, where he presided over a Roman Catholic congregation. He was much attached to the study of ecclesiastical antiquities, on which he published several works, and displayed so much skill and learning as to be admitted, in 1790, into the Royal Society of Antiquaries. Milner also engaged in several religious controversies among the Roman Catholic clergy; and published several works on such subjects. He was appointed, in 1803, vicar apostolic of the midland district, and bishop of Castabala. He died in 1826. Milner's principal publications are:—*A Dissertation on the Modern Style of Altering Cathedrals*; *History, Civil and Ecclesiastical, and Survey of the Antiquities of Winchester*; *Treatise on the Ecclesiastical Architecture of England during the Middle Ages*.

MILNTHORPE or MILLTHORPE, a market-town of England, county of Westmoreland, near the east bank of the estuary of the Kent, and on the Preston and Carlisle railway, 7 miles S.S.W. of Kendal. It has manufactures of sacking and twine, and some trade by means of small coasting vessels, which come up, by means of the tide, opposite the town. Market-day, Friday. Pop. (1851) 1534.

MILO, T. ANNÍUS PAPIANUS, son of C. Papius Celsus, was born at Lanuvium. Little is known of his life till the year 57 B.C., when he became tribune of the people, and attached himself to the party of Pompey. The object of this party, at that time, was to procure the restoration of Cicero from exile; and this measure did not fail to bring down upon Milo the hostility of Clodius, who had formerly, as tribune, been the chief supporter of the law which exiled Cicero. Both Clodius and Milo surrounded themselves with bands of armed gladiators, and frequent and bloody were the conflicts between these two factious demagogues. These riots were not allayed by the return of Cicero; for that orator and Pompey were the objects of repeated attacks from Clodius and his partizans, while Milo and his followers stood up in their defence. Both thus rendered themselves liable to prosecution for assault, and each was ready to accuse the other; but Clodius succeeded in protecting himself by obtaining the office of curule ædile for 56 B.C., and Milo was secured from danger by the influence of Pompey. In the year 53 B.C., when Milo became a candidate for the consulship, and Clodius for the prætorship, their former animosities were renewed with increasing violence; and Milo, on being attacked by Clodius in the senate on account of the debts with which he was loaded, was defended by Cicero in a speech of which some fragments have been preserved. In the beginning of the next year, as Milo with his usual escort of armed gladiators was journeying from Rome to Lanuvium, he was met near Bovillæ by Clodius, attended by a similar body-guard. After the two leaders had passed each other in quietness, a dispute arose between some of their followers, and in the fray which ensued, Clodius, whose party was inferior in strength, was dragged from a house in which he had taken refuge, and slain by the followers of Milo. For this act Milo was brought to trial by the nephews of the deceased; and, though defended by Cicero, the turbulence of the crowds who collected to witness the trial, and the soldiers with whom Pompey had caused the forum to be lined, so intimidated the orator that he was unable to deliver the speech he had prepared for the occasion. Milo was accordingly condemned and sentenced to exile, in terms of the law passed by Pompey with special reference to this case. He then retired to Marseilles; and when Cicero sent him an improved copy of the speech he should have delivered in his favour, Milo replied that it was well he had not spoken thus, "For if so," said he, "I should not now be enjoying the excellent fish of Marseilles." He remained at Mar-

seilles till 48 B.C., when he returned to Italy at the invitation of M. Cælius, who, having been expelled from the senate, was raising a rebellion in the south of Italy. Milo joined him; but their enterprise was not successful, and Milo was slain before a small fort near Thurii.

MILLO (the ancient *Melos*), an island of the Grecian Archipelago, one of the larger Cyclades, in Lat. 36. 45. N., Long. 24. 26. E. It is about 13 miles in length from E. to W., and where broadest is about 7 miles across. Area 65 square miles. Its N. coast is deeply indented by a spacious bay stretching S.E. for about 6 miles, and forming one of the best and safest harbours in the Levant. Milo is evidently of volcanic origin, and the surface is for the most part rugged and mountainous. The valleys and low grounds are of great fertility, and produce abundance of corn, wine, oil, and fruit. It has hot mineral springs, and mines of sulphur, vitriol, and alum. The highest summit is Mount St Elias, 2538 feet high. Milo, the chief town, is situated near the bottom of the bay, and is now chiefly in ruins. It is unhealthy by reason of salt marshes in the vicinity. Here the beautiful antique statue of Venus, now in the French collection, was discovered during the present century. The population of the island is said not to exceed 4000.

MILON, a famous wrestler of antiquity, the son of Diotimus, was born at Crotona. He is chiefly remarkable for his bodily strength, by means of which he obtained the crown for wrestling six times at Olympia, and as many times at the Pythian games. He flourished towards the end of the sixth century B.C.; and in 511 B.C. headed his countrymen in a successful battle against the Sybarites. Many stories are related of his strength, of which the most remarkable are, his supporting a falling house till its inhabitants escaped, and his carrying a heifer on his shoulders round the Olympic race-course. After he had become weakened by age, he is said to have seen one day in a forest a tree half split by wedges, and as he endeavoured to tear it asunder with his hands, the wedges fell out, and he being caught by the hands in the tree was devoured by wild beasts.

MILTIADES, a great Athenian general and statesman, was the second son of Cimon, and flourished in the fifth century B.C. He makes his first appearance in history at the death of his brother Stesagoras, who had succeeded to the tyranny founded over the Thracian tribe of the Dolonians by his uncle the elder Miltiades. Repairing to the Chersonese with a small handful of Athenian troops, Miltiades by a clever stratagem decoyed the Dolonian magnates into his power, and thus mounted the vacant throne without opposition. With the same promptitude he fortified his newly-attained position by enlisting a body-guard of mercenaries, and espousing Hegesipyla, the daughter of a Thracian prince, Olorus. He was reigning with great popularity when he was summoned in 513 B.C. to attend Darius Hystaspis in his expedition against the Scythians. The duty allotted to him and the other Greek commanders was to guard the bridge of boats across the Danube, while the rest of the army penetrated into the interior of the enemy's country. But as Miltiades considered the Persian monarch to be the natural foe of Greece, he advised his fellow-soldiers to destroy the bridge, and leave Darius and his host to perish in the wastes of Scythia. After a debate, however, his advice was set aside. Some time afterwards Miltiades was forced to retreat from his kingdom before an irresistible horde of Scythians, and not until the enemy had retired was he able to return. About this period also the islands of Lemnos and Imbros were wrested by him from the hands of Persia and subjected to the power of the Athenians. It is probable that this deed, and his well-known devotion to the Greek cause, drew upon himself the resentment of Darius. At any rate, Miltiades was compelled, by the approach of a Phœnician fleet, to abandon

his dominions and betake himself to Athens. No sooner had he set foot on his native soil, than he was arraigned by the Athenian democracy for supporting the cause of tyranny by his occupation of the Dolonian throne. His eloquent appeal, however, to his services in behalf of the Athenians confounded his accusers and secured his acquittal. Miltiades now rose to the highest honours and offices of the state. But not until the approach of the Persian armament under Datis and Artaphernes, in 490 B.C., did his genius and heroism rise to their full development. Then it was that he incited his fellow-citizens to proclaim their defiance of the invaders by casting into a pit the insolent Persian legates who had come to Athens to demand earth and water. Appointed one of the ten generals who led the little Athenian army forth into the plain of Marathon, he urged his fellow-commanders to meet the immense host of the enemy on a fair field of battle. His eloquence prevailed; and when it was his own turn to assume the supreme command he prepared for the fight. After selecting a position where his forces could not be surrounded by the overwhelming numbers of the enemy, he drew up his line, placing heavy phalanxes on the wings, and the light troops in the centre. His army was then ordered to move forward. As it advanced the two wings fell into double-quick march, and bore down with resistless force upon the right and left of the enemy. The Athenian centre then gave way, and suffered part of the Persian army to pass into the space between the two wings. At that instant the solid Greek phalanxes, which were by that time unopposed, wheeled round with vehement celerity and crushed the remnant of the foe between their two lines. No sooner had this victory been gained, than Miltiades posted towards Athens with a part of his army, and arrived in time to save the city from being attacked and pillaged by the Persian fugitives. He was now treated with the highest esteem by his fellow-citizens. In the public picture that was painted to commemorate the battle of Marathon, he was represented standing foremost of the ten commanders and animating his soldiers for the charge. It was not the habit, however, of the Athenians to honour a great man when his services in their behalf did not succeed. Accordingly, the unsuccessful expedition of Miltiades against the island of Paros changed his enthusiastic admirers into his deadly enemies. He was publicly impeached for having misled his country into a disastrous war, and the mob began to clamour loudly for his life. A wound which he had received in his late campaign, and which had turned into a gangrene, prevented him from confronting his accusers with his ready eloquence, and obliged him to entrust his cause to his brother Tisagoras. He was found guilty, and sentenced to pay a fine of fifty talents. As he was unable to meet the sentence, his maimed and shattered body was cast into prison. There grief and disease terminated the career of Miltiades in 489 B.C., the year after he had won the battle of Marathon. But the vengeance of his enemies was not yet exhausted. His lifeless body was denied a resting-place, until his son Cimon gave himself into custody as surety for the fine which had been imposed. The best authority for the biography of Miltiades is Herodotus. (See ATTICA.)

MILTON, or MILTON-ROYAL, a market-town of England, county of Kent, on an inlet of the channel between the Isle of Sheppy and the mainland, 11 miles N.E. of Maidstone, and 39 E. by S. from London. The town stands on the declivity of a hill; and is old and irregularly built, but it contains many good houses and cottages of recent erection. The inhabitants are principally engaged in the oyster fishery,—the "Milton natives" being in great demand in the London market. Some trade in corn and other agricultural produce is also carried on. Market-day, Saturday. Pop. of parish (1851) 2407.

Milton.

MILTON.

Milton.

JOHN MILTON was born at his father's house in Bread Street, in the city of London, on the 9th of December 1608. Nothing of the material fabric of the street in which he was born now remains, the great fire of 1666 having destroyed that with so much of the rest of old London. But the present Bread Street, which is one of the streets striking off from the great thoroughfare of Cheapside towards the river, occupies the exact site of the old Bread Street; and the spot in which Milton was born may be yet identified as being that occupied by the third or fourth house on the left, going from Cheapside. Here, as one of a line of very respectable shops, and dwelling-houses over them, inhabited chiefly by merchants, and all, as was then the custom, distinguished by signs over the doors and not by numbers as at present, there stood, prior to the great fire, a house and shop known as the Black-Spread Eagle. Milton's father, whose name was also John, had occupied this house since 1603, and carried on in it the business of a scrivener or a copying-lawyer. The story is, that he had betaken himself to that profession some fifteen or twenty years before, on being disinherited by his father, a substantial yeoman in Oxfordshire, for having abandoned the Catholic faith. He had prospered well, and had become possessed of considerable property, including the house in Bread Street; and the sign of the Spread Eagle affixed to the house was no other than the armorial device of his family. Before removing to this house, and when verging on forty years of age, he had married a lady considerably younger than himself, whose name, according to one account, was Sarah Bradshaw, but according to another, Sarah Caston. Five children were the issue of the marriage, of whom only three attained to mature years,—a daughter, Anne, a year or two older than the poet; the poet himself; and a son named Christopher, exactly seven years younger than the poet.

In Milton's case there is less trace of the effect of that rude, though powerful kind of education which is afforded to all children by the mere miscellany of external circumstance amid which they live, than of the effect of the more express education of orderly domestic training. Here, to use a common phrase, he had every advantage. Peace, piety, and comfort reigned in the home in Bread Street. Like most of the substantial London citizens of the time, the scrivener was of Puritan leanings in the matter of religion, and his household was regulated on Puritan principles. But he was also a man of liberal culture and taste. He was especially skilled in music; and specimens of his skill in this art may be seen in various musical publications of the day. It was from him that Milton derived his musical ear and his first tuition in music as an art and a science. This excellent man discerned the genius of his son from the first, and found the chief pleasure and pride of his life in fostering it and watching its growth. Of Milton's mother we hear less. She was, according to Milton himself, "a most amiable woman, particularly noted for her charities in the neighbourhood;" and Aubrey adds that she had such weak eyes, that before she was thirty years old she had to wear spectacles.

It was in his father's house that Milton received his earliest literary education. His first teacher was Thomas Young, a Scotchman, who, after having been educated at one of the Scottish universities, had migrated into England. His connection with the Milton family may have begun as early as 1618, when his pupil was ten years of age; and it must have closed by 1623, when Young went abroad as chaplain to the British merchants at Hamburg,

from which exile he returned in 1628 to be settled as vicar of Stowmarket in Suffolk. While still under Young's care Milton was sent to St Paul's School—a public grammar school of as high celebrity as any in London, and convenient as being situated within a minute's walk of Bread Street. The head master of the school was Alexander Gill, a Lincolnshire man, whose reputation as a teacher was then great; and the usher, or under-master, was his son, the Rev. Alexander Gill, junior, who had recently left Oxford with a considerable name as a scholar. With him Milton contracted an acquaintance, which was continued afterwards; and he also formed a friendship with a fellow-pupil at the school, named Charles Diodati, the son of an Italian physician settled in London. Diodati left school for Oxford in 1621; but Milton remained at school three or four years longer. At school, according to Aubrey, "he studied very hard and sat up very late, commonly till twelve or one o'clock, and his father ordered the maid to sit up for him; and in these years he composed many verses which might well become a riper age." Of these early poetical exercises, the only remaining specimens are his English Paraphrases of Psalms cxiv. and cxxxvi., which bear to have been done in his sixteenth year. Milton himself, however, confirms Aubrey's account of his excessive studiousness from his earliest boyhood; and he says, that when he was sent to the university he was already "instructed in various tongues," and had "no mean apprehension of the sweetness of philosophy."

Cambridge has the honour of counting Milton among her many eminent sons. He was entered as a lesser pensioner at Christ's College, Cambridge, on the 12th February 1624-5, when he was sixteen years and two months old; and he continued his studies in the college for the full academic period of seven years. Concerning his college life there has been much difficulty among his biographers. Johnson was the first to hint the belief that while at college he sustained some punishment at the hands of the college authorities, if not the indignity of corporal chastisement. The original authority, however, for such a statement is Aubrey, whose memoir of Milton, accessible in print since 1813, Johnson had probably seen in MS. at Oxford. Aubrey says, that Milton having received "some unkindness" from his first tutor at college, left him for another; and over the words "some unkindness" there are inserted in the MS. the words "*whipt him*." On this, taken in connection with Milton's first Latin elegy, in which, writing to his friend Diodati, he seems to refer to some difference with the college authorities which was occasioning his temporary absence from college, the whole controversy has been raised. From the investigation we have been able to bestow on the subject, the facts seem to be these:—That about the second or third year of his residence at college Milton did have some difference with his first tutor, Mr William Chappell, then one of the most distinguished tutors in the university; and afterwards Bishop of Cork and Ross; that this difference did involve some interference on the part of the master of the college, Dr Bainbridge, in consequence of which Milton left college for a time; but that eventually the difference was adjusted by his being transferred from Chappell's tutorship to that of the Rev. Nathaniel Tovey, afterwards a parish clergyman in Leicestershire. It is certain, at least, that any "rustication" to which Milton was subjected did not involve the loss of a single term of his academic course. He took both his degrees exactly at the proper time—his B.A. degree in January 1628-9, and his M.A. degree in July 1632. Apart,

Milton.

Milton.

however, from the controversy as to his rustication, it is certain, from Milton's own statements, that at first, owing to a certain haughtiness of manner, and also to a certain obstinacy in pursuing his own course of study, he was unpopular within the walls of the college. His college fellows, he tells us, used to nickname him "The Lady," in allusion partly to the delicacy of his personal appearance, and partly to his moral fastidiousness. He informs us distinctly, however, that this unpopularity was but temporary, and that long before he left college he had won the respect not only of the college, but of the whole university. He speaks in one place of "that more than ordinary favour and respect which he found *above any of his equals* at the hands of those courteous and learned men" who were the authorities of his college, and who, he says, when he left them in 1632, "signified in many ways how much better it would content them that he would stay." In short, Milton left the university with the highest possible reputation. "By his indefatigable study," says Anthony Wood, "he profited exceedingly, and was esteemed to be a sober and virtuous person, yet not to be ignorant of his own parts." These last words are worth noting. From the very first there is discernible in Milton a vein of noble self-respect, and even self-assertion; a conviction of superior power when measured with others; a conscious dedication of his life to noble ends; and a resolution to preserve unstained the purity of his moral being, as essential to the capacity of truly great work in the world, or truly great endeavour of whatever kind.

On going to the university Milton had been destined for the church. For this purpose he had gone through the usual course of study in rhetoric, logic, and the scholastic philosophy and theology—studies, however, which even then he regarded in the main as barren and unprofitable, and on which, as on the whole system of university training, he afterwards looked back with vehement contempt. There is evidence that during the seven years which he spent in Christ's College he led a life of singular intellectual independence, performing his academic tasks duly, but occupying himself with much else of his own choosing. The following is a list of his remaining writings during this period (1625–1632):—

I. LATIN.—(1.) In *prose*, the first four of his *Familiar Epistles*, written in 1625 and 1628, and addressed to Thomas Young and Alexander Gill the younger; and seven college themes or orations on various subjects written between 1626 and 1632, and first published by him, along with his *Familiar Epistles*, in 1674, under the title of *Prousiones quadam Oratorice*. (2.) In *verse*, thirteen pieces, chiefly on incidents of his university life; to wit, the seven pieces in the elegiac metre which form his *Ellegiarum Liber*, and the first six pieces of his so-called *Sylvarum Liber*.

II. ENGLISH.—Thirteen poems, longer or shorter, as follows:—*On the Death of a fair Infant dying of a cough*, 1626—the infant being the poet's niece, the daughter of his sister Anne, who in 1624 or 1625 had married Edward Phillips from Shrewsbury, who held a situation in the Crown Office, London; part of a *Vacation Exercise at College*, 1628; *The Hymn on the Nativity*, 1629; *On the Passion*, 1630; *On Time*, 1630; *On the Circumcision*, 1630; *At a Solemn Musick*, 1630; *On May Morning*, 1630; *On Shakspeare*, 1630; *On the University-Carrier* (Hobson), "who sickened in the time of his vacancy (January 1630–1), being forbid to go to London by reason of the plague;" another on the same; *An Epitaph on the Marchioness of Winchester*, 1631; Sonnet on his twenty-third birthday 1631.

No one can read these juvenile compositions now without discerning in them ample promise of what Milton became. The English poems are best known; and in one or two of them—as in that on the Fair Infant and that on Christ's Nativity—there is evidence of true poetic genius and of the most exquisite skill in words and verse. But it is in the less read Latin compositions, perhaps, that the leading traits in the *character* of the young poet are best exhibited. There, while we admire the strong understanding and a command of the Latin tongue in comparison with

Milton.

which the usual classical Latinity of modern scholars is forced and feeble, and while also, even in the cumbrous element of the Latin, we discern the graceful winging of the poetic muse, we see at the same time, better than we can see in the English poems, the habitually grave and austere tone of Milton's mind from his earliest youth,—its tendency, on the one hand, to scorn, and a kind of ferocity of disgust and reprobation; and on the other, to high ideal views and contemplations such as enter only the spirits of the sublime. Nowhere else in the range of juvenile writing known to us is there such distinct evidence of what Horace has called the "*os magna soniturum*,"—the mouth formed for great utterances. The very heaviness of such attempts as there are at the facetious and the humorous proves that it was not in these that Milton was fitted to excel. "*Festivitates et sales*," he says himself in one of the pieces, "*in quibus perexiguam agnosco facultatem meam*." In other words, the basis of his character was a moral austerity inconsistent with mere frolic or frivolity, though not inconsistent with the free exercise, on the one hand, of a powerful and inquisitive intellect, or, on the other, of a phantasy delighting in the minutest forms of the musical and the graceful.

It is to be remembered that, though Milton had the compositions above mentioned in manuscript before leaving Cambridge, none of them was published prior to that time except the Epitaph on Shakspeare. It appeared anonymously among the laudatory verses prefixed to the second folio *Shakspeare* in 1632; and it is interesting to know that Milton's first appearance in print was on such an occasion. He was then in his twenty-fourth year. According to his original intention, he would about this time have been passing from college to some country curacy; and one can hardly help speculating as to what might have been the result for the Church of England had he done so. A Milton among the ecclesiastics of the days of Laud would have been a phenomenon of some interest. Long ere leaving college, however, he had abandoned the idea of being a clergyman. The reason was his jealous concern for his intellectual and religious freedom—a state of mind for which the condition of the Church of England under the ascendancy of Laud afforded little chance of satisfaction. Whoever would become a clergyman at that time must, he said, "subscribe slave, and take an oath withal, which, unless he took with a conscience that could not retch, he must strait perjure himself." He describes himself, therefore, as "church-outed by the prelates," and as having no other prospect left to him than that of a life devoted to study and literature. It says much for the liberality and discretion of his father, that in these circumstances, instead of urging him into a profession against his will, he suffered him to take his own way. Till he was thirty-one years of age Milton did not earn a penny for himself.

The five years of Milton's life which followed his leaving college (1632–1637) were spent by him at Horton in Buckinghamshire, about 20 miles from London, whither his father had retired in his old age after giving up business. These five years, according to his own account, were spent in complete literary leisure and the enjoyment of the quiet rural beauty of the neighbourhood; not but that sometimes he "exchanged the country for the town, either for the purpose of buying books or for that of taking lessons in music or mathematics." During this time, he says, he turned over the Greek and Latin writers; doubtless also the Italian, French, and English; and there is proof also that he entertained for a time the notion of studying law along with his younger brother Christopher, who had adopted the law as his profession. Of his literary assiduity during the same period there is ample evidence in a long list of subjects for dramas and other poems, drawn out by him in the course of his miscellaneous reading, and now preserved, with

Milton. others of his manuscripts, in the library of Trinity College, Cambridge. Of his actual and surviving writings during this period, however, the following is a list:—

I. Three Latin *Familiar Epistles*,—the first dated 1634, and addressed to Alexander Gill the Younger, and the other two dated September 1637, and addressed to Charles Diodati. Possibly also a scrap or two of Latin verse.

II. The following well-known English poems:—

1. The *Sonnet to the Nightingale*; and possibly one or two other sonnets.

2. The two exquisite companion poems *L'Allegro* and *Il Penseroso*.

3. "*Arcades*," part of an entertainment presented to the Countess Dowager of Derby at Harefield by some noble persons of her family, who appear on the scene in pastoral habit." The Dowager Countess of Derby here alluded to was the same lady who, in her youth forty years before, had, under the name of Amaryllis, been the theme of Spenser's song. After the death of her first husband, Lord Strange, who succeeded his father as Earl of Derby in 1594, she had married the lord keeper, afterwards Lord Chancellor Egerton, by whose death in 1617 she was left a widow for the second time. She lived at Harefield House, near Uxbridge, where she frequently had her younger relatives about her, including the Earl of Bridgewater, her second husband's eldest son, who had married one of her daughters by her first husband. It has been supposed that this venerable lady and her family had discovered the poetic talent of Milton, and had him frequently with them as a favoured guest; but the more probable supposition is, that the young people of her family, having resolved, according to the custom of the time, to get up a masque or musical entertainment in her honour, Milton wrote the words of the *Arcades* to oblige his intimate friend Henry Lawes the musician, who had been charged with the arrangements. The date of the entertainment was 1633 or 1634; and *Arcades* was therefore written when Milton was in his twenty-sixth year.

4. "*Comus*," a masque presented at Ludlow Castle 1634, before John, Earl of Bridgewater, then President of Wales." Pleased with the *Arcades*, the young people of the Bridgewater family had determined on a longer and more elaborate performance of the same kind; and they found an excellent opportunity for it in the autumn of 1634, when the earl went to Ludlow Castle in Shropshire to take up his official residence there as Lord President of Wales. His children,—Lord Brackley, Mr Thomas Egerton, and Lady Alice,—went with him; and there was a congress of the neighbouring nobility and gentry. The masque for such an occasion required to be something beyond ordinary; and while Lawes did his best for the music, it was felt by the family that it would raise the character of the entertainment if Milton would undertake the poetry. He did so; and taking a hint, it is said, from an adventure which had befallen Lady Alice in Haywood Forest, produced the beautiful masque of the Lady lost in the Enchanted Wood, and beguiled by Comus and his crew, till her brothers find her. It was by far the most considerable poem that Milton had yet produced, and the rumour of it must have carried his name into many circles. That it did so, we learn from the fact that Lawes published the poem in 1637, with a dedication to Lord Brackley, in which he says, that "although not openly acknowledged by the author, yet it is a legitimate offspring, so lovely and so much desired, that the often copying of it hath tired my pen to give my several friends satisfaction," and wrought me to a necessity of producing it to the public view."

5. *Lycidas*; a monody on the death of Mr Edward King, a young gentleman of great promise, who had been Milton's college companion at Cambridge. He was drowned in August 1637 in crossing from Chester to Ireland, where his friends resided; and the event seems to have produced a great sensation at Cambridge, where a volume was published in the following year, containing three Greek, nineteen Latin, and thirteen English poems to his memory. Milton's *Lycidas*, which is signed "J. M.," closes the volume. He had most probably written it at Horton and sent it to Cambridge. He was then in his twenty-ninth year.

Such were Milton's productions during the five years of his residence under his father's roof at Horton, or from his twenty-fourth to his twenty-ninth year. They are small in bulk, but how exquisite in quality! The minor poems of Milton are, and ever will be, the admiration of critics; and had Milton died at the same time as the friend whom he celebrates as *Lycidas*, we should still have had, in virtue of those poems, to pronounce his beautiful name among those of the sons of the English muse.

Considered, however, in relation to our knowledge of Milton as he was all in all through life, there is a peculiarity

in these early poems. They are truly Miltonic; but they are Miltonic, not in the sense that they represent the whole of Milton, even as he was when he wrote them, but in the sense that they represent him in those moments when he bent his softer genius to the exercise and relaxation of English verse. The poems belong, on the whole, to the idyllic, or what may be called the sensuous-ideal class; that is to say, they are rather poems of rich and beautiful phantasy, of quiet thoughts and imaginations sweetly linked, than of powerful human interest or greatly agitated feeling. They are in this respect not unlike the poetry of Spenser and Keats. According to Coleridge's remark, however, they prove all the better on this account that Milton was by nature a poet. The tendency to choose themes lying remote from ordinary social interests, and the ability, in treating such themes, to wander on and on in a purely ideal manner, weaving a tissue of sensuous fancies connected by occult relations of beauty rather than by the direct associations of place and time, are, according to Coleridge, the most hopeful signs in a youthful poet. These signs were visible in Milton from the first. With all his moral austerity, all his learning, all the strength of his understanding, and all his sterner inclination to the dogmatic, the indignant, and the polemical, his main delight from the first, when he was free to choose, was in purely literary and especially poetic recreation; as if to show how, by reason of very strength, a soul might come to rest in the sweet and exquisite, and so make true his own maxim,—

"How charming is divine philosophy!"

Not harsh and crabbed as dull fools suppose,
But musical as is Apollo's lute."

His early preferences in literature, he tells us himself, had been for the "smooth elegiac poets," whom, both for their matter and "the pleasing sound of their numerous writing," he found "in imitation most easy, and most agreeable to nature's part" in him. He means here poets of the sensuous or sensuous-ideal order, and refers chiefly to Ovid and other classic and Italian poets, though Spenser may be included. That he was right in saying that, as regards their form, the imitation of these poets was agreeable to nature's part in him, no reader of the minor poems can doubt. One of the most striking things about them, especially when compared with the contemporary English poetry produced under Ben Jonson's critical supremacy during the last years of his laureateship, is the perfection of their literary texture,—the taste and finish of their language and versification. Ben died in 1637, and they were therefore in existence in time for him to have seen them, or some of them; and if he had seen them, he would have found even his own most graceful masques, and much more the productions of the Randolphs and others whom he regarded as his literary children, but slovenly things in comparison. But while the *form* of the poets whom he admired presented no difficulty to Milton, was rivalry with them in *matter* equally agreeable to nature's part in him? On this point there have been varieties in opinion. That all in all Milton was a poet; that he possessed the poetic faculty *par excellence*,—call it imagination, ideality, or what we will,—no one has yet been bold enough to deny; and there are perhaps few who would not agree with Coleridge that the nature of this "poetic imagination"—this "vision and faculty divine"—may be better studied in Milton, by reason of its colossal proportions in him, than in any other English poet. If imagination in the poet is the power of thinking in concrete circumstance, of embodying meanings and states of mind in imaginary scenes, incidents, and objects of beauty, which remain in the memory as "a joy for ever,"—what imagination in the *Penseroso* and the *Allegro*, where the poet has collected and woven together with such musical art the circumstances of nature and life suggestive to the recluse of melancholy on the one hand, and of cheerfulness on the other; in the *Arcades*, where, upon the simple

Milton.

Milton. incident of two or three young people advancing on an English lawn with the homage of a speech and songs to a venerable lady seated under the trees to receive them, the poet has framed so complete and so charming a phantasy for ear and eye; in the *Comus*, where, on the suggestion of a larger incident of the same kind, he has provided for us, and placed irremovably in our literature, that phantasy of the enchanted forest, more British than any in Spenser, and yet wholly air-hung, through which the lost maiden is ever wandering, and the noble pair of brothers are ever searching for her, and the magical crew are ever revelling with evil intent, and the attendant spirit of purity, disguised as a shepherd, is ever walking his watchful round; finally, in the *Lycidas*, where, because a hopeful youth has died, we are back among the streams and dells of Arcadia, and behold a landscape in tears! And yet here occurs a question. Imagination or poetry consists in embodying meanings and feelings in forms, which forms must be sensuous; but can it be that a mind should have this poetic tendency, to sensuous embodiment of an ideal kind without having a fondness for what may be called the actual sensuous, or, in other words, a love of natural beauty and an accurate perception of it? As regards Milton, this question has been raised incidentally by Mr Ruskin, who, in a classification he has given of eminent moderns according to the degree in which they seem to him to have possessed a constitutional delight in nature, or the habit of accurately perceiving natural beauty, has placed Milton, along with such men as Bacon and Johnson, among those in whom this quality was moderate or defective, as distinct from those, such as Shenstone, Keats, and poets generally, in whom it was evidently great. Now there is much importance in this separation of the men of thought and energy on the one hand, who act outwards upon nature, and whose greatness consists in such action, from the men of sensibility on the other, who are tremulous to the sights and sounds of nature, and find their function in recording and reproducing them; nor is Mr Ruskin wrong when he places Milton among the men of thought and dogma, who had strength within themselves, and whose faculty did not lie mainly in the tips of their outer senses. He seems to be unjust to Milton, however, in the negative part of his criticism, which denies to Milton keenness of external perception and sensibility to natural beauty along with his moral and speculative strength. His minor poems have much of their charm in their sensuousness; this is, indeed, the word that would be used to characterize what is most evident in them. By Wordsworth himself,—who recalled our poetry to truth and nature, and who was at war with almost all our poets from Dryden downwards, precisely because, as he said, they had never looked at nature for themselves, but had spoken of her by rote,—the accuracy of Milton's images from nature was never impugned, but was, on the contrary, asserted and exemplified, and held up by way of example; and it would take much argument now, to prove that the sensuousness of Milton's poetry was a simulated or merely literary sensuousness, and not the real sensuousness of a man who delighted in the fields, and the flowers, and the clouds, and whose mind teemed with recollections of them. We do not find in Milton, indeed, that universal retentiveness of objects and facts of all kinds, from the oddities of street life, up through the beauties of sylvan scenery, to the splendours of celestial space, which we find in Shakespeare, and to which, so far as facts of the lower or more uncouth order are admitted along with those of the higher, a certain humorous lightness of disposition, such as Milton did not possess, seems to be essential. It may be also that, in Milton as in other men, there had been developed a kind of secondary love of nature, as already transfused and attenuated into literature, and seen through the mist of beautiful speech. All in all, however, as it was certainly the bent of his genius to express itself in sensuous imaginations, so there seems to

have been no film separating him from the world of actual existence whence the materials for these imaginations are usually drawn; but, on the contrary, such a habitual intimacy of his senses with whatever in nature or life was beautiful or impressive, that whenever his phantasy began to work, his memory was ready with authentic forms, sounds, colours, or whatever else was necessary for any poetic combination. His woods, his flowers, his atmosphere, are the woods, the flowers, and the atmosphere of genuine English nature.

Underneath the grace and the flowers, however, there are in these minor poems of Milton all the signs of his manly strength. We have called them sensuous-ideal in their general character, and have spoken of them as being, even in virtue of their singular excellence in this kind, essentially Miltonic; but they are Miltonic also in a higher and more complete sense, as indicating the massiveness of Milton's moral, and the height of his intellectual, nature. The purity of tone in all of them is as perfect as the literary taste; and every now and then, from amid the softness and the luxuriance there breaks forth a passage of luminous speculative meaning or sublime moral maxim. In *Comus* the very theme is the inviolability of virtue by all the powers and wiles of assailing circumstance; and here, as also in the later poem of *Lycidas*, there are outbreaks of the spirit of the future polemic and stern social reformer.

Just before *Lycidas* was written Milton's mother had died (Aug. 3, 1637) at Horton, where she lies buried. From his father, now about seventy-four years of age, the poet not long after obtained leave to make a continental tour, more expressly for the purpose of visiting Italy. He set out with one servant towards the end of the year, taking with him some letters of introduction, and some good advice from Sir Henry Wootton, provost of Eton, who had been King James's ambassador at Venice. He was kindly received at Paris by Lord Scudamore, the English ambassador, who introduced him to Grotius, then ambassador in Paris for Queen Christina of Sweden, and also gave him letters to English merchants in Italy. He went to Genoa by way of Nice, and from Genoa to Leghorn, Pisa, and Florence. At Florence he remained two months, frequenting the society of artists and men of letters. From Florence he went to Siena, and thence to Rome, where he also stayed some time and formed some useful acquaintances. He next visited Naples, where he received much attention from the aged Giovanni Battista Manso, Marquis of Villa, the friend and patron of Tasso. Manso at parting took him to task in a friendly manner for his imprudence in speaking too frankly of religious matters. From Naples it was Milton's intention to proceed to Sicily and Greece; but the news which he received of the imminence of a civil war in his native land determined him to return. "I thought it dishonourable," he says, "that I should be travelling at my ease for amusement when my fellow-countrymen at home were fighting for liberty." Returning northwards, therefore, he reached Rome again, where he was told that the Jesuits had laid a plot against him; but though he remained two months more there, and made no concealment of the strength of his Protestantism, he was not molested. From Rome he went again for two months to Florence; thence to Lucca, and so across the Apennines, through Bologna and Ferrara, to Venice. Thence, after a month's stay, and having shipped for England the books he had bought in Italy, he travelled, by Verona, Milan, and the Pennine Alps, to Geneva, where he became acquainted with the theologian Diodati, the uncle of his friend Charles; and so through France back again to England, from which he had been absent in all a year and three months. While still abroad, Milton had heard of the death of his friend Charles Diodati; and on his return he wrote his Latin poem entitled *Epitaphium Damonis* in honour of his memory.

Milton.

Milton.

One result of the Italian tour, which has not perhaps been sufficiently noted, was its effect in stimulating his literary ambition. While in Italy he had shown about, according to the custom, or had recited in literary circles, some of his juvenile compositions in Latin and English, and had also written some additional trifles, among which were his few Italian sonnets, and his three short Latin poems, *Ad Leonoram Romæ canentem*; and the two longer ones, entitled *Mansus* and *Ad Salsillum poetam Romanum agrotantem*. These specimens of his taste and skill had won him, in return, complimentary letters and copies of verses from the Italian scholars and wits, some of which he thought worth preserving, to be shown afterwards to his less appreciating countrymen. "Gratified," he says, with encomiums of this kind, "which the Italian is not forward to bestow on men of this side the Alps," he had no sooner returned to England than he felt the desire for literary production more strongly than ever. "I began," he says, "thus far to assent both to them and to divers of my friends here at home, and not less to an inward prompting which now grew daily upon me, that by labour and intent study (which I take to be my portion in this life), joined with the strong propensity of nature, I might perhaps leave something so written to aftertimes as they should not willingly let it die." His aspirations had even taken a certain determinate direction as regarded the work on which he was to spend his strength. Knowing that "it would be hard to arrive even at the second rank among the Latins," he had resolved that his literary labours thenceforth should be chiefly in his mother tongue, "not caring once to be named abroad, though perhaps he could attain to that, but content with these British islands as his world." He had resolved, moreover, that his main work should be a poem, and a poem of the higher order, in which "what the greatest and choicest wits of Athens, Rome, or modern Italy, and those Hebrews of old, did for their country," he "in his proportion, with this over and above of being a Christian," might do for his. As to the precise form and subject of such a poem, however, he had not made up his mind—whether it should be epic, after the model of Homer, Virgil, and Tasso, and if epic, what king or knight of British history before the Conquest should be chosen as the hero; or whether it should be a stately drama, in which something of the form of Sophocles and Euripides should be combined with still higher forms, of which the Bible, and especially the Apocalypse, afforded examples; or whether, finally, it should be some grand lyric, such as heathen genius had hardly yet attempted.

Alas! these schemes and ruminations were destined to a speedy and severe interruption. The civil war, prognostications of which had reached him in Italy and hastened his return, was now about to begin in earnest; and for a period of twenty years Britain was to be the scene of a social strife such as had been scarce paralleled in the world before. During these twenty years there was very little literature produced in England that was not polemical in its tenor. There were controversial treatises and pamphlets in abundance; there were also satires and songs for political purposes, and full of political allusions; but of pure history, pure philosophical writing, or pure poetry, there was little. The men of talent from whom literature of such kind was to be expected were either dispersed abroad, or, if they remained in England, were whirled along in the common agitation. In the lives of Shirley, Waller, Hobbes, Davenant, Cleveland, Denham, and Cowley, and even in those of men like Jeremy Taylor and Fuller, the effects of the civil wars of Charles's reign, as bending them somewhat, both in external and in internal respects, out of what might otherwise have been their course, may be traced without difficulty. But in the case of Milton the effect is infinitely more striking. But for the civil wars we should have known but half the man. In his case there was a

Milton.

pre-established harmony of mind with the great national revolution through which he had to pass; there were elements in his moral and intellectual being which actually waited for the convulsion; nay, of him alone, in the midst of the Davenants, and Cowleys, and Wallers, can it be said that there was something in his very notions of literature itself which, corresponding as it did by a profound affinity to the new Puritan spirit then beating in the heart of the English people, pointed for that very reason to a literary development which should be no mere continuation of the dregs of Elizabethan wit, but an outburst as original intellectually as the Puritan movement was socially, and requiring partizanship with that movement as its explanation and comment. On the first manifest signs of that movement he consented, as he says, "to lay aside his singing-robcs" for a more convenient season, and "to leave a calm and pleasing solitariness, fed with cheerful and confident thoughts," in order to "embark in a troubled sea of noises and hoarse disputes." He imagined that a year or two of such work, to which he felt that he was lending "only his left hand," would be all that would be required of him. But once engaged in the controversies of the time, he was led on and on; and for the space of full twenty years we see him only as a polemical prose writer, giving and taking blows in the cause of the Revolution, and producing nothing at all in verse except an occasional Latin scrap or epigram, and a few English sonnets suggested by passing occurrences. To attempt here a full and connected narrative of this period of his life is evidently impossible; it will be sufficient to present a chronological scheme of the main facts, including a list of his successive publications.

1640-42 (Milton *ætat.* 31-33).—The Long Parliament met November 3, 1640. Milton had by this time changed his mode of life. The household at Horton having been broken up, and his father having gone to reside at Reading with his younger son Christopher, then a barrister-at-law and of royalist politics, Milton had taken lodgings in the house of one Russell, a tailor in St Bride's Churchyard, Fleet Street. Here he took to lodge and board with him his two young nephews, Edward and John Phillips, then about nine or ten years of age, the sons of his sister Anne, now married for the second time to a Mr Agar of the Crown Office. The arrangement seems to have been one of mere kindness at first; but his friends having suggested to him that he might take a few more boys to educate, he removed in 1641 to a larger house in Aldersgate Street, situated in a garden, and out of the bustle of the city. Here he received some additional pupils, the sons of wealthy friends, and occupied his time partly in educating them after a peculiar system of his own, and partly in private studies. It was in these circumstances that he wrote his first pamphlet. Amid the numerous matters occupying the attention of Parliament—the trial of Strafford, &c.—that of church reform was paramount. The root of the evil, it was felt by the Puritans, was in the prelatial constitution of the church; and already there were petitions and bills having for their object nothing less than an abolition of bishops, deans, and chapters, and all Episcopal forms, and a reconstruction of the Church of England after the Presbyterian model. Into this controversy Milton threw himself; and, the press being then free for such opinions, he published in 1641 a treatise or bulky pamphlet in two books, in the form of a letter to a friend, entitled *Of Reformation, touching Church Discipline in England, and the Causes that hitherto have hindered it*. The treatise answers to its name, and is throughout a vehement attack on Prelacy in its forms and essence. It helped to infuriate the controversy which was already waging. A defender of Episcopacy appeared in Hall, Bishop of Norwich. Hall was answered by a counterblast from five Puritan ministers—Stephen Marshall,

Milton. Edward Calamy, Thomas Young (Milton's old tutor), Matthew Newcomen, and William Spurstow—who clubbed the initials of their names together so as to form the word "Smectymnus;" and Archbishop Usher came to the rescue of Hall, and wrote a confutation of Smectymnus. Milton feeling that the prelates were likely to have the best of the debate, both in learning and in literary talent, unless he interfered, grappled with Usher and his associates in two additional pamphlets; the one, entitled *Of Prelatical Episcopacy*, addressed mainly to the question of the apostolical origin of Episcopacy; the other, which is much the longer, entitled *The Reason of Church Government urged against Prelacy*. Nor was this all. Bishop Hall having himself written a reply to Smectymnus, entitled *The Remonstrant's Defence*, Milton produced a fourth tract, written in the form of a dialogue, and entitled *Animadversions upon the Remonstrant's Defence*, &c.; and, finally, these "Animadversions" having drawn forth an anonymous reply, supposed to be by a son of Bishop Hall, in which Milton's character was scurrilously attacked, the controversy was wound up (1642) by Milton's *Apology against a Pamphlet called "A Modest Confutation of the Animadversions upon the Remonstrant against Smectymnus."*

1643-45 (Milton *etat.* 34-36).—The civil war had now fairly begun. The king had his head-quarters at Oxford, and his troops and those of the Parliament were fighting for the possession of the country. The Westminster Assembly had met to help the Parliament in discussing the religious question. In the midst of this confusion Milton took a step usually taken in quieter times. "About Whitsuntide" (1643), says his nephew Phillips, "he took a journey into the country, nobody about him certainly knowing the reason, or that it was more than a journey of recreation. After a month's stay from home, he returns a married man who set out a bachelor; his wife being Mary, the eldest daughter of Mr Richard Powell, then a justice of the peace of Forest Hill, near Shotover in Oxfordshire." There had been a previous acquaintance and some money transactions between the two families. What occurred after the marriage is known to everyone. Being no Minerva, but a simple and apparently rather stupid country girl, "accustomed to dance with king's officers at home," the young wife found the life she was leading intolerable, and could see nothing in her husband but a man of harsh and morose ways, whom she could not understand, and who was always at his books. She asked leave to return home on a short visit, and, having gone, she flatly refused to come back. Her parents abetted her in the refusal, and seem, among other things, to have alleged their son-in-law's politics as a reason, they being royalists. Milton's conduct on the occasion was most characteristic. Where other men would have remained quiet, or, if so inclined, have consoled themselves in secret, he made his case the matter of public argument. In a subsequent sketch, indeed, of his own life about this time, he speaks as if it was less any private reason than the systematic prosecution of a path of activity which he had marked out for himself that led him to the public discussion in which he now engaged. While other men were fighting for liberty, he says, *he* had resolved to do what he could for the same great cause by expounding the true theory of liberty; and having already written on ecclesiastical liberty, and seen that question brought by events to some sort of settlement, he now saw remaining the equally important questions of private liberty and civil liberty. This is no doubt substantially accurate; and Milton's views on the marriage question were no doubt so properly a part of his general philosophy, that they might have been evolved in the mere course of speculation, without the stimulus of any private interest in the matter. On the whole, however, their connection with his own case is undeniable. It is as if he said,—"I have found myself in circumstances in which a fundamental rule

of society as it exists has come in conflict with my comfort in such a manner as to lead me to examine its validity by the higher laws and principles on which it professes to rest; and as I am not a man to do anything underhand, I here publish my views in justification of whatever I may see fit to do." He published in quick succession four tracts on this subject,—*The Doctrine and Discipline of Divorce restored to the good of both Sexes from the Bondage of Canon Law*, &c. (1644, in which year two editions appeared, both addressed "to the Parliament of England, with the Assembly"); *The Judgment of Martin Bucer touching Divorce* (a translated series of extracts, also published in 1644); *Tetrachordon, or Expositions upon the four chief places in Scripture which treat of Marriage or Nullities in Marriage* (published in 1645, and addressed to the Parliament); and *Colasterion; a Reply to a Nameless Answer against the Doctrine and Discipline of Divorce* (1645). The doctrine in all these tracts is, that moral incompatibility is as good a ground for divorce as conjugal infidelity, if not a better—a doctrine leading to numerous applications which he does not state, and which it is needless to say no civilized society has yet seen fit to adopt. One notices in the tracts, too, a singular disposition to treat the question as if it were entirely a man's question; and indeed they are full of those notions of the inferiority of women which Milton held all his life, and which are generally repudiated with indignation by those who now adopt views similar to his as to the theory of the marriage bond. At the time, the pamphlets produced some sensation, and the author was nearly being taken to task for them by Parliament at the instance of the Presbyterian divines in the Assembly. As regards Milton himself, his views were never carried out, the king's waning fortunes having made it convenient for his wife's family to bring about a reconciliation, the effect of which was, that towards the end of 1645 Mrs Milton was again domiciled with her husband. It was not to the house in Aldersgate Street, however, that she returned, but to a larger house which Milton had taken in Barbican, and which was then getting ready. Here, besides her husband and his pupils, she found old Mr Milton the father, who had been obliged during her absence to leave his younger son's house in Reading, in consequence of the surrender of that town to the Parliament, and to take up his quarters with his son John. It remains to add, before quitting Aldersgate Street, that here Milton wrote, besides his divorce pamphlets, his tract *On Education*, addressed to Mr Samuel Hartlib, and his noble *Areopagitica, or Speech for the Liberty of Unlicensed Printing*. Both were published in 1644, and they contain Milton's views on questions of great public interest at the time—the first, his views on the state of the universities, and his plan of a gymnasium which should supersede both them and the grammar schools, and do the work of both better in a much shorter time; and the second, his views on the liberty of the press, in the form of an appeal to Parliament to reconsider an order they had just passed subjecting books to a censorship. When we add, that about the same time Milton prepared for the press the first edition of his poems (published in 1645, in a small volume, by Humphrey Moseley, the Tonson of his day, and containing, besides the pieces in English and Latin already named, some sonnets written in the meantime), it will be seen that there was industry enough in the house in Aldersgate Street during the absence of Mrs Milton.

1646-48 (Milton *etat.* 37-39).—Mrs Milton's return, indeed, seems rather to have interrupted than to have forwarded his literary activity. One reason of this may have been that she brought her whole family after her. Her father, mother, brothers, and sisters were in Oxford when it surrendered to the parliamentary army in June 1646; and, being thus driven from home, they came up to London

Milton. and were kindly received by Milton into his house till matters could be better arranged. As old Mr Milton was still there, and as Milton's first daughter Anne had just been born (July 29, 1646), the house seems to have been inconveniently crowded; at least Phillips hints as much when he says that after their departure it "looked again like a house of the muses." This cannot have taken place prior to the 1st of January 1646-7, when the father-in-law died in Milton's house. Milton's own father died in the March following, at the age of eighty-four or upwards. These deaths, the return of the Powells to Oxfordshire, and probably also a falling-off in the number of Milton's pupils, determined him to give up his house in the Barbican, and to remove (1647) to a smaller one in Holborn, having its back to Lincoln's Inn Fields. He does not seem to have continued to receive pupils long after this time, but to have been content with his scholarly studies and the quiet exercise of his pen. It has been remarked by Mr Keightley, that Milton was fond of the humble literary practice of compilation when there was nothing better for him to do; and accordingly it seems to have been during the years (1646-1648) when he was living in the Barbican and at Holborn, waiting for the farther issue of events, that he prepared for his own use, or for that of his pupils, some of those compilations which he afterwards published. At this time, at all events, he wrote a portion of his *History of England*. In poetry he still did next to nothing.

1648-9 (Milton *ætat.* 40).—On the 30th January 1648-9 Charles was beheaded, and England became a Commonwealth, presided over by a council of state, served in the field by Cromwell and other generals, and assisted in legislation by the Rump Parliament. The Revolution had thus been borne on by its bolder spirits to a stage at which, while the outside world stood aghast, multitudes of those in Britain itself who had followed it so far, including the Scots and the Presbyterians generally, fell off or turned reactionary. At this crisis Milton came forward to justify what the bolder spirits had done, and "to compose the minds of the people," naturally unsettled by the charges, flung upon them on all sides, that they had murdered their sovereign. Within a week or two after the execution of Charles he published a short pamphlet, the full title of which it is worth while to quote:—*The Tenure of Kings and Magistrates; proving that it is lawful, and hath been held so through all ages, for any who have the power to call to account a tyrant or wicked king, and, after due conviction, to depose and put him to death, if the ordinary magistrate have neglected or denied to do it; and that they who of late so much blame deposing [i.e., the Presbyterians] are the men that did it themselves.* So seasonable an interposition could not be overlooked by the government of the Commonwealth; and as Milton was personally known to Bradshaw and others of the council of state, they were empowered to consult with him as to his willingness to accept the office of foreign or Latin secretary to the council. He did accept the office, with a salary, as it appears, of about £290 per annum, and his appointment is dated the 15th of March 1648-9. In order to be near the scene of his duties, he removed from Holborn to lodgings at Charing Cross; he was subsequently in the course of the year accommodated with rooms at Whitehall, but only till an official residence which had been assigned him in Scotland Yard could be got ready. Prior to his acceptance of the foreign secretaryship he had published a pamphlet entitled *Observations on Articles of Peace between the Earl of Ormond and the Irish Rebels*, in which is discussed the policy of the late king in the matter of Irish Popery and Presbyterianism.

1649-53 (Milton *ætat.* 40-44).—Milton's official duties consisted in preparing drafts of such letters in Latin as the council desired from time to time to address to foreign princes, governments, and ambassadors; and a series of

forty-six such letters, written by him for the council, and the publication of which was prevented during his lifetime, was edited from his papers after his death. But much more important work was devolved on Milton by the council. The famous *Ikon Basilike* had just appeared, and was circulating in hundreds of copies through the country, representing the late king, on the professed authority of his own private papers, as a saint ever on his knees during his hours of solitude and misfortune, and doing much, therefore, to win popular acquiescence in the use of the term "royal martyr," as already posthumously applied to him. By way of counteractive, Milton wrote and published a long pamphlet entitled *Εικονοκλαστης*, in which, without questioning the authenticity of the pretended manifesto of royalty, he criticizes it mercilessly. The preparation of this pamphlet must have occupied him during a considerable portion of the year 1649; but it was hardly finished when a still harder piece of work was required of him. Charles II., then a refugee in Holland, had got the great scholar Salmasius, *alias* Claude de Saumaise, of the university of Leyden, to undertake the advocacy of his cause in a treatise such as might be submitted to the learned throughout Europe; and the Continent was now ringing with the fame of the *Defensio Regia pro Carolo Primo ad Carolum Secundum* which Salmasius had published. Fearful of the damage that such a work might do abroad, the English council of state bethought themselves of their secretary as the man to answer it suitably. On the 8th of January 1649-50 it was ordered by the council "that Mr Milton do prepare something in answer to the book of Salmasius, and, when he hath done it, bring it to the council." In execution of this commission, Milton prepared his famous *First Defence for the People of England; or, Pro Populo Anglicano Defensio, contra Claudii anonymi alias Salmasii Defensionem Regiam*, the order for the publication of which appears in the council-minutes under date December 23, 1650. It has been stated that Milton received £1000 for the performance; but the minutes of council exhibit nothing more than a vote of thanks. The success of the treatise was infinitely beyond what might have been expected. Salmasius found himself assailed in his philosophy, in his Latinity, and in his powers of opprobrious rhetoric, by a man who was more than his match in all; and it is even said that his death, which occurred not long afterwards, was caused by chagrin at his loss of credit. Satisfied with his triumph, Milton rested from literary exertion, except of a private kind, for about two years. It was during this time that he removed from Scotland Yard to a house "in Petty France, Westminster, opening into St James's Park," which house (afterwards occupied by Bentham) he continued to live in till the Restoration. It was about this time also, and apparently in the house in Petty France, that he was visited by the great calamity of his life—his blindness. From a letter on the subject written by him at a later period, it appears that his eyesight had begun to fail as early as 1644, when he was about thirty-five years of age, and that the process of obscuration was so gradual that it was not till about 1650 or 1651 that total blindness was threatened. The preparation of the treatise against Salmasius was believed by himself to have hastened the fatal result. At all events, by the end of the year 1653 Milton was totally blind, and the fact of his blindness was publicly talked of both by his friends and his enemies. The fatal affection was of the kind called *gutta serena*; and Milton himself tells that it left his eyes perfectly clear and without any mark, speck, or external disfigurement whatever. It may have been while the blindness was not yet total, but only nearly so, that he sustained what even for him, in such circumstances, must have been another great loss, and which was certainly a great loss for his children. This was the death of his

Milton.

Milton. wife, the precise date of which has not been discovered, though it was either in 1652 or 1653. She left three children, all daughters,—the eldest, Anne, about seven years of age; the second, Mary, about five; and the third, Deborah, a mere infant in arms. Although she may not have been the fit person to be the wife of Milton, one cannot but imagine the house in Petty France more desolate from her absence; the blind and austere widower left in one part of it to contemplations in which some thoughts of Mary Powell, as she was when he first bore her away from her Oxfordshire home, can hardly have been wanting; and the poor motherless children, known to him only as tiny voices of complaint going about in the darkness near, with none but an alien voice any more to hush or overawe them!

1653–1658 (Milton *ætat.* 44–49).—Notwithstanding his blindness, Milton continued in the active discharge of his duties as Latin secretary during the whole protectorate of Cromwell, which began on the 16th of December 1653, and terminated on Cromwell's death on the 3d of September 1658. Between seventy and eighty Latin letters, written by him in Oliver's name, are included in the collection of his state letters; and besides these he wrote a Latin state paper of some length on the subject of the Protector's differences with the Spanish court. He had, however, an assistant in his office who relieved him of a part of the work; and there is a council order, dated April 17, 1655, reducing his salary to L.150 per annum, with the proviso that the same should be paid to him during his life. It seems, however, that both Milton and his friend Andrew Marvell, who was latterly associated with him in the office, received an actual salary of L.200 a year. That Milton was not only an admirer of Cromwell's genius,—he had already celebrated him in a sonnet as “Cromwell, our chief of men,”—but also an entire believer in the necessity and the advantage of his government, is proved by the tenor of his writings during the Protectorate. These consisted of three pamphlets growing out of the *Defensio pro Populo Anglicano*. As early as 1651, indeed, an anonymous reply to this treatise had appeared; but Milton, who attributed it to Bishop Bramhall, left the confutation of it to his nephew John Phillips, and only revised what Phillips had written. Another work having appeared abroad, however, in 1652, with the title *Regii Sanguinis Clamor ad Cælum adversus Parricidas Anglicanos*, Milton, who was grossly and calumniously attacked in it, and represented as a blind monster, thought it fit to reply in person. The real author of the work was the Frenchman Peter Dumoulin, afterwards a prebendary of Canterbury; but the reputed author at the time was Alexander More, a Scotchman, settled in France, who had been concerned in seeing it through the press; and against him Milton directed the full force of his vengeance. In the *Defensio Secunda pro Populo Anglicano*, which was not published till 1654, Milton meets the personal accusations of his antagonist, and retaliates with scurrilities quite as coarse and offensive, though doubtless better founded; but he also returns to the main question, in the course of the discussion of which he introduces a splendid panegyric on Cromwell, and brief eulogistic sketches of some of the other heroes of the Commonwealth. Not content with what he had said in his own defence in this pamphlet, he followed it up by another entitled *Authoris pro se Defensio contra Alexandrum Morum, Ecclesiasten* (1655); and More having rejoined, he wound up with *Authoris ad Alexandri Mori Supplementum Responsio*, published in the same year. These pamphlets must necessarily have been written by the method of dictation, and in the first of them there is a passage written with express reference to his blindness. During the remaining three years of the Protectorate, Milton had leisure to fall back upon the compilations which he had on hand. During the same

period he married his second wife, Catherine Woodcock, daughter of a Captain Woodcock of Hackney, of whom little or nothing is known. The marriage took place on the 12th November 1656 by civil contract; and on February 1656–57 Milton was again left a widower by the death of his wife in childbirth. He has testified his affection for her in a well-known sonnet.

1658–1660 (Milton *ætat.* 49–51).—The twenty months which followed the death of Cromwell were a time of varying anarchy and uncertainty, in the midst of which events slowly shaped themselves towards one inevitable issue, which men began to think of by themselves long before they dared to speak of it to one another,—the restoration of Charles II. The state of Milton's mind and the course of his life during these perplexing months are to be inferred from what remains of his writings during them. As Latin secretary he wrote eleven letters for Richard Cromwell, and two letters in the name of the Restored Parliament after Richard's abdication. The last letter is dated May 15, 1659, after which we hear no more of Milton officially. But as a citizen he was not idle; and if the resolution and the reasonings of one man could have maintained republicanism in England, and kept the door fast against the return of royalty, whether accompanied by Prelacy or by Presbytery, the work would have been done by Milton. His revived anxiety on the religious question was exhibited in two tracts, both written in 1659, and addressed to Parliament; the one entitled *A Treatise of Civil Power in Ecclesiastical Causes, showing that it is not lawful for any power on earth to compel in matters of religion*; and the other, *Considerations touching the likeliest means to remove Hirelings out of the Church; wherein is also discoursed of Tithes, Church Fees, and Church Revenues, and whether any maintenance of ministers can be settled by law*. As these tracts were intended by their author to stem what he considered a return of the national mind towards intolerance in religion, so his anxiety with respect to what was more properly the political reaction was shown in *A Letter to a Friend concerning the Ruptures of the Commonwealth* (dated October 1659, though not then published), and in a subsequent more public pamphlet entitled *The Ready and Easy Way to establish a Free Commonwealth, and the excellence thereof compared with the inconveniences and dangers of readmitting Kingship into this nation*. The views addressed in this pamphlet to the public at large were even recapitulated by him at the last hour for the private eye of General Monk, in a short letter headed *The Present Means and Brief Delineation of a Free Commonwealth, easy to be put in practice and without delay*. Monk's mind, however, was better made up than Milton's as to the ease or difficulty of the solution in question; and the last act of the despairing republican was to publish *Brief Notes upon a Late Sermon titled “The Fear of God and the King,” preached and since published by Matthew Griffith, D.D., and Chaplain to the late King*. No *Blind Guides* was the title as well as the tenor of a short answer to this criticism, written by L'Estrange the essayist; and in May 1660 Charles II. was on the throne. Milton, as almost coming within the doomed category of the regicides, was for some time in danger of being included among those whom the new government exempted from amnesty. His more obnoxious writings were called in by proclamation, and publicly burnt by the hands of the hangman; he was actually in custody after the Act of Indemnity had been passed; and that he escaped finally without punishment is said to have been owing chiefly to the intercession of the poet Davenant.

The period of Milton's life which we have thus hastily traversed, extending from his thirty-second to his fifty-second year, and coinciding, therefore, with what may be

Milton.

called his middle life or manhood,—was, we would again observe, all but entirely a period of polemical prose-writing. The four-and-twenty separate pamphlets, treatises, &c., which he wrote during these twenty years, make in all, when collected, three or four goodly volumes; while the stray sonnets and other metrical scraps, in which during these years he hinted rather than asserted that he had not parted with his title as a poet, do not amount to more than a few pages. The reader will do well to note this interpolation of a middle period of prose polemics between a poetic youth and an old age dedicated to poetry again, as a significant fact in the life of Milton. It arose, as we have seen, from an imperative necessity of the times, which affected other lives besides his, and the result of which in the aggregate was an apparent break or variation in our literary history co-extensive with the entire period of Puritan ascendancy. But that this fact in the general life of the nation should be illustrated so visibly, and with such mechanical exactness, in the life of Milton, marks him out as pre-eminently, in literary respects, the representative of his age. All the other wits and writers of any note were on the other side, and therefore represent the contemporary mind of England only negatively; in him alone among the writers have we a colossus marching by the law of his own independent constitution in the direction of the movement and in the midst of it, and capable, therefore, of illustrating it positively.

Milton was fitted for the part he performed in connection with the Puritan movement by that very peculiarity of constitution to which we have already referred as distinguishing him from most poets. Poets generally, it is supposed, are and ought to be characterized by an excess of sensibility over principle,—a certain mobility of the whole mind and temper rather than the prevalence in the mind of any one moral mood or gesture. Milton, however, as we have seen, was one of a class of poets, claiming also such poets as Dante and Wordsworth, of whom this cannot be said. Whatever his sensibility, whatever the range and freedom of his imagination, he was a man at the basis of whose nature was a moral austerity compacted of certain definite and deliberate conclusions as to what was right or wrong, allowed or forbidden, everlastingly true and expedient, or everlastingly false and pernicious. Being such, he was necessarily, in relation to the society in which he moved, a man of dogma and asseveration as well as a poet. Possibly this alone might account for the part he took in the social controversies of the time, and for the unusual combination he presents of the reformer with the poet; for generally such a nature, by reason of its dissatisfaction with much that exists, will ally itself to what seems the innovative or progressive tendency; whereas that absence of opinion, except on matters of taste, which is believed to characterize poets and artists as a class, will in itself usually function as an opinion in favour of things as they are. In order to account fully, however, for Milton's thorough identification of himself with the most advanced social tendencies and aspirations of his age, we must think not only of the strength of the moral or dogmatic element in him, but also of the peculiar effects of this dogmatic habit when associated with a most courageous and inquisitive intellect. No man of the time was more resolute in asserting that right of free thought, the recognition of which, as applied to the Bible, he regarded as the essence of Protestantism; no man spurned more angrily all trammels which tradition, authority, and custom would impose on a mind already sufficiently bound, as he thought, by its own idea of allegiance to its Maker. Hence, in his conclusions on social questions, he came uniformly to occupy ground on the farthest verge of the speculation of the time, so far as it still acknowledged the Christian creed and the code of Christian ethics. Nay, on various questions on which men

Milton.

who had passed over to Pyrrhonism were practically conservative, he, the English Christian, was practically revolutionary. In the language not only of Johnson, but of those of our own time to whom his opinions on church and state are still offensive, Milton was one of the rebellious or anarchical order of spirits. In the matter of ecclesiastical polity, for example, he had passed through Church of England Puritanism and Presbyterianism to take up a station somewhere among, if not already beyond, the Independents and other extensive sects of Nonconformists. In some of his writings he appears as a pioneer of the Voluntary Principle. In his opinions on marriage he was heterodox among the heterodox. He had notions of education such as would hardly be propounded now by the most radical of university reformers. He advocated toleration of all Protestant sects, and the freedom of the press, at a time when these ideas were new, in language from which even those who now profess them as a matter of course are accustomed sometimes to abate a little. In state politics he was an ultra-republican, with some modifying reservations. It is, in fact, owing to the peculiar *ensemble* which his creed presents of so many extreme views harmonized in his case unto a kind of unity, but otherwise only found detached and scattered among the sects of his time, that it is reckoned impossible to identify him with any of these sects in particular, or even, as some think, with the Puritans as a party. Both Coleridge and Mr Macaulay have noticed this eclectic character of Milton's intellect as shown in his writings. "From the Parliament and from the court," says Mr Macaulay; "from the conventicle and from the Gothic cloister, from the gloomy and sepulchral rites of the Roundheads and from the Christmas revel of the hospitable cavalier, his nature selected and drew to itself whatever was great and good, while it rejected all the base and pernicious ingredients by which these finer elements were defiled." In the sense in which it is intended this is true. As a man of scholarship and academic culture, as a lover of music and of art generally, and with a fancy accustomed to range in search of beauty through the whole world of fact and of literature, it was not to be supposed that the partizanship of Milton, even when most resolute, would be of a barbarous or meagre kind, confounding principle with forms and minutiae. Like Cromwell, who was also exempt from the prejudices of his party against art and liberal culture, he fought in the struggle as a general fights, and not as the common soldier. Nevertheless, it is to be remembered that he did fight; and as the true spirit of a cause is better and more profoundly represented in its leaders than in its inferior adherents, so it would be but pedantry to say, that because Milton wore his hair long, or because he has spoken reverently of the richly-stained glass and the pealing organ of a Gothic cathedral, therefore he was not a Puritan. Let us make whatever we can of the fact, he did belong, with his whole heart and soul, to the English Puritan and republican movement of the seventeenth century. He honoured what it honoured; he hated what it hated; he shared its detestation and intolerant dread of Popery. If he was not a Puritan, it was because he was a Puritan and something more; that "something more" being an expression for much that Milton's mind, rolling magnificently within itself, had thought out as properly belonging to Puritanism, and as necessary to be worked into it in order to give it its full development. In this sense, because Milton was an ideologist in the van of the extreme sects, it might perhaps be argued that he did not properly belong to a sect at all. The idealism of Milton's politics,—the spirit of prophetic enthusiasm rather than practical tact with which, in his political speculations, he wraps the facts of his time, and even human nature in general, round his own inwardly evolved theories and his schemes of what might be,—must strike every reader.

Milton. of his prose writings. In reading them we at once see the difference between a Milton theorizing nobly for Puritanism in his closet, and a Cromwell as the man of action, with enthusiasms as fervid and an ideal as high, grappling in the same interest with events and contingencies. Milton's plans, for example, submitted to Monk for averting the Restoration are interesting now chiefly as very simple-minded proofs of his tenacity as a theorist.

It is not only, however, as illustrating Milton's character, or the higher tendencies of that historical movement with which he was associated, that his polemical prose writings are now of interest. They have an interest other than historical. It is because the bulk of polemical writing is on points of ephemeral importance, and is therefore of ephemeral application, that so little of it endures in proportion to what has been produced, and that ages which may have teemed with such literature appear often as mere blanks in the retrospect of the literary historian. The pamphlets did their work; and when the day for which they were calculated was over, they disappeared with its buzzing insects. Their very efficiency sometimes might be measured by the rapidity with which they were forgotten. But as there are certain controversies which are not ephemeral, so there is polemical writing, the lease of which, to borrow Milton's own figure, may be "for three lives and downwards." To a great extent Milton's prose writing is of this class. Two centuries have elapsed since he lived and wrote, but (and it would have surprised him to learn that it would be so) the war in which he fought is not yet over. In Europe,—nay, in Great Britain itself,—some of the questions which he discussed are not yet settled, or, after having apparently been settled, are again rising ominously into sight. Hence, as Milton did not concern himself with the accidents of these questions, but invariably plunged into their essentials, there is still, with every allowance for the change in the intellectual point of view between his time and this, a permanent interest in most of his argumentations. Apart, however, from the interest which these prose writings thus retain as belonging in the main to one side of a yet unfinished controversy, they have an interest of a more general kind to which none can be indifferent. As Burke's political writings are admired for their elevation of sentiment, and the richness of their intellectual matter, by those who either dissent from their practical tenor or care little about it, so, and even in a more superb degree, there is that in Milton's prose treatises which will keep them immortal. They are as truly Miltonic as his poetry. As Milton's poetry is unique in one section of our literature, so is his prose in the other. It is prose of that old English, or as some might say, old Gothic kind, which was in use among us ere yet men had given their days and nights to Addison, and when it seemed as lawful that thought in prose should come in the form of a brimming flood, or even of a broken cataract, as in that of a trim and limpid rivulet. But even amid the greatest specimens of such prose of the pre-Addisonian period Milton's prose is peculiar. That of Bacon may roll with it a richer detritus of speculative hints and propositions; that of Jeremy Taylor may have a mellow beauty; but no prose in the language is grander than Milton's, or more indicative of moral greatness. Its characteristic in its best passages is a kind of sustained and sometimes cumbrous and operose magniloquence. Milton tells us himself that he wrote slowly; and one can see that as he wrote he was abashed by no weight of thought or sublimity of fancies that could come to him, but would pile thoughts and fancies together till no prose sentence could carry the whole burden in its cadence, and the residue had to be conveyed in a poetic chant. Many passages in his treatises might be read apart as prose odes; and even where he is roughest and most controversial, and where his actual reasonings seem,

as they often do, poor and inconclusive, it is as if, in order to bury his adversary anyhow, he were tumbling, in sheer rage, a temple into ruins. This is true of his Latin prose writings (of which no fit translation exists) as well as of his English.

Milton.

Milton survived the Restoration fourteen years (1660–1674), and these fourteen years form the third period of his literary life. To him, if to any man, those days must have seemed dark and evil. One set of men had gone out of office, and been thrust down into the obscurer recesses of the body-politic, there to cherish their principles secretly until such time as they should reappear in the guise of modern Whiggism and modern Dissent. The public direction of affairs had passed into the hands of men of principles directly opposite. Of the state of manners and morals in the court of the witty and licentious Charles II., and of the contrast which it presented to the Puritan government which it had superseded, all have some idea. The superficial change throughout the nation at large, and especially in and about the metropolis, corresponded with this change in the *personnel* of the government. Execration of Puritanism, and a reaction in favour of whatever Puritanism had forbidden or denounced, characterized the popular conduct and every department of the public procedure. Above all, the change was visible in the new literature which began at this time to spring up in consequence of the social calm, such as it was, that had followed an age of conflict and turmoil, and especially in those portions of this new literature which depended on the patronage of the court, or appealed most directly to popular and metropolitan feeling. The literature of the Restoration, as all know, was marked by a certain combination of qualities distinguishing it as a whole from the literature of any preceding, and from that of most subsequent, eras of our national history. It was in the main low in aim, and coarse in tone, exhibiting a robustness in the organs of appetite, accompanied by some keenness in those of perception, rather than a predominance of the imaginative or higher intellectual faculties such as had borne up the Elizabethan literature into universal grace and proportion. Above all, it was pervaded by an anti-Puritan spirit, or spirit of retrospective disgust for the Puritan rule, which showed itself partly in direct satires and denunciations of Puritanism, whether in prose or verse; partly in a predominant tendency towards the comic and jocose in all forms. The reopening of the theatres, and the consequent revival of dramatic writing, gave an increased stimulus to the anti-Puritan spirit, and afforded a special outlet for it. Initiated by Davenant and other survivors of the literary school of the reign of Charles I., among whom were Shirley and Cowley, the drama of the Restoration attained its height in Dryden, who succeeded Davenant as poet-laureate in 1670, precisely because of his dramatic successes during the ten preceding years, and who thus became officially, as he was by right of genius, the chief star of the new literary cluster. Around Dryden, and belonging to the same literary cluster, might be seen, earlier or later, between the years 1660 and 1674, such men as Butler, the author of *Hudibras*, the Duke of Buckingham, the Earls of Dorset and Roscommon, Sir Charles Sedley, Sir George Etherege, William Wycherley, and Thomas Shadwell. These, and such as these, were the so-called "wits of the Restoration;" while the honours of philosophic or other graver prose literature were supported by the veterans Hobbes and Izaak Walton, or by Clarendon, Browne, Barrow, and South. It is worth noting also, that these first fourteen years of the reign of the second Charles, remembered as they chiefly are as a period of spiritual degeneracy in our literature, were the era of the rise among us of mathematical and physical science. The Royal Society dates its existence almost ex-

Milton.

actly from the Restoration; and Boyle, Barrow, Wallis, Wilkins, Wren, and Hooke, were already busy with their researches, and waiting for the appearance among them of young Mr. Newton.

It was rather on the border of this, the well-known world of Pepys and Aubrey, than as actually in it and belonging to it, that Milton spent his declining years. He still, indeed, made London his home; living from 1660 to 1662 in a house in Holborn, near Red Lion Square; then from 1662 to 1665, or thereabouts, in a house in Jewin Street, near his old quarters in Aldersgate Street; then for a short time in lodgings with Millington, a famous book-auctioneer of the day; and finally, from 1665 onwards, in a small house in Artillery Walk, leading into Bunhill Fields. Of course there may have been occasional visits to the country; and one such visit was in the year 1665-6, when, on account of the great plague in London, he took a cottage for some months in the village of St Giles Chalfont, Buckinghamshire. Two years prior to this—in 1662-3, when he was living in Jewin Street—he contracted his third marriage. He was then fifty-four years of age; his wife, who was about twenty-eight years younger, was Elizabeth Minshull, daughter of Mr Ralph Minshull, of a good family in Cheshire. The marriage, which was arranged for him by his friend Dr Paget, was one of convenience—occasioned, it would appear, chiefly by the fact that his daughters, who had grown up without any maternal care, had become a trouble rather than an assistance to him in his housekeeping. At the date of the marriage the eldest of the daughters (who was lame and otherwise deformed) was nearly seventeen years of age, the second nearly fifteen, and the youngest not eleven; and they appear all to have remained with him for some years afterwards in a state of chronic contention with their step-mother. Her temper, it is stated, was none of the best; but we have it on her husband's own authority, that "she was very kind and careful of him;" and we have the same authority for the sad fact that his children were "unkind and undutiful." It is an evidence that his brother Christopher had heard him complain that "they were careless of him, being blind, and made nothing of deserting him;" and also that he complained that "they did combine together with the maid to cheat him in her marketings," and that "they made away with some of his books, and would have sold the rest to the dunghill woman." This, so far as it relates to their conduct before his third marriage, must apply chiefly to the two eldest daughters, Anne and Mary. The youngest, Deborah, probably as being the youngest, and as having therefore come more within the control of the third wife, has left a more amiable memory of herself. She is said to have been her father's favourite reader and amanuensis so long as she remained with him; she, as well as her sister Mary, having been trained by him to what they thought the irksome work of writing to his dictation, and reading to him in several languages without understanding their meaning. But she too ultimately quarrelled with her step-mother; and about the year 1669 all the three sisters, according to Phillips, were "sent out to learn some curious or ingenious sorts of manufacture that are proper for women to learn, particularly embroidery in gold and silver." Accordingly, during the last four or five years of his life we are to imagine Milton's household in Artillery Walk as consisting but of himself, his wife, and one or two servants; his three daughters no longer living under the same roof. Whether they lived with him or not, however, his circumstances were such as to enable them to depend on him as long as might be necessary. He had now, indeed, no official or stated income as formerly; any casual receipts from his writings can hardly have amounted to much; his first wife's marriage portion of £1000 had never been paid; and there is proof that the property left him by his father

had been impaired by considerable losses or forfeitures at the Restoration. Still, enough remained for his moderate wants as long as he lived, and at his death there was a residue over.

Milton.

Shut out from the busy world in some measure by the unpopular political recollections which attached to his name, and shut in from it still more by his blindness and by his undisguised scorn of nearly all that had the privilege of sight remained to him, there would have been for him there to see, Milton found his solace in his own thoughts, in the conversation of a few friends who would drop in to enjoy his society and were proud to lead him out in his daily walks, and also in his books and in continued literary occupation. He did not yet cease from prose writing, but finished or prepared for the press various works which he had begun before the Restoration, and from time to time undertook new ones. The following is a list of his prose writings published during this period, and of such works as, though left ready for the press, were not published till after his death:—

1. *Accedente Commenc't Grammar*; a short skeleton of Latin grammar, possibly prepared many years before, though not published till 1661.

2. *The History of Britain, that part especially now called England, from the first Traditional Beginning, continued to the Norman Conquest*; collected out of the antientest and best authors thereof. This was not published till 1670, though much of it was written before the Restoration.

3. *Artis Logicæ Plenior Institutio, ad Petri Rami Methodum con-cinnata*. This is a Latin compendium of logic after the method of Ramus, in two books, with a brief Life of Ramus appended. It was published in 1672, but may have been in manuscript many years before.

4. *Of True Religion, Heresie, Schism, Toleration, and what best means may be used against the growth of Popery*. This little tract was published in 1673, and was doubtless written at that time as a contribution to a controversy again rising into interest. It is written in a calm spirit, and with none of the vehemence of his earlier polemical writings, and is interesting as showing his matured views on the subject of religious toleration. He is for the absolute toleration, both as regards doctrine and as regards worship, of all Protestant sects,—the Church of England, Presbyterians, Independents, Anabaptists, Arians, Socinians, &c.; but, as regards worship, he excludes Roman Catholics, partly on the civil ground that they acknowledge a foreign allegiance, partly on the theological ground that they deny the paramount authority of Scripture, which denial, and nothing else, he holds, is heresy. He is not for punishing them "by corporal punishment or fines on their estates," because he supposes this "stands not with the clemency of the gospel more than what appertains to the security of the state;" but he is for suppressing their worship and removing its furniture.

5. *Epistolarum Familiarium Liber Unus; quibus accesserunt Pro-lusiones quædam Oratoricæ*. These are the "Familiar Epistles" and the "Oratorical Exercises at College," already alluded to. They were printed in 1674, the last year of Milton's life, apparently not on Milton's own motion, but as a speculation of the publisher.

6. *A Brief History of Moscovia and of other less known Countries lying eastward of Russia as far as Cathay; gathered from the writings of several eyewitnesses*. This short sketch was left in manuscript, and was published eight years after Milton's death.

7. *Litteræ Senatus Anglicani; neonon Cromwellii, &c., nomine ac jussu conscriptæ*. These are the "Letters of State" already referred to as written by Milton in his official capacity under the Commonwealth. The bookseller who published his "Familiar Letters" intended to publish these in the same volume, but was warned not to do so, and they were not edited till after Milton's death.

8. *Johannis Miltoni Angli de Doctrina Christiana ex Sacris duntaxat Libris petitâ, Disquisitionum Libri Duo*. This is the famous "Treatise on Christian Doctrine," the manuscript of which having been accidentally discovered by Mr Lemon in 1823 in the State Paper Office, was edited and subsequently translated by the Rev. Charles R. Sumner, afterwards Bishop of Winchester. The history of the work is as follows:—In his mature life Milton, dissatisfied with such systems of theology as he had read, and deeming it to be every man's right and duty to draw his theology for himself from the Scriptures alone, had begun to compile a system for his own use, carefully collecting texts, and aiming at doing little more than grouping and elucidating them. He continued this work till he had finished it. Considering it of importance enough to be published, but knowing that it contained some matter which might

Milton. be thought heterodox in England, he gave the manuscript, along with a transcript of his "State Letters," to a Mr Daniel Skinner of Trinity College, Cambridge (a relative of his friend Cyriack Skinner), who was going over to Holland, desiring him to arrange for their publication with some Dutch printer. Elzevir, in whose hands they were placed, having declined to have anything to do with them, they were given back to Skinner, who still remained abroad. Meanwhile the existence of the MSS, and the intention to publish them, had become known to the English government; and letters were sent to Skinner from Barrow, the master of Trinity College, warning him of the risk he was running, and ordering him to return to his college under pain of expulsion. This was in 1676, or two years after Milton's death; and Skinner seems to have returned soon after, and to have delivered the MSS. to Sir Joseph Williamson, one of the secretaries of state. By him they were stowed away, with other papers, in the press where Mr Lemon found them a hundred and fifty years afterwards still in the original wrapper.

Besides the above, there are some other things which are supposed, on evidence more or less slight, to have come from Milton's pen in his later life; and it is known that in 1661 he edited from a manuscript of Raleigh's entitled *Aphorisms of State*. (He had previously, in 1658, edited another MS. of Raleigh's entitled *The Cabinet Council*.) In addition to all this, he had collected a considerable quantity of materials towards a dictionary of the Latin language, the papers containing which fell into the hands of Edward Phillips, who is supposed to have used them in compiling the *Cambridge Dictionary* of 1693. How he managed in his blindness to go through so much labour of mere reading and accumulation, is explained partly by what Phillips tells us of his methods. The severe use which he made of his two younger daughters, till at last they would bear it no longer, and detested the very sight of him and his books, has already been mentioned. There were others, however, who, both while his daughters lived with him and after they went away, were but too glad to serve the scholarly and exacting old Lear. "He had daily about him," says Phillips, "one or other to read—some, persons of man's estate, who of their own accord greedily caught at the opportunity of being his readers, that they might as well reap the benefit of what they read to him as oblige him by the benefit of their reading; others, of younger years, who were sent by their parents to the same end." One of his readers, recommended to him by Dr Paget, was a young Quaker named Ellwood.

Milton's later prose writings, however, derive most of their interest from the fact that they belong to the same period as his later poems. It was not to them, nor even to the much more splendid polemical writings which had preceded them, that Milton could point as the fulfilment of his early pledge, that if God gave him strength, he would leave behind him some worthy work of Christian genius in which Britain should exult as a national possession, and which posterity would not willingly let die. Often as, amid the turmoil of his middle life, this pledge had recurred to him, how he must have sighed over the work that was then occupying him, and felt it all to be very sickening, and longed for a sabbath at the end of his life when his soul might sail again into the haven of a majestic calm! After all, controversy was but the work of his "left hand," and he longed for the time when his *right* hand should again have its turn, and he could rejoice in the renewed sensations of its superior strength and more natural cunning. His sonnets and other stray pieces of verse written during the civil wars and the Commonwealth, and perhaps also those occasional passages of lyric grandeur in his prose writings where he seems to be spurning prose underfoot, and almost rising for the moment on poetic wings, may be regarded as so many brief efforts whereby he assured himself; while his higher and finer faculty was in abeyance, that he had not lost it. It was not till towards the end of Cromwell's protectorate, however, and when already he had for several years been

blind, that he was able to begin an undertaking commensurate with his life-long aspiration. According to Aubrey, it was then (1658), when it appeared as if, under the settled rule of Cromwell, the nation was entering on a long period of peace and leisure, that the *Paradise Lost* was begun. Whether it was then begun in the actual shape in which we now have it, or whether Milton was at this time only turning over the subject in his mind, and ruminating it in that form of a sacred mystery or drama in which we find it first rudely sketched in the Cambridge manuscripts, can hardly be ascertained. Cromwell was not to live long enough to initiate by his great and peaceful rule that new literature, signs of the rise of which were not wanting towards the close of his protectorate. When the new literature did arise, it was in the guise of the literature of the Restoration; and whatever progress Milton may have made in his great poem before the accession of Charles II., the bulk of it was written after that monarch was on the throne.

The facts respecting *Paradise Lost*, and the other later poems of Milton, will be best presented in a table of his later poetical publications supplementary to that of his later prose writings already given:—

1. *Paradise Lost*. This poem was certainly complete by the 27th of April 1667 (Milton *ætat.* 68), on which day it was sold to Samuel Simmons, bookseller, for L.5 down, with a promise of L.5 more when 1300 copies of the first edition should have been sold, another L.5 more when 1300 copies of the second edition should have been sold, and so on for successive editions,—each edition to consist of 1500 copies. According to Ellwood, however, the poem must have been ready more than a year before that time; for he says, that on visiting Milton while he was at Chalfont, in Buckinghamshire (1665-6), he gave him the complete manuscript of the poem to read. As originally published, the poem consisted of ten books, and was sold at three shillings per copy. The stipulated 1300 copies must have been sold before the 28th of April 1669, on which day Milton signs a receipt for the second L.5. This was a very good sale in two years; but the remaining copies do not seem to have gone off so fast, as it was not till 1674, or the year of Milton's death, that a second edition was published. In this second edition the ten books were converted into twelve by a division of the seventh and tenth; and there were some other alterations. A third edition was called for in 1678; and in December 1680 Milton's widow parted with all her interest in the work for one sum of L.8, paid to her by Simmons.

2. *Paradise Regained*. When Ellwood returned the manuscript of *Paradise Lost* to Milton, they had some talk, he says, as to the merits of the poem, in the course of which Ellwood ventured pleasantly to say to him, "Thou hast said much here of paradise lost; but what hast thou to say of paradise found?" To this, he says, Milton made no answer, but fell into a muse, and broke off the discourse. When, however, some time after the sickness was over, Ellwood revisited Milton in London, he showed him *Paradise Regained*, saying, "This is owing to you; for you put it into my head by the question you put to me at Chalfont, which before I had not thought of." Assuming this to be literally accurate, we should have to suppose *Paradise Regained* finished in 1667, if not earlier; but it was not published till 1671 (Milton *ætat.* 62), on which occasion it was issued, not by Simmons, but by another bookseller, in the same volume with *Samson Agonistes*.

3. *Samson Agonistes*, a Dramatic Poem, published as above, 1671.
4. A second edition of his minor poems was published in 1673, the year before his death, containing the pieces which had appeared in the edition of 1644, with some additions.

At this point it is that the fact of the interposition of a middle period of prose polemics between the earlier and the later poetry of Milton becomes of importance to the critic of his works. Poetry, as such, is the exercise of imagination; and when a man makes poetry his work, or, after having been engaged on other kinds of work, returns to poetry, it is implied that the whole strength of his mind passes for the time being into the imaginative faculty. But here, as usual, it becomes apparent that our distinctions of faculties are partly devices for our own convenience, in conceiving of things. Imagination is not, properly speaking, the imagining part of the mind, but rather the whole mind in the act of imagining; and hence, though some

Milton.

Milton. minds tend more to this act than others, yet the nature and the worth of the imaginations of any particular mind are determined by the total character and contents of that mind. On this principle, also, we see how it is that in one and the same mind there may be poetic development, and how a poet's later muse may differ from his earlier, just as a philosopher's later may differ from his earlier doctrine. Imagination is said to be the faculty of youth; which, however, is true to some extent only in this sense, that men as they advance in life have so many things to do that, even if they set out with a strong imaginative tendency, they indulge it less and less. In the cases of professed poets, however, who preserve and cherish their imaginative tendency, and go through the working world laurelled and privileged to dream, it is not observed that the imagination grows weaker so long as there is growth in the being at all, but, on the contrary, that it gains strength. By the mere necessities of existence, acquisition, and experience, it is a more rich and powerful imagining mind in the later than it was in the earlier stages of the progress. And so also if, after an intermediate period of non-poetical activity, or of activity in the main non-poetical, a mind originally poetical reverts, before decay has set in, and ere the old habit has been forgotten by too much disuse, to its first occupations. In either case there will be differences between the earlier and the later poetry. The themes in all probability will be different, and the style and manner of treatment will be different likewise. So it was with Milton. In his youth his was the imagination of a mind naturally firm and austere, it is true, and already cultured and well equipped with learning, but still sufficiently untorn and unexercised in the contemporary medley of human things to find its delight in fancies of the sweet and sensuous order, in themes of idyllic grace, or of purely ideal beauty. In his old age, or second poetic period, it was different. Imagination was again his darling faculty; but it was now the imagination of the same mind tried and disciplined in a thousand things by what it had meanwhile passed through,—heavily freighted, as it were, with twenty years of griefs, ideas, recollections, and experiences, which had not at first belonged to it. If, then, imagination is the whole mind in the act of imagining, and if, accordingly, the poems which a poet successively puts forth may be regarded as in a profound sense allegories, on a larger or smaller scale, of his entire being at the moments to which they appertain, it was in the nature of things that Milton's later poetry, though bearing certain resemblances to his earlier, should yet differ from it. By universal admission such is the fact. In *Paradise Lost*, *Paradise Regained*, and *Samson Agonistes*, we have the same peculiar Miltonic genius which we discern in *Penseroso*, *Comus*, or *Lycidas*; but it is as if that genius had meanwhile absorbed and incorporated into its fibre all that we know of the intermediate polemic and prose writer. The themes are of larger dimensions and of more direct human and historic interest; the filling up is more various, erudite, and elaborate; the artistic harmony is more complex; and while the whole matter is cast in the mould of the imagination, much of it is of independent and extra-poetical, not to say controversial, value.

Each of the three later poems of Milton has its separate merits as a poem, and also its separate interest in connection with the poet's biography. In the noble Æschylean drama of the blind Samson among the Philistines, one seems to see a scarcely disguised allegory of the poet himself agonizing in the midst of evil times. There is no need to ask how that subject occurred to him. As regards the *Paradise Regained*, though here also we can discover points of contact between the subject and the author, such as might have determined him independently towards the choice of that epic from the first, we yet know that it was composed mainly as a sequel to the *Paradise Lost*. It remains, then,

to account for the origin of this greater epic, the crowning glory of Milton's life, and to which it is owing that he is remembered and will be remembered for ever, not only as a noble Englishman who did his duty manfully in a troublous period of his nation's history, nor even only as this, with the addition of having been a notable English poet, but as one of those select few of the children of men who, having wedded their genius to universal themes, stand apart as the great poets of the world, and the authors of the world's masterpieces. Notwithstanding the tradition, through Phillips and Ellwood, of Milton's preference for the *Paradise Regained*, there can be no doubt that it was to the *Paradise Lost* that he himself looked as the fulfilment of his life-long promise.

The most important act of the artist, and that which involves the greatest amount of presumptive evidence respecting him, is his choice of a subject. Milton, we have seen, had wavered long before deciding as to the best theme for his intended masterpiece. Like Wordsworth before he determined on his long philosophical poem, he appears to have ranged through history in search of a subject of sufficient interest and capability; going back through British history, and there resting fondly for a time on the subject of King Arthur, then deviating into general mediæval history, and finally extending his quest still backward and backward through ancient to primeval times. At last in his search he reaches a point beyond which it was impossible to go—the point where human history itself began, and where our planet, with life but newly planted upon it, is seen emerging for its special voyage out of the obscurities of prior and universal existence. The more he thinks of this subject, already familiar to him in its biblical relations, the more sensible he becomes, not only of its intrinsic capabilities, but also of its fitness for himself. The qualities and endowments for which it affords scope,—an imagination delighting in conceptions of the physically vast, as in astronomy, and yet capable of that kind of sensuousness which consists in love of the physically rich, as in landscape and vegetation; great acquired learning, classical and theological; a moral sublimity of nature almost at war with human society as seen around it, and driven, therefore, to communion with objects and intelligences unseen; an intellect withal massive and severely logical to exclude in the process of imagination whatever should be beneath the philosophy of the time, and to shape all into clear form and sequence according to high literary rule;—these are the very qualities and endowments which he is conscious of possessing. On the other hand, those qualities of the want of which he was or might have been conscious,—humour, for example, as in Chaucer and Shakspeare, and the corresponding dramatic faculty of light incident and varied painting of physiognomies and characters to pass and repass in quick succession in a story,—were qualities the exercise of which the theme itself precluded. What room for humour in the grand story of our earth's beginning, or for elaborate portrait-painting in the description of a world tenanted as yet but by the two first beings of our race? In short, by the instinct both of what he could and of what he could not do, Milton's choice was made; and, it having been also at last decided that the form of the poem should be the epic and not the dramatic, and moreover (which was then a great innovation, and was proclaimed by Milton to be such) that the verse employed should be the heroic blank and not rhyme, *Paradise Lost* slowly grew into being. For seven years or thereby, and mostly amid the streets of bustling London, where Charles was amusing himself with his court, and Dryden was seeing his plays acted, and poor Butler was growing morose from ill usage, and Pepys was running about and taking notes, the plan was carried in the blind man's head, till at last, by dictations of twenty or fifty lines at a time, the work was completed.

Milton.

Milton.

"Things unattempted yet in prose or rhyme," is Milton's description of the matter of his poem. The description is just; and it is part of his title to immortality that he spent his genius on a theme of universal interest, which, seeing that it had been reserved for him to sing it, could certainly now, for that very reason, never be sung a second time even had he sung it worse.

"Of man's first disobedience, and the fruit
Of that forbidden tree whose mortal taste
Brought death into the world and all our woe,"

is his opening more particular definition of the purport of his song. This definition, however, if taken by itself, is totally inadequate; nor, if this were the theme, could it be said to have been unattempted before. The true theme of *Paradise Lost* is the story of the connection of this world, as a whole, with what may be called the larger universe of ante-human existence; and "man's first disobedience" is but the last incident in the story, to which, as to a narrow point, all the prior incidents tend. The true hero of the poem,—the being in whose movements and actions from the beginning to the end the unity of the epic is maintained,—is the archangel Satan. Adopting the scriptural account of this great being, as one in whose life the past and primeval system of things is fatally connected with ours, and adhering also with theological conscientiousness to whatever circumstantialia Scripture has supplied towards filling out the story, the poet has passed the whole through the mould of his imagination in such a manner that now it is Milton's story of the origin and first events of the universe, rather than the biblical outline which suggested it to him, that has taken possession of the British mind. As, however, there is no contradiction of the biblical narrative, but only an expansion of it, the majority of readers find in the poem an absolutely unexceptionable rendering of the theme; while, on the other hand, even those who hold aloof from theology in such matters, or would treat the Mosaic account rather as a figure than as a narrative, admit that, as there must be some conception of the theme for the mind of man to take hold of, so no more sublime conception of it than Milton's has been provided by a human poet, or could be presented to the Christian world. To both classes of readers the poem properly shapes itself as in the main a Sataniad, or epic of Satan's life from the time of his being an archangel among the hosts of heaven to the time of the execution of that scheme whereby, after the fall of himself and his fellow-rebels, he becomes the lord and minister of evil on our particular earth.

From the very nature of the theme it arises that the extent of physical space which the poem fills is larger than that which any other known poem takes in, or any other conceivable poem could possibly require. The universe of Dante's poem, physically regarded, is but a nutshell to that of Milton's, which stretches in its totality beyond all telescopic bounds, and incloses, as but a drop of central azure, the whole visible region of the stars and galaxies. A diagram of the plan of the poem would illustrate this. It presents to us the first primeval Infinity, not as a universe of stars at all, but as a sphere, if we may so say, of infinite radius, divided into two and only two parts—the higher or upper hemisphere of Heaven, which is a region all of light, formed forth in some inconceivable way into tracts of field and continent, and populated in some inconceivable way by angelic beings, all near to Deity, and doing his missions, but distributed into hosts and hierarchies, and leading lives of freedom; and the lower or nether hemisphere of Chaos, where no such beings habitually are, but which is a great sea or swelter of darkness and confusion,—a limitless, fathomless quagmire of elemental pulp. While we are contemplating this eternal Infinity, divided equatorially, as it were, into a Heaven above and a Chaos below,—lo! the event which breaks in on the grand monotony of ante-

Milton.

human history, and, by means of moral, necessitates physical, changes! Satan and his fellow-angels rebel; there are the wars in Heaven; and when these are over, the rebels, driven headlong into the yawning gap which opens to disgorge them into Chaos, are pursued by the Messiah's wrath, down and still down through its dark abysses, till they reach that space or pit of fire which is now prepared for their reception in nethermost Chaos, under the name of Hell. This third region, so created for the first time, is, as it were, the antarctic zone of the universal sphere, separated from the hemisphere of Heaven by the vast intervening belt of Chaos as it still remains. Stunned and confounded by their fall, the rebel spirits lie long inactive in the fiery lake, till at last, roused by Satan from their stupor, they realize the past and look forward to the future. Amid a Babel of counsel it is Satan that devises a plan. The creation of Hell in the nethermost region of Chaos has not been the only physical change introduced about this time into the universal order. Contemporaneously with the fall of the rebel angels God has executed through his Son the scheme foreordained from everlasting, of the creation at this time of a new race of beings differing from the angels, and of a world fitted to receive them. By the exercise of the creative energy a great mine or hollow has been cut or scooped out of upper Chaos at its junction with Heaven; into this hollow the light has gushed down from above, so that it is now no longer a part of Chaos; and under the influence of the principles of rotation and gravitation planted in it of express purpose, the matter that existed in it chaotically has become coagulated into balls and planets, moving in regular orbits, and separated by clear interspaces. This, in short, is our human or telescopic universe, with its suns, its stars, its moons, its nebulae; all in apparent diurnal rotation round that little earth of ours, which was to be the centre of the whole experiment. Thereon already walked Adam and Eve, in a paradise of trees and flowers, the fairest and happiest of God's creatures. It was of this new creation, known to him not as yet by eyesight, but only conceived vaguely from recollection of the tradition of it as discussed so long in Heaven, that Satan bethought himself in his fallen estate in Hell. His plan is to abstain from all mere general endeavour against the Almighty, and to gain admission, if possible, into this new creation so as to vitiate and ruin it. His scheme having been approved by his co-mates, he himself sets forth to execute it. Leaving the rest of the fallen host to organize their new kingdom and build the palace of Pandemonium, he climbs his arduous way through superincumbent Chaos till the light of the young creation appears above him, and he emerges within its transparent bosses. At first amazed and almost softened by the sight, he at length arouses himself to his task, and having ascertained which of all the shining orbs was the seat of man, he alights on its surface, and, despite the vigilance of angels celestially commissioned to oppose him, completes, in the shape of a serpent, his fiendish errand. When he returns to Hell in triumph, his fellows have already bridged the interval between Hell and Creation so as to make the intercommunication easy; the two regions are thenceforth associated; and though the price to the rebel angels themselves of this voluntary concentration of their energies on one poor world is a further degeneracy of their form and nature, Humanity is their prey for the appointed season.

There is no need here to dilate on the consistency with which Milton has conducted this magnificent story, or on the power of various invention with which he has filled it up; nor need we refer to such adverse criticisms as have been from time to time ventured against portions of the poem. We refrain also from an inquiry which might more properly belong to us, as to the influence of Milton's blindness, not only in determining him to such a subject, but also

Milton.

as perhaps positively qualifying him for that kind of imagination and description of which five-sixths of the poem consist—the imagination and description of vast physical space, variously shaded and divided; of luminous orbs in quiet motion through the nocturnal deep; of luminous or else shadowy beings passing or repassing singly or in battalions; of contrasts of light and darkness in all their forms. In the remaining parts of the poem, where the poet condescends on our own earth, and describes the beauty of Paradise, there is certainly no lack of sensuousness, in the more ordinary sense of the term; but it may be questioned whether, with all the richness of those paradisaic descriptions, there is not evidence that the poet was now but living fondly on his recollections of a world of colour and vegetation from which he had been long shut out. At all events, much even of the subsidiary and terrestrial imagery of the poem will be found to consist of light and darkness worked cunningly into visual contrast; and the florid offering on the bier of Lycidas is richer in botanical colour and embroidery than the nuptial bower of Eve.

A question as to Milton's theological belief, which was suggested to some keen critics by certain passages of his *Paradise Lost*, has been answered, in favour of their conjecture, by the discovery of his *Treatise on Christian Doctrine*. In one chapter of that work he expresses views at variance with the orthodox notions of the Trinity. Bishop Sumner gives a summary of these views in theological language. Milton asserts, he says, "that the Son of God existed in the beginning, and was the first of the whole creation;" that "by his delegated power all things were made in heaven and in earth;" that "he was begotten within the limits of time," and "indued with the Divine nature and substance, but distinct from and inferior to the Father." In other words, Milton in his later life was an Arian, and there is a trace of at least incipient Arianism in the *Paradise Lost*.

Milton lived seven years and a half after the publication of his *Paradise Lost*, and three years after the publication of his subsequent volume containing the *Paradise Regained* and *Samson Agonistes*. The personal sketches which we have of him refer mostly to this time of his life.

Of a stature somewhat below the average, Milton had in his youth been singularly handsome, with a complexion of delicate white and red, dark gray eyes, light auburn hair, parted in the middle, and altogether an appearance of slender and even feminine grace, which it required his manly bearing and his confidence as a swordsman to contradict. Even in later life he was usually mistaken for ten years younger than he really was. In his old age, however, his blindness, accompanied by the gout and other infirmities, had abated his activity and vigour. "An aged clergyman of Dorsetshire," says the painter Richardson, "found John Milton in a small chamber hung with rusty green, sitting in an elbow chair, and dressed neatly in black; pale, but not cadaverous; his hands and fingers gouty, and with chalk-stones. He used also to sit in a gray coarse cloth coat at the door of his house near Bunhill Fields, in warm sunny weather, to enjoy the fresh air; and so, as well as in his room, received the visits of people of distinguished parts as well as quality." To this we may add some particulars from other sources. "He was an early riser," says Aubrey; "to wit, at four o'clock in the morning, yea, after he lost his sight." In winter his hour of rising was five; and sometimes he would lie in bed after he was awake composing mentally or dictating. He had a man to read to him as soon as he got up, and also after breakfast, and he always began the day with a chapter or two of the Hebrew Bible. The early part of the day was spent by him in reading and writing; "the writing," says Aubrey, "usually as much as the reading." He used to dictate, sitting obliquely in an elbow chair, with his leg thrown over the arm. At one

Milton.

o'clock, after a short walk, he dined, eating well of such dishes as he liked, but drinking little except water. "God have mercy, Betty," he said to his wife one day at dinner about a year before his death, "I see thou wilt perform according to thy promise, in providing me such dishes as I think fit whilst I live, and when I die thou knowest that I have left thee all." After dinner he used to walk again in the garden or out in the neighbourhood, with some one guiding him; or sometimes he would take exercise in a kind of swinging chair which he had contrived; generally, however, in the course of the afternoon, playing for an hour on the organ or the bass-viol, and either singing himself or making his wife sing, who, he said, had a good voice, but no ear. An hour or two towards evening were again given to his books; about six o'clock visitors would drop in, whom he would entertain till eight; he then had olives or something light by way of supper with them; and, after a pipe of tobacco and a glass of water, he went to bed. "Extremely pleasant in his conversation at dinner, supper, &c., but satirical," says Aubrey, who adds, that "he was visited by the learned much more than he did desire." In particular, foreigners of note, when in London, would seek him out; and, indeed, before the publication of *Paradise Lost* he was liable to the visits of admiring foreigners, some of whom, according to Aubrey, regarded him as hardly less a lion than "O. Protector" himself, and would insist (the Great Fire not having yet done its work) on seeing the house and chamber where he was born. "He was much more admired abroad," says Aubrey, "than at home." At home, however, more especially after the publication of his great epic, he did not lack admirers. Which of the "quality" paid him visits we do not know; but among the "people of distinguished parts" was Dryden, whose admiration of him was extreme, and who on going to see him was, it is said, received civilly, though Milton had a low idea of Dryden's poetry. Hobbes was not of his acquaintance, nor had he any liking for Hobbes, but acknowledged him to be a man of great parts. His familiar friends were men of the graver sort, among whom were Andrew Marvell, Dr Paget, and Cyriack Skinner. He attended no church and belonged to no particular communion; nor had he any rites of worship in his family—though what were his reasons for this was not very well known even to his friends. He remained a theoretical republican to the last. His favourite poets among the classics are said to have been Homer, Euripides, and Ovid; and among the English, Spenser, Shakespeare, and Cowley. Aubrey adds that, in speaking or reading, he pronounced the letter *r* very hard; "*litera canina*," as Dryden said to Aubrey, "a certain sign of a satirical wit." From Ellwood we learn that he could not endure the English mode of pronouncing Latin, and that his ear was so quick that he knew at once when his reader had come to a sentence which he did not understand.

The date of Milton's death was November 8, 1674. The cause, according to Aubrey, was "gout struck in;" but his death was calm and easy. He was then close upon being sixty-six years old. He was buried beside his father, in the church of St Giles, Cripplegate. Shortly after his death there was a lawsuit between his widow and his daughters as to the inheritance of his remaining property, which amounted to about £1500. The widow pleaded a nuncupative, or declaratory will, made by the deceased before witnesses, to the effect that she was to be his sole heir, and that the daughters, having been "very undutiful" to him, were to receive nothing except their interest in their mother's marriage-portion, which, though never paid, was yet in good hands, and recoverable. The decision, however, was so far favourable to the daughters, that each got something out of the property. The subsequent history of the family was as follows:—The widow survived her husband not less than forty-five years, dying, in very old age,

Milwaukee in 1729, at her native place of Nantwich in Cheshire, where she was a member of the Baptist communion. Of the three daughters, the second, Mary, died unmarried; the eldest, Anne, married rather late in life a master-builder, and died in her first childbirth; and the youngest, Deborah, alone left issue. She had gone over to Ireland as companion to a lady before her father's death; there in 1674 she married a Mr Abraham Clarke, a silk-weaver, with whom she returned to London in or about 1687, and settled in Spitalfields, where Addison and others saw her, and asked her questions about her father; and she died in 1727, after having had a large family, of whom only one son and one daughter survived. The son, who was named Caleb, went to the East Indies, and died at Madras in 1719, leaving children, whose issue cannot be traced. The daughter, whose name was Elizabeth, married a Thomas

Foster of Spitalfield, who afterwards kept a small chandler's shop in Holloway, and was in very poor circumstances. Some money was collected for her in 1750 by Dr Birch, Johnson, and others; and she died at Islington in 1754, having had seven children, none of whom survived, or at least left descendants. Thus disappeared all the direct posterity of the poet. It remains to be added, that his brother Christopher, having adhered steadily to his royalist politics, was knighted by James II. in 1686, and became one of that king's servile judges, but was set aside at the Revolution, and died at Ipswich in 1692; that the two Phillippes, the poet's nephews, had some reputation as hack-writers in the reigns of James and his successor; and, finally, that their mother, the poet's only sister, had other children by her second marriage, whose descendants are still to be traced.

Minas Geraes.

(D. M.—N.)

MILWAUKEE, a town and lakeport in the state of Wisconsin, North America, is situated at the mouth of a river of the same name, on the W. shore of Lake Michigan, 90 miles N. of Chicago, and 75 E. of Madison. The town stands partly on the low banks of the river, and partly on the high grounds on the borders of the lake; and is well built of a sort of brick, of very excellent quality, which is manufactured here. Milwaukee has 30 churches, of which 4 belong to the Roman Catholics; 5 public schools; several academies; 3 orphan hospitals; besides other educational and charitable institutions. The chief manufactures of the place are,—iron, bricks, flour, and articles of cooperage, besides wood-working, soap, candles, shingles, and tobacco. In 1855 the total value of the aggregate and miscellaneous manufactures of this rapidly increasing town amounted to more than L.1,000,000 sterling. The harbour of Milwaukee is very good, being formed by the river, which may be ascended by large vessels for 2 miles above its mouth. The commerce is very extensive; in 1854 the value of the imports here amounted to L.2,317,726, while in the following year it rose to L.3,885,381; the value of the exports in 1855 was L.3,610,327. The former consist chiefly of salt, coal, lime, plaster, fruits, &c.; and the latter of wheat, flour, pork, beef, lead, shot, the products of the manufactures, &c. The number of vessels that arrived here in 1855 was 2802, with a total tonnage of 980,700. Milwaukee communicates with the interior by several lines of railway; and it is thus the principal outlet for the productions of the country. The town has risen very rapidly to its present condition, as the place was not settled till 1835. Pop. (1850), 20,061; (1856), about 45,000.

MINA, DON FRANCISCO ESPOZ Y, a Spanish general, was born in 1781, at Idozin, a small village of Navarre. When the insurrection against the French broke out in 1808, Mina took part in the guerilla warfare then carried on, and soon distinguished himself so much by his skill and courage as to collect a large body of men under his standard. He thus rose to be the head of all the troops of Navarre, and urged the war with great vigour, inflicting many heavy blows on the French. He displayed great activity and rapidity in his movements, and gained many successes by falling suddenly and unexpectedly on the French convoys proceeding between Madrid and France; and although the French organized a large army to secure their possession of the country infested by him, he always succeeded in baffling their attempts by dispersing his troops among the ravines and mountain passes, and reuniting them again at a different place a short time after. During all these exploits Mina acted not only as the general directing the movements of his band, but fought himself as actively as any soldier in the ranks. On one occasion he was severely wounded, and on another narrowly escaped with his life, when having been surprised in a house to which he had betaken

himself, and not having time to seize his arms, he only saved himself from certain destruction by defending himself with an iron bar. Mina was raised to the rank of colonel in 1811, and to that of brigadier-general in 1813. At the close of the war he was at the head of more than 30,000 men, who had taken 13 fortified places, and captured upwards of 14,000 prisoners. In 1814 Mina was invited to the court of Ferdinand VII.; but he did not conceal his disapproval of the abrogation of the constitution of 1812, and was accordingly sent back to Navarre, where, shortly after, along with the other generals and the greater part of the army, he openly joined the liberal party, and was obliged to save himself from the fate of his companions by taking refuge in France. (For a full account of the events of this period, and of Mina's share in them, see SPAIN.) The Spanish ambassador in France demanded the delivery of the fugitive; but Louis XVIII. not only refused to do so, but insisted on the recall of the ambassador, and gave Mina a pension. On the restoration of Napoleon he refused to enter his service, and retired to Switzerland; but returned to France on the fall of the emperor. In 1820 Mina returned to the theatre of his old exploits; and the remembrance of his former achievements soon put him at the head of a large army. When the constitution was again accepted by the king, Mina was appointed captain-general of Navarre; and in 1821 he held the same office in Galicia; but was soon after deprived of his command, when he retired to Sigüenza. He was recalled, however, in 1822, and took the command of the constitutional army in Catalonia, with which he obtained great successes over the enemy. The invasion of a French army, however, compelled Mina, after resisting as long as possible, to give up the contest, and to retire to England. After the revolution of 1830 he repaired to Paris, where he and Valdes planned an invasion of Spain. The latter, more impatient than Mina, entered Spain in 1830; and as his expedition was not successful, Mina crossed the frontier in order to save his companions, though with faint hopes of the success of his enterprise. After displaying great courage and passing through the greatest dangers, he reached with difficulty the French frontier. In 1834, on the breaking out of the civil war, Mina was recalled to take the command of the army of the queen. But he was now opposed to his old followers the peasants of the north, who embraced the side of the Carlists, and turned against Mina those very tactics which he had taught them, and by which he had gained along with them so many successes. His health, too, was injured by the incessant activity, sufferings, and dangers of his laborious life; and he was obliged to resign his command in 1835, without having gained any great success. He died the following year at Barcelona.

MINAS GERAES, a mountainous province of Brazil, situated between Lat. 14. 30. and 23. S., and Long. 40. and 51. W., is bounded N. by the province of Bahia, W. by

Minchin-
hampton
Mindanao.

Goyaz, S. by Sao Paulo, and E. by Rio de Janeiro and Espirito Santo. It is about 600 miles in length from N. to S., by 350 in average breadth, and has an estimated area of about 216,000 square miles. This is the most elevated province of Brazil, as well as the richest in minerals, and the most populous. It occupies an elevated table-land traversed by detached mountain ranges, separated from each other by sloping and pastoral but not very deep valleys. The most elevated summits are Itacolumi, 5750, and Itambi, 5900 feet above the level of sea. Owing to its elevation, the climate of Minas Geraes is temperate when compared with that of other countries under the torrid zone. It is abundantly watered by numerous small streams, which fall into larger currents. The principal of the latter is the Sao Francisco, which flows northward through almost the entire province, and after passing through Bahia and forming the boundary between that province and Pernambuco, and between Sergipe del Rei and Alagoas, falls into the Atlantic Ocean. The Rio Grande and the Rio Parnahiba flow southward to form the Rio Parana; and the Rio Doce and the Jequitinhonha flow eastward into the Atlantic. The soil is in general very fertile, yielding in abundance, and with little labour, the grains and fruits of Europe, besides the aromatic plants and other vegetable productions characteristic of such regions, as cotton, tobacco, sugar, maize, manioc, coffee, indigo, ipecacuanha, jalap, liquorice, &c. The forests abound in valuable timber; and vast herds of swine and cattle are reared. The great wealth of the province, however, is in its mineral resources. Among the metals and minerals found here are gold, silver, copper, platina, iron, lead, mercury, antimony, bismuth, limestone, millstone, alum, and sulphur. The manufactures are still very imperfectly developed; but there are some extensive ironworks in the neighbourhood of the capital, Ouro Preto. Pop. (1852) 1,300,000.

MINCHINHAMPTON, a market-town of England, county of Gloucester, and 12 miles S. by E. from the town of that name. It is pleasantly situated on a gentle declivity of the Cotswold Hills, but is irregularly built. The parish church is a large cruciform edifice surmounted by an octagonal tower. There are several dissenting places of worship, and national and other schools. The inhabitants are chiefly employed in the cloth manufacture, which forms the staple of an extensive district. Pop. of parish (1851), 4469.

MINCIO (the ancient *Mincius*), a river of Northern Italy, which issues from the S. extremity of the Lago di Garda, and flowing southward, passes Mantua, and falls into the Po 12 miles below that town, after a course of about 40 miles. In the neighbourhood of Mantua the waters stagnate so as to form shallow lakes of considerable extent. The Mincius is celebrated by Virgil, who dwelt on its banks.

MINDANAO, or MAGINDANAO, the most southerly of the Philippine Islands, and the second in size of that group, is situated between 5.32. and 9.50. N. Lat., and 122. and 126. 13. E. Long., having a length of about 300 miles from N. to S., a breadth somewhat less, and an area estimated at 36,140 square miles. The general form of the island is that of a triangle having its base towards the E.; but its outline is very irregular, and in one part it is almost divided into two by bays running deep into the land. Of these the southern is called the Bay of Illano, and the northern the Bay of Siddum. The island is mountainous, containing several volcanoes; and the hills are covered with dense forests nearly to their summits. A great part of the low lands of the island is also wooded; but there are in many places extensive plains covered with fine grass. Mindanao contains a large number of lakes, and from this circumstance the island derives its name. The largest lake is that of Malanao or Lano, near the centre of the island. There are also many rivers, of which the principal is the Batuan. The products of Mindanao are similar to

Minden
||
Minehead.

those of the other islands of the group to which it belongs, and consist of gold-dust, timber, coffee, cocoa, rice, nutmeg, cinnamon, pepper, &c. The principal animals found here are buffaloes, horses, oxen, deer, goats, and wild hogs. The island was visited by Mohammedans from Arabia at an early period; but the first European who reached it was Magelhaens, who took possession of the island for Spain in 1529. The Spaniards, however, have only colonized the northern part, and have great difficulty in retaining possession even of that portion. Their territory is divided into two provinces, Caraga and Misamis, the former of which is very rich in gold. The chief town in the Spanish possessions is Samboangan, which is used as a place of banishment for the Philippines, and is strongly fortified. The inhabitants resemble greatly those of the surrounding islands; and though some tribes are said to be cruel and ferocious, others are mild and inoffensive, employing themselves in gathering gold-dust, and bartering it with the Spaniards. The south-eastern corner of the island belongs to the sultan of Mindanao, and is inhabited chiefly by Malays; while the S. and S.W. portions are occupied by the Illanos, a tribe of pirates, who have their chief seat on the Bay of Illano. These people, who are a mixed race, partly of Malayan and partly of native extraction, profess to be subject to the sultan of Mindanao, but are in reality quite independent. They are Mohammedans in religion, and live entirely by piracy, scouring the sea with light vessels of a peculiar construction. Their voyages extend as far as New Guinea towards the E., and Malacca towards the W., and they sometimes even enter the Bay of Manilla in defiance of the Spanish authorities. Pop. of the whole island probably about 1,000,000; of the Spanish provinces, 76,298.

MINDEN, a strongly fortified town of Prussian Westphalia, capital of a government of the same name, on the left bank of the Weser, here crossed by an old bridge 600 feet long, 37 miles W. from Hanover. This is one of the oldest towns in Germany. The Emperor Henry IV. resided here for a long time; and at the imperial diet held here in 1026 his father Henry III. was chosen emperor. The town is irregularly built, and contains few good buildings. It has five churches, the principal of which, the cathedral, is a handsome edifice 200 feet long by 82 wide. Among its educational institutions are a gymnasium, a normal school, and a Lutheran young ladies' seminary. The manufactures are considerable, comprising woollen stuffs, linen, hosiery, hats, leather, tobacco, soap, beer, brandy, sugar, &c. Minden also carries on some trade by means of the river. The French were defeated in the vicinity of this town on 1st August 1759 by an Anglo-Hanoverian army under Prince Ferdinand. Pop. (1849) 13,060.

MINDORO, one of the Philippine Islands, is situated to the S. of Luzon, from which it is separated by the Strait of Manilla, between 12. 10. and 13. 30. N. Lat., and 120. 27. and 121. 43. E. Long. Length about 100 miles; average breadth between 40 and 50; area estimated at 4150 square miles. Its form is triangular, and the coasts are skirted with a range of hills; while in the interior the surface gradually rises to a very great elevation. The surface is well wooded, and watered by a great number of streams rising in the centre of the island. There are some Spanish settlements in Mindoro; and the aborigines are employed largely in piratical expeditions. Pop. 28,060.

MINEHEAD, a decayed borough and market-town of England, county of Somerset, on the Bristol Channel, 22 miles W. by N. from Taunton. Minehead was formerly a place of some trade, and returned two members to Parliament till disfranchised by the Reform Act; but it is now chiefly known as a watering-place. A small trade is still carried on with Bristol and Wales; and the herring fishery is prosecuted to some extent. Pop. of parish (1851), 1542.

Mineral
Waters.

MINERAL WATERS. Great curative powers have always been ascribed to certain natural sources of waters springing from the ground, and differing for the most part from ordinary sources, either by the excess or remarkable character of their constituents, or by their temperature. The savage of America, the Romans, the inhabitants of Asia, not to speak of the moderns, have all expressed in various modes their conviction of the fact. The way in which some of the more important springs have been discovered,—either by the congress of animals and their cure from various diseases (and there are more authentic narratives of the kind than that of Bladud and his swine), or by fortuitous cures in man, many of which are well authenticated,—is in itself a strong presumption in favour of the actual power of many mineral waters. But when we add to this the fact, that the chemical composition of many waters is that of very powerful medicinal agents; when we consider the effects which, on physiological principles, are likely to result from the imbibition of quantities of water well imbued with mineral principles, as well as from bathing in such waters hot or cold,—little doubt can remain as to the possession of real power by mineral waters. Add to this, that the remedy, such as it is, is generally administered with all the accessories likely to increase its beneficial action. Removal from care, good air and exercise, and improved hygienic relations, are almost always employed in conjunction with this cure.

1. The principal difficulty which we encounter at the outset of any inquiry into the nature of mineral waters is to determine what a mineral water really is. All waters, except very carefully distilled water, contain salts. Rain water, river water, and spring water, all contain salts. Malvern, one of the purest springs in England, contains about five grains of salts to the gallon. The question is, to what extent is the solution of foreign substances in a water to proceed,—or how far can it depart in other respects from the characters of ordinary water,—to entitle it to be called *mineral*?

Perhaps when the amount of salts and other solids held in solution in a water exceeds 60 grains in the imperial gallon it should be entitled to the term mineral. It is to be observed, that the constituents of a water which may exercise medicinal effects cannot be restricted now-a-days to the mineral or gaseous constituents of water only, seeing that a principle or congeries of substances, which exists in a great many mineral waters, of an organic vegeto-animal nature, variously termed zoogine, glairine, baregine, &c., is supposed to produce considerable effects. The extractive matters derived from the earth and from plants also contribute to the action of waters. The amount of gases, or the temperature of the water, may be sufficient to give the characters of mineral waters where the solid constituents are in very small quantities. Thus in this country the waters of Moffat and Gilsland are entitled to be called mineral, although there is nothing in the amount of salts they contain to give them this character. It is due, however, to their gaseous constituents, especially their sulphuretted hydrogen, one of the most powerful poisonous and medicinal agents, and in solution especially calculated to act upon the skin or the kidneys, and excite their secretions. On the Continent the waters of Pfeffers and Wildbad have been found by long experience to be capable of curing disease, although their mineral constituents are insignificant.

2. The most obvious division of mineral waters is into thermal and cold. Of the origin of the former many theories have been given. They probably arise from more than one source, and from various causes. The origin of thermal springs may be ascribed to the following causes:—1st, To water coming in contact with certain chemical agents in the interior of the earth; 2d, The proximity of volcanoes; 3d, The internal heat of the earth; and, 4th, To

electrical changes, in which the very production of these mineral springs, and the charging of them with their various constituents, are concerned.

None of these explanations, except the last, satisfies all the conditions of the problem, and the last itself is altogether hypothetical. Against the second hypothesis it may be urged, that on the volcanic theory we cannot account for the uniform constitution of almost all thermal springs at different times and at all times; and that many hot springs occur which are neither in volcanic regions nor in the neighbourhood of volcanoes. It is an undoubted fact, proved by the phenomena observed in regard to Artesian wells, and by observations in mines, that the temperature of the earth increases as an approach is made towards the centre of the planet, in the ratio of $1^{\circ} 8'$ of Fahrenheit for every 101 English feet. This theory of the depth may account very well for the heat of many thermal springs, but not for all; for although most thermal springs continue to preserve the same temperature, others occasionally vary, and many have been observed to undergo great changes during earthquakes. Thus Carlsbad and Aix in Savoy lost temperature at the time of the earthquake at Lisbon. The electrical theory would account for almost everything, including the chemical composition of many thermal spas; since such gases as free carbonic acid and sulphuretted hydrogen are precisely the gases which we might expect to have disengaged by the chemical action of electrical currents; and the heat-producing power of electricity admits of no doubt: but what do we know concerning the currents of electricity in the interior of the earth? We must be content, then, with admitting, that of the causes of the thermality of many mineral springs we know little with certainty. In all ages these natural hot baths, some of which issue at the temperature of boiling water, have been preferred to artificial baths. The Romans in all the conquered provinces invariably seized with avidity on these sources, and erected splendid thermæ, with which nothing in modern times can compare. The admitted superior efficacy of the natural over the artificial baths has led to many conjectures as to the cause. The supposition that the specific heats of natural and artificial waters were different was refuted by a series of careful experiments performed by M. Longchamps and others. There remains the supposition, thrown out of late years, that the superior efficacy of natural thermæ may be due to their electricity; but at present it is unsupported by direct experiment. Besides those springs of the temperature of the body or above it, which deserve to be called hot, as Wildbad, about 98° , Bath, 118° , there are other springs below the temperature of the body, yet hotter than ordinary water, as Buxton, 83° , and the misnamed hot wells of Bristol, only 76° .

After thermal springs come the cold, which are variously classified, according as the writer gives more or less importance to this or that predominating ingredient. Perhaps the best and most natural division is into sulphuretted, carbonated, saline, and chalybeate. The first contain large quantities of sulphuretted hydrogen gas, with or without saline ingredients. Thus Harrowgate and Gilsland contain about 2 cubic inches of sulphuretted hydrogen to the pint (imperial); but the former (old well) contains 133.76 grains of salts in that quantity, while the latter has only 2.93. The carbonated waters are those which are highly charged with carbonic acid gas, a very valuable property, since it causes them to sit easy on the stomach. These waters, besides being grateful to the palate, possess stimulating and tonic properties. In this class of waters Britain is unfortunately entirely deficient. It is true the Leamington waters contain above 2 cubic inches of it to the pint; but this quantity is not sufficient, as it would be in the case of sulphuretted hydrogen, to give the characteristic properties. On the Continent some of the waters,

Mineral
Waters.

Mineral
Waters.

as Pyrmont, are so highly charged that the gas escapes almost with explosive violence. The saline waters admit of a very important subdivision,—viz., into alkaline, muriated, and sulphated. The first are characterized by the presence of such a quantity of the carbonate of soda as to give them marked alkaline properties; in some cases, as at Vichy, these waters are thermal. In this valuable class of waters we are unfortunately deficient in this country. Their alkalinity renders them especially useful in gouty and calculous affections; and when, besides, they are thermal, they may be considered invaluable, admitting of the use of hot alkaline baths and the absorption of the curative agent through the skin, as well as of its internal administration. We have in this country waters containing trifling quantities of carbonate of soda, but nothing to give an alkaline *character* to the waters. Many of these waters also contain large quantities of carbonic acid. The muriated waters are those which contain large quantities of alkaline and earthy muriates or chlorides. The sulphated waters are those which contain as their chief ingredients the alkaline and earthy sulphates. Metallic sulphates, as those of iron and manganese, do also exist, but the waters then generally belong to the class of chalybeates. Chalybeate waters are those which contain iron almost always in the form of the carbonate or sulphate, in such quantity as to cause the effects of the water to be ascribed chiefly to its iron. The carbonate is generally held in solution by excess of carbonic acid. This is the reason why, on boiling such waters, a portion of the iron is precipitated, owing to the carbonic acid being driven off; and why, also, the stones in the course of chalybeate waters exhibit a red tinge, as the excess of carbonic acid with which the water was imbued flies off on exposure to the air, and the oxide of iron is precipitated. Most of the carbonated-iron waters are weak; still they produce undoubted effects. Tunbridge wells contain a very little more than the quarter of a grain in the pint. The sulphated-iron waters, again, are of a very different character, both because the ingredient itself is more powerful, and because, being exceedingly soluble, much larger quantities of it are held in solution. Very valuable waters of this class exist in Great Britain, some of them but little known. Some of these waters are too strong for use in an undiluted form, as Sandrook in the Isle of Wight, which contains no less than 41·4 grains of the sulphate of iron in the pint.

Besides these classes of bodies, other substances of importance exist in mineral waters. Iodine and bromine are found occasionally in saline springs. The former element has been found so useful in scrofula and bronchocele that its presence has been considered of much consequence. Woodhall spa, in England, contains rather more than half a grain of iodine in the gallon. Arsenic of late years has been discovered in minute quantities in several waters in France and Germany; and in fact the only limit to the number of substances found in mineral waters would appear to be the extent to which the analyses are carried. Organic acids, as the acetic and formic, as well as others of a different kind, have lately been found by Scherer in the waters of Bruckenan. The principle termed zoogine or glairine, already alluded to, deserves consideration; and so much weight has been attached to it, that in artificial sulphur baths animal gelatine is sometimes substituted for it.¹

¹ Several species of confervæ have been found in this substance: *Calothrix norea* in the sulphur springs of Yorkshire, Durham, and Aix-la-Chapelle; also in the hot sulphur springs of Greoulx in Provence; *Oscillaria labyrinthiformis*, the *Tremella thermalis* of some, one of the most common species, in several of the continental thermal-sulphur and other springs. But these confervæ are not the sole constituents of this matter. An animal principle also exists in many cases which some have supposed to be derived from organic

Mineral
Waters.

The analysis of mineral waters does not give the principles either as they exist in the waters, or as they are generally arranged in the published tables. For instance, in a water said to contain so much sulphate of soda and so much muriate of lime, in reality the sulphuric acid is obtained by throwing it down by means of muriatic or nitrate of baryta in the form of sulphate of baryta, from the weight of which the amount of sulphuric acid in the water is calculated. The other acids and bases are obtained by analogous methods,—the bases generally in combination with an acid, the acids with a base; and from these new compounds the amounts of acids and bases in the waters are calculated. The general rule is to give the strongest acid to the strongest base. In this way the constitution of waters is generally arrived at with considerable accuracy.

The most powerful of all mineral waters of the saline class is the sea itself. It differs somewhat in composition according to the amount of evaporation. Thus the water of the Mediterranean is more dense and saline than that of the ocean. According to the analysis of MM. Mialhe and Figuier, the water of the British Channel at Havre contains 280 grains of salts to the pint. The chief ingredients are chlorides of sodium, magnesium, and potassium, and sulphates of magnesia and lime; with a proportion of bromide of sodium. There are also other salts, traces of iodine, and probably of everything that is found soluble on the earth's surface.

3. *Of the Applications of Mineral Waters, and their Use in the Cure of Disease.*—Their use is external and internal. The external use of mineral waters is almost confined to the thermal waters. Here the alleged superiority of natural heat over artificial again becomes a question, several of the thermal springs being nearly pure water. How much of the superiority of these baths may be ascribed to the same causes as those which tell in favour of mineral waters generally—as change of air and scene, and improved regimen—it is most difficult to say. In speaking of the waters of Leuk in the Valais, Sir John Forbes has some excellent observations on this point in his *Physician's Holiday*. The springs are merely pure water, and if of ordinary temperature might be used as good drinking water. They vary in temperature from 95° to 124°. The baths are employed for many chronic diseases, but their greatest reputation is in cutaneous diseases, scrofula, chronic rheumatism, and indolent gout. The effect of such bathing is to stimulate greatly the powers of the skin, and so to cause free perspiration, thereby carrying off effete principles from the system, and causing a derivation from the internal organs, as the liver, lungs, and kidneys; increasing also the energy of the heart's action. Hence these thermal springs are chiefly employed in gout and rheumatism of a chronic character, in skin diseases, diseases of the joints, old wounds, and diseases of the bones, tumours of all kinds, and sometimes in dyspepsia. By increasing the energy of the circulation, they tend to produce absorption. In kidney diseases and in diabetes, and in chronic dropsical affections, where there is little or no disease of the heart, those springs which are sulphuretted possess, in addition to their heat, a principle, sulphuretted hydrogen, which, applied in this way, powerfully excites the skin, and is perhaps absorbed into the system. This class of waters is especially beneficial in skin diseases and in chronic rheumatism. Of the effect of other gases, as carburetted hydrogen, azote, and carbonic acid, in thermal springs, little is known, except that the last produces a prickling sensation on the surface of the body, which it greatly stimulates.

Among the number of external applications must be

remains. It is that which gives the odour of chicken broth, or bad broth much rotted, as one writer calls it, to such waters as the Kochbrunnen at Wiesbaden.

Mineral
Waters.

mentioned the mud baths much in use lately. The most important of these are at Franzensbad in Germany. The mineral mud of which they are prepared is found in great abundance, and is very rich in active substances. Its principal constituent parts are salts of iron, soda, lime, and alumina; it also contains ulmic acid in large quantity, and other vegetable matters of a gummy or resinous character. The mud is smooth and soft to the touch, and of an extremely styptic taste; heated by steam, or diluted with water, it forms a sort of cataplasm like bread crumb coloured with ink, and is used for baths or fomentations locally. From this application the best effects are said to have been derived in anemia and chlorosis (green sickness), in old rheumatic and gouty affections, sciatica, paralysis where there is no organic disease of the spinal cord or brain, in old fractures, and in some diseases of the skin. After the surface of the body has been washed on leaving the bath, the skin is unctuous and smooth; and on taking exercise perspiration is readily induced.

Cold sulphuretted waters are sometimes heated for baths, as is practised at Harrogate; but there is in this case much escape of the sulphuretted hydrogen. This remedy is chiefly used in skin diseases, chronic liver diseases, and chronic rheumatism. Few of the ordinary cold waters are used externally. The celebrated fountain at Ilkley in Yorkshire is merely pure cold water issuing in a full stream from the mountain, and which, applied as a douche or used as a plunge-bath, produces excessive chill, then great reaction either in the part to which it is applied or the whole surface of the body, and therefore comes under the category of simple cold baths. Besides these applications, all waters may be directed as douches to any particular part; ascending douches are used in several female complaints, and in this way carbonic and sulphuretted hydrogen gases from springs have been applied either by tubes to some particular part (carbonic acid, for example, to the ear in certain cases of deafness), or to the whole body inclosed in a suitable apparatus.

With regard to the action of cold mineral waters, it is generally either what is termed alterative or tonic. In the former case the fluids are altered in character, and this is mostly done by exciting the secretions, especially those of the skin and kidneys. The effect of this increased secretion is to remove more quickly from the system the worn-out constituents of the frame, and with them many morbid elements, and thus give fair play to the vital forces of the system, if these still retain sufficient energy to set about the work of reparation. Many of the saline waters, especially those containing alkaline sulphates and muriates, associated with sulphuretted hydrogen or without it, act powerfully on the bowels and promote the action of the liver. Of this class are Harrogate and Cheltenham in this country, and Carlsbad abroad, which is, however, also a thermal water.¹ Cheltenham waters contain various proportions of salts. The strongest of them, the Old Well and the Montpellier, have respectively 81·51 and 80·13 of solids to the imperial pint, being muriates and sulphates of soda, and muriates of lime and magnesia. Of the efficacy of this and similar waters in liver affections, the constant resort of sufferers from the diseases of tropical climates may be supposed to afford a proof. The saline muriated waters, many of which contain traces of iodine and bromine, besides their alterative properties, act as tonics, and are especially suited

¹ Carlsbad waters contain a large quantity of carbonic acid, and are remarkable for the variety of their contents: manganese and iron, iodine and bromine, arsenic and boracic acid, copper, lead, tin, and antimony, are among these. Perhaps the variety of the constituents has to do with the number of diseases in which these waters are found beneficial. Two of their best ascertained beneficial effects are in cases of recently united fractures, in consolidating the callus, and in reducing enlarged livers.

Mineral
Waters.

for scrofulous affections, especially if they contain iron. In many of these waters it is possible for a patient to take into the system in the course of the day a medicinal dose of the earthy muriates long ago recommended by *Hufeland* as powerful remedies in scrofula; and in addition to these large quantities of muriate of soda, also a remedy in scrofula, with small quantities of bromides and iodides, whose efficacy in this class of diseases is undoubted. And it is a curious fact, that the springs in Piedmont, in which iodine was first discovered by M. Cantu, had been long renowned in scrofula; just as the ashes of burnt sponge were recognised as a remedy in goitre hundreds of years before iodine was discovered, or they were known to contain it, or M. Coindet of Geneva had demonstrated the efficacy of iodine in this disease, so common in the valleys of Switzerland and Savoy.

The virtues of chalybeate waters are popularly appreciated, and the diseases in which they are beneficial generally known. They act by strengthening the tone of the stomach, and perhaps by some chemico-vital influence in increasing the number of red particles in the blood, in which iron forms an important ingredient, and has been supposed by Liebig to perform an active part in the phenomena of respiration. Certain it is, that of all the class of tonics none equal iron in giving a healthy bloom to the complexion. The use of chalybeates is apt, however, to congest the head, and therefore they should be employed with caution where there is any tendency to such congestion. The waters containing iron are among the few requiring often some kind of medicinal preparation for their use. The bowels should be well opened previously, if possible, by some mild preparation, as the compound rhubarb pill, and their state should be attended to while the use of the water is continued. In waters containing the sulphate, alumina is often present, which makes it the more requisite to observe this caution. The dose of the sulphate should not exceed one, or at most, two grains twice a day. In those waters which contain manganese as well, it may be reckoned as so much iron. Very powerful effects indeed are often obtained from such waters, in chlorosis, anemia, general debility, &c.¹

Among the prodigious list of diseases which have been supposed to be benefited by the use of mineral waters may be enumerated phthisis and chronic bronchitis. Some of the mild thermal waters, as those of Wiesbaden, taken internally, have been found beneficial in allaying pulmonary irritation in these diseases. Hot bathing in such cases is a very dangerous remedy. Chalybeate waters in incipient phthisis have been often found beneficial; but in this class of diseases, as a general rule, removal to a spa should only take place when the situation affords a favourable change in hygienic conditions. The same may be said of asthma and diseases of the heart. In diarrhoea from debility, the strong astringent ferruginous waters, especially those which contain sulphate of iron and alumina, have been found beneficial. In constipation, hypochondriasis, enlargement of the liver and spleen, biliary calculi, all the saline waters, both sulphated and muriated, thermal, or impregnated with sulphuretted hydrogen and carbonic acid gas, are useful; and in biliary calculi the alkaline waters, as those of Carlsbad and Vichy, have been found especially valuable. In catarrh of the bladder, gravel, and urinary calculi, mild thermal waters, baths of these, and alkaline saline waters, especially those of Vichy and Carlsbad, have been attended with the best results. In amenorrhœa and dysmenorrhœa, chalybeates; in the latter, thermal waters externally and in-

¹ It has been proved by the experiments of Andral, Gavarret, Becquerel, and others, that of 1000 parts of blood the quantity of red globules, which was 46·6 before the use of preparations of iron, was augmented by the use of this agent to 95·7. In some cases under the use of iron the solids of the blood increased by one-half, while the water diminished in the proportion of 871 to 806.

ternally; in the former, and in cases of sterility, sea-bathing, especially combined with the use of chalybeates,—a combination which may be obtained, for example, at Scarborough,—should be employed. The same have been found useful in certain male affections of a sexual character. In diseases of the skin especially, the sulphuretted waters should be used externally and internally. In chronic rheumatism and gout the thermal waters are the best. In these diseases we have in this country the well-established renown of Buxton and Bath. Where gouty deposits are formed there is little chance of their removal by the use of any mineral water. In those formidable diseases, diabetes and albuminuria, thermal waters (in the former especially the waters of Vichy) should be employed. In old wounds, and the results of contusions and fractures, the same class of waters have been found beneficial.

It has been a question how far artificial waters are able to supply the place of the natural springs. In point of fact, most of the natural waters can be imitated with sufficient exactitude. The artificial seltzer water manufactured at Brighton is perhaps even superior to that of the renowned spring itself; but the adjuncts of change of air, freedom from the usual sources of anxiety, pleasant scenery, &c., are wanting. The same applies to waters sent to a distance from the springs. It is as in an ordinary prescription, where the physician to the basis of his prescription adds what will assist its operation and render it as grateful as possible. The *adjvantia* to the use of mineral waters are the *air* and the *places*, without which the medicine loses very much of its effect; not but that a vast number of mineral waters are real medicines, which may be taken anywhere with benefit.

(R. M. G.)

MINERALOGICAL SCIENCE.

On account of the sudden death of Professor Edward Forbes, who had engaged to furnish the article GEOLOGY for this work, it was found necessary to defer it to the present heading. Under MINERALOGICAL SCIENCE, therefore, will be found first, MINERALOGY properly so called; and secondly, GEOLOGY.

I.—MINERALOGY.

MINERALOGY is sometimes understood as comprising the natural history of every portion of inorganic nature. Here we consider it as limited to the natural history of simple minerals or mineral species. In the strictest sense, a mineral species is a natural inorganic body, possessing a definite chemical composition, and assuming a regular determinate form or series of forms. This definition excludes many bodies often regarded as minerals: as, all the artificial salts of the chemists, all the inorganic secretions of plants and animals, all the remains of former living beings now imbedded in rocks. Some substances originally organic products have indeed, by common consent, found a place in mineral systems, as coal, amber, and mineral resins; but this is a departure from the strictness of the definition, and in most cases had perhaps better have been avoided. So also some amorphous substances, with no precise form or chemical composition, as some kinds of clay, have been introduced into works on mineralogy, but we believe often improperly, and with no beneficial result. Aggregates of simple minerals or rocks are likewise excluded from this science, though the various associations of minerals, their modes of occurrence, and their geological position, are important points in the history of the different species.

One most important object of a treatise on mineralogy

should be to give such descriptions of minerals, their essential properties and distinctive characters, as will enable the student to distinguish the various species, and to recognise them when they occur in nature. But to accomplish this he must first become acquainted with the terminology or nomenclature of the science; that is, with the meaning of the terms used in describing these properties, and the various modifications they may undergo. With this is necessarily conjoined an account of the properties themselves, and of the more general laws by which their various changes are regulated. A second and closely-related portion of mineralogy is the system or classification, giving an account of the order in which the species are arranged, and the reasons for which it has been adopted. The third and most important part of mineralogy, to which these two are properly preparatory, is the physiography of the various species, giving an account of their characteristic marks, and a description of their appearance or external aspect and forms; their principal physical and chemical properties; their mode of occurrence, with their geological and geographical distribution; and their various uses, whether in nature or in the arts. Each of these departments will be considered in the following treatise in the order just mentioned.

PART I.—TERMINOLOGY.

CHAP. I.—FORM OF MINERALS.

The physical properties of a mineral comprise all those properties belonging to it as a body existing in space, and consisting of matter aggregated in a peculiar way. The more important of these are,—its form as shown in crystallization; its structure as determining its mode of cleavage and fracture; its hardness and tenacity; its weight or specific gravity; and its relations to light, heat, electricity, and magnetism.

Crystalline and Amorphous.—Mineral substances occur in two distinct modes of aggregation. Some consist of minute particles simply collected together, with no regu-

larity of structure or constancy of external form, and are named amorphous. All fluid minerals are in this condition, together with some solid bodies, which appear to have condensed either from a gelatinous condition like opal, when they are named *porodine*, or from a state of igneous fluidity like obsidian and glass, when they are named *hyaline*. The other class have their ultimate atoms evidently arranged according to definite law, and are named *crystalline*, when the regularity of structure appears only in the internal disposition of the parts; and *crystallized*, when it also produces a determinate external form, or a *crystal*.

Faces, Edges, Angles, Axes of Crystals.—The word *crystal* in mineralogy designates a solid body exhibiting an

Crystals.

Minera-
logy.

original (not artificial) more or less regular polyhedric form. It is thus bounded by plane surfaces, named *faces*, which intersect in straight lines or *edges*, and these again meet in points and form *solid angles*, bounded by three or more faces. The space occupied by a crystal is often named a *form of crystallization*, which is thus the mathematical figure regarded as independent of the matter that fills it. Crystals bounded by equal and similar faces are named *simple forms*; whilst those in which the faces are not equal and similar are named *compound forms*, or *combinations*, being regarded as produced by the union or combination of two or more simple forms. The cube or hexahedron (fig. 1), bounded by six equal and similar squares; the octahedron (fig. 2), by eight equilateral triangles; and the rhombohedron, by six rhombs,—are thus simple forms. An *axis* of a crystal is a line passing through its centre and terminating either in the middle of two faces, or of two edges, or in two angles; and axes terminating in similar parts of a crystal are named similar axes. In describing a crystal, one of its axes is supposed to be vertical or upright, and is then named the *principal axis*, and that axis is chosen which is the only one of its kind in the figure. A few other technical terms used in describing crystals will be explained as they occur.

Systems of Crystallization.—The forms of crystals that occur in nature seem almost innumerable. On examining them, however, more attentively, certain relations are discovered even between highly complex crystals. When the axes are properly chosen, and placed in a right position, the various faces are observed to group themselves in a regular and beautiful manner around these axes, and to be all so related as to compose connected series produced according to definite laws. In every mineral species there is a certain form of crystal from which, as a primary, every other form of crystal observed in that mineral species may be deduced. In each species the axes, bearing to each other definite numerical proportions, intersect at angles which are constant. So also the faces of the various forms are related to each other, and to their primary, according to certain definite laws. When viewed in this manner, and referred to their simplest forms, the innumerable variety of crystals occurring in nature may all be reduced to six distinct groups, or, as they are named, systems of crystallization. The following are the names given to these systems of crystallization in some of the best authors:—

Naumann.	Mohs.	Weiss and G. Rose.
1. Tesseral System.	Tessular.	Regular.
2. Tetragonal System.	Pyramidal.	2 and 1 axial.
3. Hexagonal System.	Rhombohedral.	3 and 1 axial.
4. Rhombic System.	Orthotype.	1 and 1 axial.
5. Monoclinohedric System.	Hemiorthotype.	2 and 1 membered.
6. Triclinohedric System.	Anorthotype.	1 and 1 membered.

In the following treatise the terminology of Naumann is adopted, his method of classifying and describing crystals appearing the simplest and best adapted to promote the progress of the student.

Holohedric and Hemihedric.—Before describing these systems, it must be observed that certain crystals appear as the half of others, and are therefore named *hemihedric*; whilst the crystals with the full number of faces are named *holohedric*. Hemihedric crystals are formed when the alternate faces or groups of faces of a holohedric crystal increase symmetrically, so as to obliterate the other faces. Thus, if four alternate faces of the octohedron increase so as to obliterate the other four, a tetrahedron with half the number of faces is formed.

1. Tesseral system. The first, or *Tesseral System*, named from *tessera*, a cube, which is one of the most frequent varieties, is characterized by three equal axes intersecting each other at right angles. Properly speaking, this system has no chief axis, as any one of them may be so named, and placed upright in drawing and describing the crystals. Of these there are thirteen

varieties, which are thus classed and named from the number of their faces:—

1. One Tetrahedron, or form with four faces.
2. One Hexahedron, with six faces.
3. One Octahedron, with eight faces.
4. Four Dodecahedrons, with twelve faces.
5. Five Icositetrahedrons, with twenty-four faces.
6. One Tetracontaoctahedron, with forty-eight faces.

The dodecahedrons are further distinguished, according to the form of their faces, into rhombic, trigonal, deltoid, and pentagonal dodecahedrons; and some of the icositetrahedrons have also received peculiar names.

The following is a description, with figures, of the different forms above mentioned, beginning with

The *Holohedric forms*.

1. The hexahedron or cube (fig. 1) is bounded by six equal squares, has twelve edges, formed by faces meeting at 90°, and eight trigonal angles. The principal axes join the centre points of any two opposite faces.—Examples are fluor spar, lead-glance, boracite.

Fig. 1.

Fig. 2.

2. The octahedron (fig. 2), bounded by eight equilateral triangles, has twelve equal edges, with planes meeting at 109° 28', and six tetragonal angles. The principal axes join the opposite angles, two and two.—Example, alum, spinel, magnetic iron ore.

3. The rhombic-dodecahedron (fig. 3) is bounded by twelve equal and similar rhombs (diagonals as 1 and $\sqrt{2}$),

Fig. 3.

Fig. 4.

has twenty-four equal edges of 120°, and six tetragonal and eight trigonal angles. The principal axes join two opposite tetragonal angles.—Ex., garnet, red copper ore, boracite.

4. The tetrakis-hexahedrons (variety of icositetrahedron, fig. 4), are bounded by twenty-four isosceles triangles, arranged in six groups of four each. They have twelve longer edges which correspond to those of the primitive or inscribed cube, and twenty-four shorter edges placed over each of its faces. The angles are eight hexagonal and six tetragonal; the latter joined two and two by the three principal axes. This form varies in general aspect, approaching, on the one hand, to the cube; on the other, to the rhombic-dodecahedron.—Ex., fluor spar, gold.

5. The triakis-octahedrons (variety of icositetrahedron, fig. 5), are bounded by twenty-four isosceles triangles, in eight groups of three, and, like the previous form, vary in

Minera-
logy.

Mineralogy.

general aspect from the octahedron on one side, to the rhombic-dodecahedron on the other. The edges are twelve longer, corresponding with those of the inscribed octahedron, and twenty-four shorter, three and three over each of the faces. The angles are eight trigonal and six ditetragonal (formed by eight faces); the latter angles joined two and two by the principal axes.—Ex., galena, diamond.

Fig. 5.

Fig. 6.

6. The icositetrahedrons (most common variety, fig. 6) are bounded by twenty-four deltoids or figures with four sides, of which two and two adjacent ones are equal. This form varies from the octahedron to the cube, sometimes approaching the former and sometimes the latter in general aspect. The edges are twenty-four longer and twenty-four shorter. The angles are six tetragonal joined by the principal axes, eight trigonal, and twelve rhombic, or tetragonal with unequal angles.

7. The hexakisoctahedrons (fig. 7), bounded by forty-eight scalene triangles, vary much in general aspect, approaching more or less to all the preceding forms; but most frequently they have the faces arranged either in six groups of eight, or eight of six, or twelve of four faces. There are twenty-four long edges, often corresponding to those of the rhombic-dodecahedron; twenty-four intermediate edges lying in pairs over each edge of the inscribed octahedron; and twenty-four short edges in pairs over the edges of the inscribed cube. There are six ditetragonal angles joined by the principal axes, eight hexagonal and twelve rhombic angles.—Ex., fluor spar, garnet, diamond.

Fig. 7.

The seven forms of crystals now described are related to each other in the most intimate manner. This will appear more distinctly from the following account of the derivation of the forms, with which is conjoined an explanation of the crystallographic signs or symbols by which they are designated. We have adopted these symbols throughout this work, in the belief that they not only mark the forms in a greatly abbreviated manner, but also exhibit the relations of the forms and combinations in a way which words could hardly accomplish.

Derivation of crystalline forms.

The derivation of forms is that process by which, from one form chosen for the purpose, and considered as the type—the fundamental or primary form—all the other forms of a system may be produced, according to fixed principles or general laws. In order to understand this process or method of derivation, the student should keep in mind that the position of any plane is fixed when the positions of any three points in it, not all in one straight line, are known. To determine the position, therefore, of the face of a crystal, it is only necessary to know the distance of three points in it from the centre of the crystal, or the points in which the face or its supposed extension would intersect the three axes of the crystal. The portion of the axes between this point and the centre are named parameters, and the posi-

Mineralogy.

tion of the face is sufficiently known when the relative length or proportion of these parameters is ascertained. When the position of one face of a simple form is thus fixed or described, all the other faces are in like manner fixed, since they are all equal and similar, and all intersect the axes in a uniform manner; and the expression which marks or describes one face, marks and describes the whole figure.

The octahedron is generally adopted as the primary or fundamental form of the tesseral system, and distinguished by the first letter of the name, O. Its faces cut the half axes at equal distances from the centre; so that these semi-axes, or the parameters of the faces, have to each other the proportion 1 : 1 : 1. In order to derive the other forms from the octahedron, the following construction is employed. The numbers refer to the descriptions above.

Suppose a plane so placed in each angle of the octahedron as to be vertical to the axis passing through that angle, and consequently parallel to the two other axes (or to cut them at an infinite distance = ∞); then the hexahedron or cube (1) is produced, designated by the crystallographic sign $\infty O \infty$; expressing the proportion of the parameters of its faces, or $\infty : \infty : 1$. If a plane is supposed placed in each edge parallel to one axis, and cutting the two other axes at equal distances, the resulting figure is the rhombic-dodecahedron (3), designated by the sign ∞O , the proportion of the parameters of its faces being $\infty : 1 : 1$. The triakis octahedron (5) arises when on each edge of the octahedron planes are placed cutting the axis not belonging to that edge at a distance from the centre m which is a rational number greater than 1. The proportion of its parameters is therefore $m : 1 : 1$, and its sign mO ; the most common varieties being $\frac{3}{2}O$, $2O$, and $3O$. When, on the other hand, from a similar distance m in each two semi-axes prolonged, a plane is drawn to the other semi-axis, or to each angle, an icositetrahedron (6) is formed; the parameters of its faces have consequently the proportion $m : 1 : m$, and its sign is mOm ; the most common varieties being $2O2$ and $3O3$, the former very frequent in leucite, analcime, and garnet. When, again, planes are drawn from each angle, or the end of one semi-axis of the octahedron, parallel to a second axis, and cutting the third at a distance n , greater than 1, then the tetrakis hexahedron (4) is formed, the parameter of its faces $\infty : 1 : n$; its sign ∞On ; and the most common varieties in nature $\infty O\frac{3}{2}$, $\infty O2$, and $\infty O3$. Finally, if in each semi-axis of the octahedron two distances, m and n , be taken, each greater than 1, and m also greater than n , and planes be drawn from each angle to these points, so that the two planes lying over each edge cut the second semi-axis belonging to that edge, at the smaller distance n , and the third axis at the greater distance m , then the hexakis octahedron (7) is produced, the parameters, which are $m : n : 1$, its sign mOn , and the most common varieties $3O\frac{3}{2}$, $4O2$, and $5O\frac{3}{2}$.

The next class of crystals are the *semi-tesseral forms*; and first, those with oblique faces, often named tetrahedral, from their relation to the tetrahedron. (1.) This form (fig. 8)

Fig. 8.

Fig. 9.

is bounded by four equilateral triangles, has six equal edges with faces meeting at $70^\circ 32'$, and four trigonal angles. The principal axes join the middle points of each two op-

Mineralogy.

posite edges.—Ex., gray-copper ore, boracite, and helvine. (2.) The trigonal dodecahedrons (fig. 9) are bounded by twelve isosceles triangles, and vary in general form from the tetrahedron to the hexahedron. There are six longer edges corresponding to those of the inscribed tetrahedron, and twelve shorter, placed three and three over each of its faces; and four hexagonal and four trigonal angles.—Ex., gray-copper ore, and bismuth-blende. (3.) The deltoid-dodecahedrons (fig. 10) are bounded by twelve deltoids, and vary in general form from the tetrahedron on the one hand, to the rhombic-dodecahedron on the other. They have twelve longer edges lying in pairs over the edges of the inscribed tetrahedron; and twelve shorter edges, three and three over each of its faces. The angles are six tetra-

Fig. 10.

Fig. 11.

gonal (rhombic), four acute trigonal, and four obtuse trigonal angles. The principal axes join two and two opposite rhombic angles.—Ex., gray-copper ore. (4.) The hexakis-tetrahedrons (fig. 11) are bounded by twenty-four scalene triangles, and most commonly have their faces grouped in four systems of six each. The edges are twelve shorter and twelve longer, lying in groups of three over each face of the inscribed tetrahedron, and twelve intermediate in pairs over its edges. The angles are six rhombic, joined in pairs by the principal axes, and four acuter and four obtuser hexagonal angles.—Ex., diamond.

The derivation and signs of these forms are as follows:—The tetrahedron arises when four alternate faces of the octahedron are enlarged, so as to obliterate the other four, and its sign is hence $\frac{O}{2}$. But, as either four faces may be thus enlarged or obliterated, two tetrahedrons can be formed similar in all respects except in position, and together making up the octahedron. These are distinguished by the signs + and —, added to the above symbol, but only the latter in general expressed thus — $\frac{O}{2}$. In all hemihedric systems two forms similarly related occur, which may thus be named complementary forms. The trigonal dodecahedron is derived from the icositetrahedron by the expansion of the alternate trigonal groups of faces. Its sign is $\frac{mOm}{2}$, the most common variety being $\frac{2O2}{2}$, found in gray-copper ore. The deltoid-dodecahedron is in like manner the result of the increase of the alternate trigonal groups of faces of the triakis-octahedron, and its sign is $\frac{mO}{2}$. Lastly, the hexakis-tetrahedron arises in the development of alternate hexagonal groups of faces in the hexakis-octahedron, and its sign is $\frac{mOn}{2}$.

The parallel-faced semitesseral forms are two. (1.) The pentagonal dodecahedrons (fig. 12) are bounded by twelve symmetrical pentagons, and vary in general aspect between the hexahedron and rhombic-dodecahedron. They have six regular (and in general longer) edges, lying over the faces of the inscribed hexahedron, and twenty-four generally shorter (seldom longer) edges, usually lying in pairs over its edges. The angles are eight of three equal

angles, and twelve of three unequal angles. Each principal axis unites two opposite regular edges. This form is derived from the tetrakis-hexahedron, and its sign is $\frac{\infty On}{2}$, one of the most common varieties being $\frac{\infty O2}{2}$, found frequently in iron pyrites and cobaltine. (2.) The dyakis-dodecahedron (fig. 13), bounded by twenty-four trapezoids with two sides equal, has twelve short, twelve long, and twenty-four intermediate edges. The angles are six equiangular rhombic, united in pairs by the principal axes, eight trigonal, and twenty-four irregular tetragonal angles. It is derived from the hexakis-octahedron, and its sign is $\left[\frac{mOn}{2} \right]$, the brackets being used to distinguish it from the hexakis-tetrahedron, also derived from the same primary form. It occurs in iron pyrites and cobaltine. There are two other tetrahedral forms, the pentagonal dodecahedron (fig. 14), and the

Fig. 12.

Fig. 13.

Fig. 14.

Fig. 15.

pentagonal icositetrahedron (fig. 15), both bounded by irregular pentagons, but not yet observed in nature.

Combinations.—These forms of the tesseral system (and this is true also of the five other systems of crystallization, not only occur singly, but often two, three, or more united in the same crystal, forming what are named combinations. In this case it is evident that no one of the individual forms can be completely developed, because the faces of one form must partially interfere with the faces of the other forms. A combination therefore implies that the faces of one form shall appear symmetrically disposed between the faces of other forms, and consequently in the room of certain of their edges and angles. These edges and angles are thus, as it were, cut off, and new ones produced in their place, which properly belong neither to the one form nor the other, but are edges or angles of combination. Usually, one form predominates more than the others, or has more influence on the general aspect of the crystal, and hence is distinguished as the predominant form, the others being named subordinate. The following terms used on this subject require explanation. A combination is *developed* when all the forms contributing to its formation are pointed out; and its sign consists of the signs of these forms, written in the order of their influence on the combination, with a point between. An angle or edge is said to be *replaced* when it is cut off by one or more secondary planes; it is *truncated* when cut by one plane, forming equal angles with the adjacent faces; and an edge is *bevelled* when replaced by two planes, which are equally inclined to the adjacent faces.

It will be readily seen that such combinations may be exceedingly numerous, or rather infinite; and only a few

Mineralogy.

Mineralogy.

of the more common can be noticed, simply as specimens of the class. Many others more complicated will occur in the descriptive part of this treatise. Among plenotesseral combinations, the cube, octahedron, and also the rhombic-dodecahedron, are the predominant forms. In fig. 16 the

Fig. 16.

Fig. 17.

cube has its angles replaced by the faces of the octahedron, and the sign of this combination is $\infty O \infty \cdot O$. In fig. 17

Fig. 18.

Fig. 19.

this process may be regarded as having proceeded still further, so that the faces of the octahedron now predominate, and the sign of the same two elements but in reverse order is $O \cdot \infty O \infty$. In fig. 18 the cube has its edges replaced by the faces of the rhombic-dodecahedron, the sign being $\infty O \infty \cdot \infty O$; whilst in fig. 19 there is the same combination, but with the faces of the cube subordinate, and hence the symbol is $\infty O \cdot \infty O \infty$. The former figure, it will be seen, has more the general aspect of the cube; the latter of the dodecahedron.

In combinations of semitesseral forms with oblique faces, the tetrahedron, the rhombic-dodecahedron, or even the hexahedron, seldomer a trigonal-dodecahedron, are the more common predominant forms. In fig. 20 two tetrahedrons

Fig. 20.

Fig. 21.

in opposite positions, $\frac{O}{2} \cdot \frac{O}{2}$, are combined. In fig. 21 a

Fig. 22.

Fig. 23.

very complex combination of seven forms is represented in a crystal of grey-copper ore, its full sign being—

$$\frac{202}{2}(l) \cdot \infty O \infty(f) \cdot \infty O(o) \cdot \frac{O}{2}(P) \cdot \frac{202}{2}(r) \cdot \frac{30}{2}(n) \cdot \infty O3(s);$$

Mineralogy.

the letters in brackets connecting them with the respective faces of the figure. As examples of combinations of semitesseral forms with parallel faces, we may take fig. 22, in which each of the angles of the cube is unsymmetrically replaced by three faces of the dyakis-dodecahedron, and hence

$$\infty O \infty \cdot \left[\frac{402}{2} \right]; \text{ or fig. 23, in which the pentagonal-dodecahedron has its trigonal angles replaced by the faces of the octahedron, consequently with the sign } \infty O \frac{2}{2} \cdot O. \text{ Figure 24 represents}$$

Fig. 24.

the same combination but with greater predominance of the faces of the octahedron, the crystal being bounded by eight equilateral and twelve isosceles triangles.

Tetragonal System.—This system has three axes at 2. Tetragonal system. right angles, two of them equal and one unequal. The last is the principal axis, and when it is brought into a vertical position the crystal is said to be placed upright. Its ends are named poles, and the edges connected with them polar edges. The two other axes are named subordinate or lateral axes, and a plane passing through them is named the basis of the crystal. The two planes that pass through the principal and one of the lateral axes are named normal chief sections, and a plane through the chief axis intermediate to them a diagonal chief section. The name tetragonal is derived from the form of the basis, which is usually quadratic.

There are eight tetragonal forms, of which five are *closed*,—that is, bounded on all sides by planes, and of definite extent; and three *open*, which in certain directions are not bounded, and consequently of indefinite extent.

Fig. 25.

Fig. 26.

The description of the varieties is as follows, it being premised that a crystallographic pyramid is equivalent to two geometrical pyramids joined base to base. **Closed forms.**—(1.) Tetragonal pyramids (figs. 25, 26) are inclosed by eight isosceles triangles, with four middle edges all in one plane, and eight polar edges. There are three kinds of this form, distinguished by the position of the lateral axes. In the first these axes unite the opposite angles; in the second they intersect the middle edges equally; and in the third they lie in an intermediate position, or divide these edges unequally; the latter being hemihedral forms. These pyramids are also distinguished as obtuse (fig. 25) or acute (fig. 26), according as the vertical angle is greater or less than in the octahedron, which, though intermediate, is never a tetragonal form. (2.) Ditetragonal pyramids (fig. 27) are bounded by sixteen scalene triangles, whose base lines are all in one plane. This form rarely occurs except in combinations. (3.) Tetragonal sphenoids (fig. 28), bounded by four isosceles

Minera-
logy.

triangles, are the hemihedral forms of the first variety of tetragonal pyramids. (4.) The tetragonal scalenohedron (fig. 29), bounded by eight scalene triangles, whose bases rise and fall in a zig-zag line, is the hemihedral form of the

Fig. 27.

Fig. 28.

ditetragonal pyramid. The latter two forms are rare. *Open forms.*—Tetragonal prisms (fig. 30) bounded by four planes parallel to the principal axis; ditetragonal prisms by eight similar planes. In these prisms the principal axis is supposed to be prolonged infinitely, or to be unbounded. Where it is very short and the lateral axes

Fig. 29.

Fig. 30.

infinite, the basal pinacoid is formed, consisting merely of two parallel faces.

The various series of tetragonal crystals are distinguished from each other only by their relative dimensions. To determine these, one of the series must be chosen as the fundamental form, and for this purpose a tetragonal pyramid of the first variety, designated by P as its sign, is selected. The angle of one of its edges, especially the middle edge, found by measurement, determines its angular dimensions; whilst the proportion of the principal axis (a) to the lateral axes supposed equal to 1, gives its linear dimensions. The parameters, therefore, of each face of the fundamental form are $1 : 1 : a$.

Now if m be any (rational) number, either less or greater than one, and if from any distance ma in the principal axis planes be drawn to the middle edge of P , then new tetragonal pyramids of the first kind, but more or less acute or obtuse than P , are formed. The general sign of these pyramids is mP , and the most common varieties $\frac{1}{2}P$, $2P$, $3P$; with the chief axis equal to $\frac{1}{2}$, twice or thrice that of P . If m becomes infinite, or $=\infty$, then the pyramid passes into a prism, indefinitely extended along the principal axis, and with the sign ∞P ; if $m=0$, which is the case when the lateral axes are supposed infinite, then it becomes a pinacoid, consisting properly of two basal faces, open towards the lateral axes, and designated by the sign OP . The ditetragonal pyramids are produced by taking in each lateral axis distances n greater than 1, and drawing two planes to these points from each of the intermediate polar edges. The parameters of these planes are therefore $m : 1 : n$, and the general sign of the form mPn , the most common values

of n being $\frac{3}{2}$, 2, 3, and ∞ . When $n = \infty$, a tetragonal pyramid of the second kind arises, designated generally by $mP\infty$, the most common in the mineral kingdom being $P\infty$ and $2P\infty$. The relation of these to pyramids of the first kind is shown in fig. 31, where $ABBBX$ is the first, and $ACCCX$ the second kind of pyramid. In like manner from the prism ∞P , the ditetragonal prisms ∞Pn are derived, and finally when $n = \infty$, the tetragonal prism of the second kind, whose sign is $\infty P\infty$.

 Minera-
logy.

Fig. 31.

Fig. 32.

The combinations of the tetragonal system are either holohedric or hemihedric; but the latter are rare. Prisms and pinacoids must always be terminated on the open sides by other forms. Thus in fig. 32 a square prism of the first kind is terminated by the primary pyramid, and has its lateral angles again replaced by another more acute pyramid of the second kind, so that its sign is $\infty P \cdot P \cdot 2P\infty$. In fig. 33 a prism of the second kind is first bounded by

Fig. 33.

Fig. 34.

the fundamental pyramid, and then has its edges of combination replaced by a ditetragonal pyramid, and its sign is here $\infty P\infty \cdot P \cdot 3P3$. In fig. 34 the polar edges of the pyramid are replaced by another pyramid, its sign being $P \cdot P\infty$. In fig. 35 a hemihedric form very characteristic of copper pyrites is represented, P and P' being the two sphenoids, a the basal pinacoid, and b, c , two ditetragonal pyramids.

Fig. 35.

The Hexagonal System.—The essential character of this system is, that it has four axes,—three equal lateral axes intersecting each other in one plane at 60° , and one principal axis at right angles to them. The extremities of the principal axis are named poles, and sections through it and one lateral axis, normal chief sections. The plane through the lateral axes is the basis, and from its hexagonal form gives the name to the system. As in the last system, its forms are either closed or open; and are divided into holohedric, hemihedric, and tetartohedral,—the last, forms with only a fourth part of their faces developed. The tetartohedral and many of the hemihedric forms are of rare occurrence, and only a few of the more common require to be here described. The hexagonal pyramids (figs. 36, 37) are bounded by twelve isosceles triangles, and are of three kinds, according

 3. Hexa-
gonal system.

Mineralogy.

as the lateral axes fall in the angles, in the middle of the lateral edges, or in another point of these edges, the latter being hemihedral forms. They are also classed as acute or obtuse, but without any very precise limits. The trigonal pyramid is bounded by six triangles, and may be viewed as the hemihedral form of the hexagonal. The dihexagonal pyramid is bounded by twenty-four scalene triangles, but has never been observed alone, and rarely even in combinations. The more common prisms are the hexagonal of six sides, and the dihexagonal of twelve sides.

Fig. 36.

Fig. 37.

As the fundamental form of this system, a particular pyramid P is chosen, and its dimensions determined either from the proportion of the lateral to the principal axis ($1 : a$), or from the measurement of its angles. From this form (mP) others are derived exactly as in the tetragonal system. Thus dihexagonal pyramids are produced with the general sign mPn , the chief peculiarity being that, whereas in the tetragonal system n might have any rational value from 1 to ∞ , in the hexagonal system it can only vary from 1 to 2, in consequence of the geometric character of the figure. When $n=2$ the dihexagonal changes into an hexagonal pyramid of the second kind, whose sign is $mP2$. When m is ∞ various prisms arise from similar changes in the value of n ; and when $m=0$ the basal pinacoid.

Few hexagonal mineral species form perfect holohedric combinations. Though quartz and apatite appear as such, yet properly the former is a tetartohedral, the latter a hemihedral species. In holohedric species the predominant faces are usually those of the two hexagonal prisms ∞P and $\infty P2$ or of the pinacoid OP ; whilst the pyramids P and $2P2$ are the most common subordinate forms. Figure 38 represents the prism, bounded on the extremities by two pyramids; one, P , forming the point, the other $2P2$ the rhombic faces on the angles, or $\infty P \cdot P \cdot 2P2$. In some crystals the lateral edges of the prism are replaced by the

Fig. 38.

Fig. 39.

second prism $\infty P2$, producing an equiangular twelve-sided prism, which always represents the combination $\infty P \cdot \infty P2$, and cannot occur as a simple form. An example of a more complicated combination is seen in fig. 39, of a crystal

of apatite, whose sign with the corresponding letters is $\infty P(M) \cdot \infty P2(e) \cdot OP(P) \cdot \frac{1}{2}P(r) \cdot P(x) \cdot 2P(z) \cdot P2(a) \cdot 2P2(s) \cdot 4P2(d)$.

Hexagonal minerals more frequently crystallize in those series of hemihedral forms that are named rhombohedral,

Fig. 40.

from the prevalence in them of rhombohedrons. These are (fig. 40) bounded by six rhombs, whose lateral edges do not lie in one plane, but rise and fall in a zig-zag manner. The principal axis unites the two trigonal angles, formed by three equal plane angles, and in the most common variety the secondary axes join the middle points of two opposite edges. When the polar edges form an angle of more than 90° the rhombohedrons are named obtuse; when of less, acute. Hexagonal scalenohedrons (figure 41) are bounded by twelve scalene triangles, whose lateral edges do not lie in one plane. The principal axis joins the two hexagonal angles, and the secondary axis the middle points of two opposite lateral edges.

Fig. 41.

The rhombohedron is derived from the first kind of hexagonal pyramid by the hemihedric development of its alternate faces. Its general

sign should therefore be $\frac{mP}{2}$;

but on several grounds it is found better to designate it by R or mR , and its complimentary figure by $-mR$. When the prism or pinacoid arise as its limiting forms, they are designated by ∞R and OR , though in no respect changed from the limiting forms ∞P and OP of the pyramid. The scalenohedron is properly the hemihedric form of the dihexagonal pyramid, but is better derived from the inscribed rhombohedron mR . If the halves of the principal axis of this are multiplied by a definite number n , and then planes drawn from the extremities of this enlarged axis to the lateral edges of the rhombohedron, as in figure 42, the scalenohedron is constructed. Hence it is designated by mR^n , the n being written on the right hand, like an algebraic exponent: and the dihexagonal prism is in like manner designated by ∞R^n .

Fig. 42.

The combinations of rhombohedral forms are very numerous, some hundreds being described in calc-spar alone. Among the more common is the prism in combination with a rhombohedron, as in the twin crystal of calc-spar (fig. 43), with the sign $\infty R \cdot -\frac{1}{2}R$, the lower half being the same form with the upper, but turned round 180° . In figure 44, the rhombohedron mR has its polar edges replaced by another rhombohedron $-\frac{1}{2}mR$; and in figure 45 its lateral edges bevelled by the scalenohedron mR^n . A more com-

Mineralogy.

Fig. 43.

Fig. 44.

being $R^5(y) \cdot R^3(r) \cdot R(P) \cdot 4R(m) \cdot \infty R(c)$. Tetartohedric combinations are seen most distinctly in pure quartz or rock-

Fig. 45.

Fig. 46.

crystal, the pyramids of the first kind appearing as rhombohedrons, those of the second kind as trigonal pyramids, the dihexahedral prisms are ditrigonal prisms, and the prism $\infty P2$ as a trigonal prism. Most of these forms, however, occupy but a very subordinate place in the combinations which consist essentially of the prism ∞P , and the rhombohedron $R = \frac{P}{4}$.

4. Rhombic system.

Rhombic System.—The rhombic system is characterized by three axes, all unequal, but at right angles to each other. One of these is assumed as the chief axis, when the others are named subordinate. The plane passing through the secondary axes or the basis forms a rhomb, and from this the name is derived. This system comprises only a few varieties of forms that are essentially distinct, and its relations are consequently very simple.

The closed forms are,—(1st.) The rhombic pyramids

Fig. 47.

Fig. 48.

(figs. 47, 48), bounded by eight scalene triangles, whose lateral edges lie in one plane, and form a rhomb. They

have eight polar edges,—four acute and four more obtuse,—and four lateral edges, and six rhombic angles, the most acute at the extremities of the longest axis. (2d.) The rhombic sphenoids (fig. 49) are bounded by four scalene triangles with their lateral edges not in one plane; and are a hemihedric form of the rhombic pyramid of unfrequent occurrence. The open forms again are, (3d.) Rhombic prisms bounded by four planes parallel to one of the axes which is indefinitely extended. They are divided into upright and horizontal prisms, according as either the principal or one of the lateral axes is supposed to become infinite. For the latter form the name *doma* or *dome* has been used; and two kinds, the *macrodoma* and the *brachydoma*, have been distinguished. Rhombic pinacoids also arise when one axis becomes $=0$, and the two others are indefinitely extended.

Fig. 49.

In deriving these forms from a primary, a particular rhombic pyramid P is chosen, and its dimensions determined either from the angular measurement of two of its edges, or by the linear proportion of its axes $a:b:c$; the greater lateral axis b being assumed equal to 1. To the greater lateral axis the name *macrodiagonal* is frequently given; to the shorter, that of *brachydiagonal*; and the two principal sections are in like manner named *macrodiagonal* and *brachydiagonal*, according to the axis they intersect. The same terms are applied throughout all the derived forms, where they consequently mark only the position of the faces in respect to the axes of the fundamental crystal, without reference to the relative magnitude of the derived axes.

By multiplying the principal axis by any rational number m , greater or less than 1, a series of pyramids arise, whose general sign is mP , and their limits the prism and pinacoid, the whole series being contained in this formula, $0P \text{ --- } mP \text{ --- } P \text{ --- } \infty P$; which is the fundamental series, the lateral axes always remaining unchanged. From each member a new series may, however, be developed in two directions by increasing one or other of the lateral axes.

When the *macrodiagonal* is thus multiplied by any number n greater than 1, and planes drawn from the distance n to the polar edges, a new pyramid is produced, named a *macropyramid*, with the sign $m\bar{P}n$, the mark over the P pointing out the axis enlarged. When $n=\infty$ a *macrodoma* results, with the sign $m\bar{P}\infty$. If the shorter axis is multiplied, then *brachypyramids* and *brachydomes* are produced with the signs mPn and $mP\infty$. So also from the prism ∞P , on the one side, numerous *macroprisms* $\infty\bar{P}n$, with the limiting ma-

Fig. 50.

Fig. 51.

Mineralogy.

cropinacoid $\infty P\infty$; on the other, numerous brachyprisms ∞Pn , with the limit form $\infty P\infty$, or the brachypinacoid. In figs. 50, 51, the two domes are shown in their relation to the primitive pyramid.

The pyramids seldom occur independent, or even as the predominant forms in a combination,—sulphur, however, being an exception. Prisms or pinacoids usually give the general character to the crystal, which then appears either in a columnar or tabular, or even in a rectangular pyramidal form. The determination of the position of these crystals,

Fig. 52.

Fig. 53.

Fig. 54.

as vertical or horizontal, depends on the choice of the chief axis of the fundamental form. In the topaz crystal (fig. 52) the brachyprism and the pyramid are the predominant elements, associated with the prism, its sign and letters being $\infty P2(l) \cdot P(o) \cdot \infty P(m)$. Fig. 53 of stilbite is another example, the macro-pinacoid $\infty P\infty$ or M , being combined with the pyramid $P(r)$, the brachypinacoid $\infty P\infty$ (T), and the basal pinacoid $OP(P)$. Another instance is fig. 54 of a lievrite crystal, where the brachyprism and pyramid combine with the macro-dome, or $\infty P2 \cdot P \cdot P\infty$. The following figures are very common forms of barytes; figs. 55 and 56 being both composed of the pinacoid, a brachy-dome and macrodome with sign $OP(c) \cdot P\infty(f) \cdot \frac{1}{2}P\infty(d)$, the variation in aspect arising from the predominance of different faces; and fig. 57 consisting of the macrodome $\frac{1}{2}P\infty$, the prism $\infty P(g)$, and the pinacoid OP .

Fig. 55.

Fig. 56.

Fig. 57.

5. Monoclinohedric system.

The Monoclinohedric System.—This system is characterized by three unequal axes, two of which intersect each other at an oblique angle, and are cut by the third at right angles. One of the oblique axes is chosen as the chief axis, and the other axes are then distinguished as the orthodiagonal (right-angled), and clinodiagonal (oblique-angled). The same terms are applied to the chief sections, and the name of the system refers to the fact that these two planes and the base, together with two right angles, form also one oblique angle C .

The forms of this system approach very near to those of the rhombic series, but the inclination of the axes, even when almost a right angle, gives them a peculiar character, by which they are always readily distinguished. Each pyramid thus separates into two altogether independent forms or hemipyramids. Three varieties of prism also occur—verti-

cal, inclined, and horizontal—with faces parallel to the chief axis, the clinodiagonal or the orthodiagonal. The horizontal prisms, like the pyramids, separate into two independent partial forms, named hemiprisms or hemidomes. The inclined prisms are often designated clinodomes, the term prism being restricted to the vertical forms. Orthopinacoids and clinopinacoids are also distinguished from their position in relation to the axes.

The monoclinohedric pyramids (fig. 58) are bounded by eight scalene triangles of two kinds, four and four only being similar. Their lateral edges lie all in one plane, and the similar triangles are placed in pairs on the clinodiagonal polar edges. The two pairs in the acute angle between the orthodiagonal and basal section are designated the positive hemipyramid; whilst the two pairs in the obtuse angles of the same sections form together the negative hemipyramid. But as these hemipyramids are wholly independent of each other, they are rarely observed combined. More frequently each occurs alone, and then forms a prism-like figure, with faces parallel to the polar edges, and open at the extremities. Hence, like all prisms, they can only appear in combination with other forms. The vertical prisms are bounded by four equal faces parallel to the principal axis, and the cross section is a rhomb; the clinodomes have a similar form and section; whilst the horizontal prisms or domes have unequal faces, and their section is a rhomboid.

Fig. 58.

The mode of derivation of these forms closely resembles that of the rhombic series. A complete pyramid is assumed as the fundamental form, and designated $\pm P$, in order to express the two portions of which it consists. Its dimensions are given when the proportion of its axes $a : b : c$, and the angular inclination of the oblique axes C , which is also that of the orthodiagonal section to the basis, are known. The fundamental series of forms is, $OP \dots \pm mP \dots \pm P \dots \pm mP \dots \infty P$; from each of whose members, by changing the dimensions of the other axes, new forms may be again derived. Thus from $\pm mP$, by multiplying the orthodiagonal by any number n , a series of orthopyramids $\pm mPn$ is produced, with the orthodomes $\pm mP\infty$ as limiting forms. The clinodiagonal produces a similar series, distinguished from the former by the sign being put in brackets, thus, $\pm (mPn)$, with the limiting clinodome ($mP\infty$) always completely formed, and therefore without the signs \pm attached. From ∞P arise orthoprisms ∞Pn , and the orthopinacoid $\infty P\infty$; and clinoprisms (∞Pn), and the clinopinacoid ($\infty P\infty$).

The combinations of this system may be easily understood from their resemblance to those of the rhombic; the

Fig. 59.

Fig. 60.

chief difficulty being in the occurrence of partial forms,

Mineralogy.

Mineralogy.

which, however, closely resemble the hemihedric forms of the previous systems. We shall therefore only select a few examples frequently observed in the mineral kingdom. Fig. 59 represents a very common form of gypsum crystals ($\infty P\infty$) (P). $\infty P(f)$. $P(b)$. The most common form of augite is represented in fig. 60, with the sign $\infty P(m)$. $\infty P\infty(r)$. ($\infty P\infty$) (l). $P(s)$. Fig. 61 is a crystal of common felspar or orthoclase, composed of the clinopinacoid ($\infty P\infty$) (M), the prism $\infty P(T)$, the basal pinacoid OP (P), and the hemidomes $2P\infty(y)$: to which, in fig. 62 of

cimens, we may notice the albite crystal (fig. 64), in which

Mineralogy.

Fig. 61.

Fig. 62.

the same mineral, the hemipyramid $P(o)$, and the clino-dome ($2P\infty$) (n), are added.

6. Triclinohedric system.

Triclinohedric System.—This is the least regular of all the systems, and departs the most widely from symmetry of form. The axes are all unequal, and inclined at angles none of which are right angles, so that to determine any crystal or series of forms the proportion of the axes $a : b : c$, and also their angles, or those of the inclination of the chief sections, must be known. As in the previous system, one axis is chosen as the principal axis, and the two others distinguished as the macrodiagonal and brachydiagonal axes. In consequence of the oblique position of the principal sections, this system consists entirely of partial forms wholly independent on each other, and each composed only of two parallel faces. The complete pyramid is thus broken up into four distinct quarter pyramids, and the prism into two hemiprisms. Each of these partial forms is thus nothing more than a pair of parallel planes, and the various forms consequently mere individual faces. This circumstance renders many triclinohedric crystals very unsymmetrical in appearance.

Triclinohedric pyramids (fig. 63) are bounded by eight triangles, whose lateral edges lie in one plane. They are equal and parallel two and two to each other; each pair forming, as just stated, a tetartopyramid or open form, only limited by combination with other forms, or, as we may suppose, by the chief sections. The prisms are again either vertical or inclined; the latter named domes, and their section is always rhomboidal. In deriving the forms, the fundamental pyramid is placed upright with its brachydiagonal axis to the spectator, and the partial forms designated, the two upper by P and P' , the two lower by P and P' , as in the figure. The further derivation now follows as in the rhombic system, with the modifications already mentioned, so that we need not delay on it longer, especially as the minerals crystallizing in these forms are not numerous.

Fig. 63.

Some combinations of this system, as the series exhibited by most of the felspars, approach very near to the monoclinohedric system; whilst others, as the blue copper, or vitriol, and axinite, show great incompleteness and want of symmetry. In the latter case the determination of the forms is often difficult and requires great attention. As spe-

Fig. 64.

P is the basal pinacoid OP , M the brachydiagonal pinacoid $\infty P\infty$, s the upper right pyramid P' , l the right hemiprism $\infty P'$, T the left hemiprism ∞P , and x the hemidome $P'\infty$. Figures 65 and 66 are crystals of axinite, the

former from Dauphiné, the latter very common in Cornwall, of whose faces the following is the development,— r the macropinacoid $\infty P\infty$; P the left hemiprism ∞P ; u the left upper quarter pyramid P' ; l the left upper quarter pyramid $2P'$; s the left upper partial form of the macro-pyramid $3P'3$, and x the hemidome $2P'\infty$.

Imperfections of Crystals.

In the foregoing description of the forms of crystals the planes have been supposed smooth and even, the faces equal and uniform, or at the same distance from the centre or point of intersection of the axes, and each crystal also perfect or fully formed and complete on every side. In nature, however, these conditions are rarely if ever realized, and the edges of crystals are seldom straight lines, or the faces mathematical plane surfaces. A very interesting variety of these irregularities, which pervades all the systems except the tesseral, is named *hemimorphism*. In this the crystals are bounded on the opposite ends of their chief axis by faces belonging to distinct forms, and hence only the upper or under half of each form is produced, or the crystal, as the name implies, is half-formed. Figure 67 represents a common variety of tourmaline, bounded on the

Fig. 67.

Fig. 68.

upper end by the planes of the rhombohedrons R and $-2R$, and on the lower end by the basal pinacoid. In fig. 68 of electric calamine the upper extremity shows the basis k ,

Mineralogy.

two brachydomes *o* and *p*; and two macrodomes *m* and *l*; whilst on the lower end it is bounded by the faces *P* of the primary form. This appearance becomes more interesting from the fact, that most hemimorphic crystals acquire polar electricity from heat,—that is, exhibit opposite kinds of electricity at opposite ends of the crystal.

The faces of crystals are very frequently rendered imperfect by *striae* or minute linear and parallel elevations and depressions. These arise in the oscillatory combination of two crystal forms, alternately prevailing through small spaces. The *striae*, therefore, are in reality the edges of combined forms. They are very common on quartz, shorl, and some other minerals; and frequently indicate combinations where only a simple form would otherwise appear to exist. The cubes and pentagonal dodecahedrons of iron pyrites are frequently striated, and in three directions at right angles to each other. In calc-spar the faces of the rhombohedron, $-\frac{1}{2}R$ (*g* in fig. 43 above) are almost never without *striae* parallel to the oblique diagonal. The striation is said to be simple when only one series of parallel lines appears on each face, or feathered when two systems diverge from a common line. In other crystals the faces, then said to be *drusy*, are covered by numerous projecting angles of smaller crystals; an imperfection often seen in fluor spar. The faces of crystals occasionally appear curved either as in tourmaline and beryl from the peculiar oscillatory combination mentioned, or by the union of several crystals at obtuse angles, like stones in a vault, as in stilbite and prehnite. A true curvature of the faces probably occurs in the saddle-shaped rhombohedrons of brown spar and iron spar, in the lens-like crystals of gypsum, and in the curved faces so common on diamond crystals. In chabazite similar curved faces occur, but concave. In galena and augite the crystals are often rounded on the corners as if by an incipient state of fusion. On other crystals the faces are rendered uneven from inequalities following no certain rule. These imperfections furnish valuable assistance in developing very complex combinations, all the faces of each individual form being distinguished by the same peculiarity of surface.

Irregularities in the forms of crystals are produced when the corresponding faces are placed at unequal distances from the centre, and consequently differ in form and size. Thus the cubes and octahedrons of iron pyrites, galena, and fluor spar, are often lengthened along one axis. Quartz is subject to many such irregularities, which are seen in a very remarkable manner on the beautiful transparent and sharply angular crystals from Dauphiné. In such irregular forms, instead of one line, the axes are then represented by an infinite number of lines, parallel to the ideal axis of the figure. The same irregularity carried to a greater extent frequently causes certain faces required for the symmetry of the form, altogether to disappear. Again, some crystals do not fill the space marked out by their outline, holes and vacancies being left in the faces, occasionally to such an extent that they seem little more than mere skeletons. This appearance is very common on crystals produced artificially, as in common salt, alum, bismuth, silver, &c. A perfect crystal can only be produced when during its formation it is completely isolated, so as to have full room to expand on every side. Hence the most perfect crystals have been originally imbedded singly in some uniform rock mass. Next to them in perfection are forms that grow singly on the surface of some mass of similar or distinct composition, especially when the point of adherence is small. An incompleteness of form, or at least a difficulty in determining it, arises from the minuteness of some crystals, or from their contracted dimensions in certain directions. Thus some appear mere tabular, or lamellar planes, whilst others run out into acicular, needle-shaped, or capillary crystals. Amid all these modifications of the general

Mineralogy.

form of the crystal, of the condition and aspect of its individual faces, or of its linear dimensions, one important element, the angular measurement, remains constant. In some monoaxial crystals, indeed, increase of temperature produces an unequal expansion in different directions, slightly changing the relative inclination of the faces, but so small as to be scarcely perceptible in common measurements, and hence producing no ambiguity. More important are the angular changes which in many species accompany slight changes in chemical composition, particularly in the relative proportions of certain isomorphous elements. But notwithstanding these limitations of the great truth of the permanence of the angular dimensions of crystals, announced by Romé de l'Isle, remains unaffected; only, as Mohs well states, it must not be interpreted with a rigid immutability, inconsistent with the whole analogy of other parts of nature.

The Goniometer and Measurement of Crystals.

The fact just stated of the permanence of the angular dimensions of crystals shows the importance of some accurate method of measuring their angles; that is, the inclination of two faces to each other. Two instruments have been specially used for this purpose,—the common or contact goniometer, invented by Carangeau, and the reflecting goniometer of Wollaston. The former is simply two brass rulers turning on a common centre, between which the crystal is so placed that its faces coincide with the edges of the rulers, and the angle is then measured on a graduated arc. This instrument is sufficiently accurate for many purposes and for large crystals; but for precise determination is far inferior to the reflecting goniometer. This requires smooth and even faces, but these may be very small, even the hundredth of an inch, in skilful hands; and as small crystals are generally most perfect, far greater accuracy can be attained, and the measurement depended on to one minute ($1'$).

The reflecting goniometer is represented in the annexed figure. It consists essentially of a graduated circle *mm*, divided on its edge into twice 180° , or more often into half degrees, the minutes being read off by the vernier *hh*. This circle turns on an axis connected with *tt*, so that by turning this the circle is moved round, but is stopped at 180° , when moving in one direction, by a spring at *h*. The other part of the instrument is intended to attach and adjust the crystal to be measured. The first axis of *mm* is hollow, and a second axis, *aa*, passes through it from *ss*, so that this and all the connected parts from *b* to *f* can be turned without moving the circle *mm*. The axis *d* passes through a hole in *bc*, so that it can turn the arm *de* into any required position; *f* is a similar axis turning the arm *og*; and *pg* a fourth axis, in like manner moveable in *g*, and with a small knob at *q*, to which the crystal to be measured is attached.

When about to use the instrument it should be placed

Fig. 69.

Mineralogy.

on a table, with its base horizontal, which is readily done by the screws in it, and opposite to a window at about 12 or 15 feet distance, so that its axis shall be parallel to the horizontal bars of the window. One of the upper bars of the window, and also the lower bar, or, instead of the latter, a white line on the floor or table parallel to the window, should then be chosen in order to adjust the crystal. The observer places himself behind the instrument with the side *a* at his right hand. The crystal is then attached to *q* by a piece of wax with the two faces to be measured upwards. The axis *fo* is made parallel to *aa*; and the eye being brought near to the first face of the crystal, the axes *aa* and *p* are turned till the image of the window is seen reflected in the face with the horizontal and vertical bars in their position. The axis *d* is then turned through a considerable angle (say 60°), and the image of the window again sought and brought into its proper place by turning the axis *f*, without moving *p*. When this is done that face is brought into its true position, normal to *d*, so that no motion of *d* can disarrange it. Hence the image of the window may now be sought in the second face and brought into its true position, with the horizontal bars seen horizontal, by moving the axes *d* and *a*. When this is done the crystal is properly adjusted, and the angle is thus measured. First bring the zero of the circle and vernier to coincide, and then turn the inner axis *a* or *ss*, and move the eye till the image of the upper bar of the window reflected from the more distant face of the crystal coincides with the lower bar or horizontal line seen directly. Keeping the eye in its place, turn the outer axis *tt* till the reflected image of the upper bar in the other face in like manner coincides with the lower line, and the angle of the two faces is then read off on the divided circle. As the angle measured is not directly that of the faces, but of the rays of light reflected from them, or the difference of the angle wanted from 180° , the circle has the degrees numbered in the reverse direction, so as to give the angle without the trouble of subtracting the one from the other.

The above apparatus for adjusting the crystal is an improvement suggested by Naumann. In the original instrument the axis *fo* was made to push in or out in a sheath, and had a small brass plate, bent at right angles, inserted in a cleft at *o*, to which the crystal was attached. The crystal was adjusted, as formerly, by moving the plate, or the axis *fo*, and by slight motion of the arm *de*, which should be at right angles nearly to *bc* when used. A considerable improvement is, to have a small mirror fixed on the stand below the crystal, with its face parallel to the axis *aa*, and inclined at 45° to the window, when the lower line can be dispensed with, and the instrument used for various other purposes of angular measurement. Many alterations have been suggested for the purpose of insuring greater accuracy; but the simple instrument is sufficient for all purposes of determinative mineralogy, and the error from the instrument will in most cases be less than the actual variations in the dimensions of the crystals. Greater simplicity is indeed rather desirable, and the student will often find it sufficient to attach the crystal by a piece of wax to the axis *a* directly, and give it the further adjustment by the hand. The only use of the parts from *b* to *q* is to enable the observer to place the crystal properly; that is, with the edge to be measured parallel to the axis of the instrument, and as nearly as possible coinciding with its centre. This is effected when the reflection of the horizontal bar in the two faces appears parallel to that edge.

Macles or Twin Crystals.

When two similar crystals of a mineral species are united with their similar faces and axes parallel, the one forms merely a continuation or enlargement of the other, and

every crystal may be regarded as thus built up of a number of smaller crystals. Frequently, however, crystals are united according to precise laws, though all their similar faces and axes are not parallel, and then are named macles or twin crystals. In one class of macles the axes of the two crystals are parallel, and in another they are inclined. The former only occur among hemihedric forms, and the two crystals are then combined in the exact position in which they would be derived from or reproduce the primary holohedric form. The second class, with oblique axes, occur both in holohedric and hemihedric forms, and the two individuals are placed in perfect symmetry to each other, in reference to a particular face of the crystal which forms the plane of union or the equator of the macle. We may also suppose the two crystals originally parallel, and the one turned round the normal of the united faces by 180° (often 90° or 60°), whilst the other is stationary. Or we may suppose a crystal cut into halves in a particular direction, and one-half turned 180° on the other; and hence the name of hemitrope given to them by Hauy. The position of the two individuals in this case corresponds with that of an object and its image in a mirror, whose surface then represents the plane of union.

The manner in which the crystals unite also differs. Some are merely opposed or in simple contact; others are, as it were, grown together, and mutually interpenetrate, occasionally so completely as to appear like one individual. The twin edges and angles in which the two unite are often re-entering; or they may coincide in one plane, when the line of union is either imperceptible, or is only marked by the meeting of two systems of striæ, or other diversity in the physical characters of the two faces.

The formation of twin crystals may be again repeated, forming groups of three, four, or more. When the faces of union are parallel to each other, the crystals form rows of indeterminate extent; where they are not parallel, they may return into each other in circles, or form bouquet-like or other groups. Where crystals are merely in juxtaposition, they are sometimes much shortened in the direction of the twin axis; and where many occur in a series with parallel position, are often compressed into very thin plates, frequently not thicker than paper, giving to the surface of the aggregate a peculiar striated aspect.

Only a few twin crystals in the different systems can be

Fig. 70.

Fig. 71.

noticed, chiefly as examples of this mode of formation. In

Fig. 72.

Fig. 73.

the tesseral system forms that unite with parallel axes pro-

Mineralogy.

Mineralogy.

duce intersecting macles like the pentagonal dodecahedrons of iron pyrites in fig. 70, and the tetrahedrons of grey-copper or fahlore in fig. 71, a similar formation also occurring in the diamond. In macles with inclined axes the two forms almost always unite by a face of the octahedron, and the two individuals are then generally apposed and shortened in the direction of the twin axis by one-half, so that they appear like a crystal that has been divided by a plane parallel to one of its faces, and the two halves turned round on each other by an angle of 180° . In this manner two octahedrons of the spinel, magnetic iron ore, or automolite (fig. 72), are frequently united. The same law prevails in the intersecting cubes of fluor spar, iron pyrites, and galena, represented in fig. 73. In fig. 74 of zinc-blende two rhombic dodecahedrons are united by a face of the octahedron.

In the tetragonal system twin crystals with parallel axes rarely occur, but are seen in copper pyrites, and one or two other minerals. Where the axes are inclined the plane of union is very often one of the faces of the pyramid $P\infty$, or one of those faces that would regularly replace the polar edges of the fundamental form P . The crystals of tin ore obey this law, as seen in fig. 75, where the individuals are pyramidal, and in the knee-shaped crystal (fig. 76), where they are more pris-

Fig. 75.

Fig. 76.

matic. Hausmanite appears like fig. 77, in which the fundamental pyramid P prevails, on whose polar edges other crystals are often very symmetrically repeated, a central individual appearing like the support of all the others. Almost identical forms occur in copper pyrites.

Fig. 77.

In the hexagonal system twin crystals with parallel axes are common, as in calc-spar, chabazite, hæmatite, and other rhombohedral minerals. In calc-spar they often form very regular crystals, the two individuals uniting by a plane parallel to the base, so as to appear like a single crystal, as in fig. 78, where each end shows the forms ∞R . $-\frac{1}{2}R$, but in a complementary position; or in fig. 79 of two scalenohedrons R^3 from Derbyshire. The rhombohedral crystals of chabazite often appear intersecting each other, like those of fluor spar in fig. 73 above. The purer varieties of quartz or rock-crystal, in consequence of the tetartohedral character of its crystallization, often exhibit twins. In these the pyramid P separates into two rhombohedrons P and r , which though geometrically similar, are yet physically distinct. In fig. 80 the two individuals are only grown together, but more commonly they penetrate each other in an irregular manner, forming apparently a single crystal. Twins with oblique axes are also

common, the plane of union being usually one face of the rhombohedron. Thus in calc-spar two rhombohedrons

Mineralogy.

Fig. 78.

Fig. 79.

Fig. 80.

are often joined by a face of $-\frac{1}{2}R$, the two axes forming an angle of $127^\circ 34'$; occasionally a third individual is interposed in a lamellar form, as in fig. 81, when the two outer crystals become parallel. This latter arrangement is very common in the highly cleavable varieties of Iceland spar. When the crystals unite in a face of the rhombohedron R , fig. 82, they form an angle of $89^\circ 8'$, differing

Fig. 81.

Fig. 82.

little from a right angle, by which the occurrence of this law is very easily recognised, especially in prismatic varieties.

In the rhombic system twin crystals with parallel axes are very rare, but those with oblique axes common, the plane of union being one of the faces of the prism ∞P . Twins of this kind are very distinctly seen in arragonite, carbonate of lead, marcasite, stephanite, mispickel, and other minerals. In arragonite the crystals partly interpenetrate, partly are in mere juxtaposition, as in fig. 83, where the individuals are formed by the combination $\infty P(m) \cdot \infty P(h)$, $\bar{P}\infty(h)$, and in figure 84 where several crystals of the same combination form a series with parallel planes of union; the inner members being so shortened that they appear like mere lamellar plates producing striæ on the faces $\bar{P}\infty$ and $\infty \bar{P}\infty$ of the macle. In fig. 85 four crys-

Fig. 83.

Fig. 84.

Fig. 85.

tals, each of the combination $\infty P \cdot 2\bar{P}\infty$, having united in inclined planes, form a circular group, returning into itself. The carbonate of lead often occurs in macles in all respects similar. In staurolite, individuals of the prismatic combination $\infty P \cdot \infty \bar{P}\infty \cdot 0P'$ combine either, as in fig. 86, by a face of the brachydome $\frac{2}{3}\bar{P}\infty$, with their chief axes almost at right angles; or, as in fig. 87, by a face of the brachypy-

ramid $\frac{2}{3}\bar{P}_2$, the chief axes and the brachypinacoids (*o*) of the two single crystals meeting at an angle of about 60°.

Minera-
logy.

Fig. 86.

Fig. 87.

Fig. 92.

' $P\infty$, or x and x' ') are a very characteristic appearance, marking out this mineral at once as a triclinohedric species. Usually the twin formation is repeated, three or more crystals being combined, when those in the centre are reduced to mere plates. When very numerous, the surfaces P and x are covered with fine striae, often only perceptible with a microscope. A second law observed in triclinohedric feldspars, particularly the albite and labradorite, is that the twin axis corresponds with that normal of the brachydiagonal, which is situated in the plane of the base. In pericline, a variety of albite, these twins appear as in fig. 93, where the two crystals are united by a face of the basal pinacoid P , whilst the faces of the two brachypinacoids (M and M') form edges with very obtuse angles ($173^{\circ} 22'$), re-entering on the one side and salient on the other. These edges, or the line of junction between M and M' , are also parallel to the edges formed by these faces and the base, or those between M and P . In this case also the macles are occasionally several times repeated when the faces appear covered with fine striae.

Fig. 88.

Fig. 89.

Fig. 90.

Fig. 9l.

In the triclinohedric system some twin formations are of great importance as a means of distinguishing the triclinohedric from the monoclinohedric species of feldspar. In one variety the twin axis is the normal to the brachydiagonal

Irregular Aggregation of Crystals.

Besides the regular unions now described crystals are often aggregated in peculiar ways, to which no fixed law can be assigned. Thus some crystals, apparently simple, are composed of concentric crusts or shells, which may be removed one after the other, always leaving a smaller crystal like a kernel, with smooth distinct faces. Some specimens of quartz from Beeralston in Devonshire consist apparently of hollow hexagonal pyramids placed one within another. Other minerals, as fluor spar, apatite, heavy spar, and calc-spar, exhibited a similar structure by bands of different colours.

Many large crystals, again, appear like an aggregate of numerous small crystals, partly of the same, partly of different forms. Thus some octahedrons of fluor spar from Schlaggenwald are made up of small dark violet-blue cubes, whose projecting angles give a drusy character to the faces of the larger form. Such polysynthetic crystals, as they may be called, are very common in calc-spar.

A similar, but still more remarkable formation, is where two crystals of distinct species are conjoined. Such unions of cyanite and staurolite have been long well known, and the graphic-granite exhibits a similar union between large feldspar crystals and many smaller ones of mica and quartz.

Forms of Crystalline Aggregates.—Crystals have often

Minera-
logy.

been produced under conditions preventing the free development of their forms. They then compose crystalline aggregates, of which the following may be distinguished:—*Granular*, formed of grains, generally angular, but rarely rounded or flattened. *Lamellar* consist of broad plates, which are *tabular* when of uniform thickness, *lenticular* when becoming thinner on the edges, *wedge-shaped* when sharpened towards one edge, and *scaly* when the plates are very small. *Columnar*, in which the individuals are drawn out in one direction more than in the others; *bacillary* or rod-like, in which the columns are of uniform thickness; *acicular* or needle-shaped, in which they are pointed; and *fibrous*, in which they are very fine. In the broad-columnar the columns are, as it were, compressed, or broader in one direction than the other. The distinctions of large, coarse, small, or fine-granular; thick or thin scaly; straight, curved, or twisted-columnar; parallel, diverging, or confused-fibrous; and such like, are easily understood.

Aggregates which have been able to crystallize, at least, with a certain degree of freedom, have been distinguished by Mohs into crystal groups and druses; the former including all unions of several imbedded crystals; the latter those of crystals that have grown together on a common support. In the groups crystals with their faces otherwise perfect are conjoined in various ways. Sometimes they radiate, as it were, from a common centre, and produce spheroidal, ellipsoidal, or other forms, frequent in gypsum, iron pyrites, and other minerals imbedded in clay. Where many such masses are united, they are named *botryoidal* when like bunches of grapes, *mammellated* where the spheres are larger and less distinct, and *reniform* or kidney-shaped where the masses are still larger. Some groups are partially attached by a small point; but the mass is generally free.

Crystals are often grouped in rows or in one direction, forming, when they are very small, capillary or hair-like, and filiform, thread, or wire-like forms, which are common among native metals, as gold, silver, copper, and bismuth, in silver glance and a few other minerals. Sometimes the masses are dentiform, consisting of portions resembling teeth; as is very common in silver. Often these groups expand in several directions, and produce arborescent, dendritic, foliated, feathered, or other forms, very common in copper. In these groups, however, a certain dependence on the crystallographic character of the species may be observed. The lamellar minerals often form fan-shaped, wheel-like, almond-shaped, comb-like, or other groups. The fibrous types, again, are disposed in parallel or diverging bundles, or in radiating, stellar, and other masses. Coral-oidal (like coral), fruticose (like cauliflower), and other forms, have also been observed.

In druses, many crystals rise side by side from a common support; sometimes only the granular mass composed of their united bases, at other times some distinct body. The form of a druse is determined by that of the surface on which it grows, and consequently is often very irregular or wholly accidental. Where completely inclosed they have been named drusy cavities, and when of a spheroidal form, geodes. A drusy crust, again, consists of a thin layer of small crystals investing the surface of a large crystal or of some other body.

The minute or cryptocrystalline minerals form similar aggregates. In the globular or the oolitic the minute crystals often appear to radiate from a centre, or form concentric crusts. Somewhat similar are the stalactites and stalagmites, in which the mineral, especially rock-salt, limestone, chalcedony, opal, limonite, has been deposited from a fluid dropping slowly from some overhanging body. In this case the principal axis of the figure, generally a hollow tube, is vertical, whilst the individual parts are arranged at right angles to this direction. In other cases the mineral

has apparently been deposited from a fluid mass moving slowly in a particular direction, which may be regarded as the chief axis of the figure, whilst the axes of the individual crystals may assume a different position.

By far the largest masses of the mineral kingdom have, however, been produced under conditions in which a free development of their forms was excluded. This has been the case with the greater portion of the minerals composing rocks or filling veins and dykes. The structure of these masses on the large scale belongs to geology, but some varieties of the texture visible even in hand specimens may be noticed. The individual grains or masses have seldom any regular form, but appear round, long, or flat, according to circumstances, and as each has been more or less checked in the process of formation. Even then, however, a certain regularity in the position of the parts is often observable, as in granite, in which the cleavage planes, and consequently the axes of the felspar crystals, are parallel. Where these grains are all pretty similar in size and shape, the rock is named massive when they are small, or granular when they are larger and more distinct. Sometimes the rock becomes slaty, dividing into thin plates; or concretionary, forming roundish masses; at other times the interposition of some foreign substance (gas or vapour) has rendered it porous, cellular or vesicular, giving rise to drusy cavities. These cavities are often empty, but have occasionally been filled by other minerals, when the rock is named amygdaloidal, from the almond-like shape of the inclosed masses.

Many of the above external forms appear also in the amorphous solid minerals, in which no trace of individual parts, and consequently of internal structure, is observable. They are not unfrequently disposed in parallel or concentric layers, of uniform or distinct colours; and may assume spherical, cylindrical, stalactitic, and other appearances.

Pseudomorphism.—When the substance of one mineral assumes the external form of some other mineral it is named a pseudomorph. In some named incrusting pseudomorphs the original crystal is covered by a rough or drusy surface of the second mineral, frequently not thicker than paper. Occasionally the first crystal has been removed, and nothing but the shell remains; or the cavity has been filled by a distinct mineral species, or a crystalloid, as it may be named, forming an exact representation of the original, but of a different substance.

More commonly the new mineral substance has gradually expelled the old, and replacing it, as it were, atom by atom, has assumed its exact form. In other cases not the whole substance of the original crystal, but only one or more of its elements, has been changed, or the whole matter has remained, but in a new condition. Thus arragonite crystals have been converted into calc-spar, the chemical composition of both being identical; or gaylussite has been changed into calc-spar, andalusite into cyanite, by the loss of certain elements. On the other hand, anhydrite becomes gypsum, red-copper-ore malachite, by addition of new matter. Or the elements are partially changed, as felspar into kaolin, quartz or pearl spar into talc, iron pyrites or iron glance into brown-iron ore, azurite into malachite, augite into green earth. The true nature of such bodies is shown by the internal structure, having no relation to the external form or apparent system of crystallization.

The process of petrification of organic bodies is in reality a species of pseudomorphic formation, and has been produced in all the above modes. External and internal casts of organic bodies are not uncommon. In other cases the original substance has been replaced by some mineral which has preserved not merely the external form, but even the minutest detail of internal structure; so that the different kinds of wood have been distinguished in their silicified trunks. The most common petrifying substances are silica and carbonate of lime. In encrynites, echinites, belem-

Minera-
logy.

Mineralogy.

nites, and other fossils, the crystals of calc-spar often occur in very regular positions. In some varieties of petrified wood both the ligneous structure and the cleavage of the calc-spar are observable.

Different from the above are mineralized bodies, in which the original structure is still retained, but their chemical nature partially changed. In these a complete series may be often traced, as from wood or peat, through the varieties of brown coal, common coal, anthracite, and graphite, perhaps even to the diamond.

CHAP. II.—PHYSICAL PROPERTIES OF MINERALS.

The physical characters of minerals comprehend,—1st. Those properties derived from the nature of the substance itself, as coherence, mode of fracture, elasticity, and density or specific gravity. 2d. Those phenomena called forth in minerals by the influence of some external power or agent, as their optical, electric, or thermal relations; and, 3d. Other characters depending on the personal sensation of the observer, on his taste, smell, and touch. All these properties furnish useful characters in distinguishing and describing mineral species.

Cleavage and Fracture.

In many species there are certain planes at right angles to which cohesion seems to be at a minimum, so that the mineral separates along or parallel to these planes far more readily than in any other direction. This property is named cleavage, and these planes cleavage-planes. They have a strictly definite position, and do not show any transition or gradual passage into the greater coherence in other directions. The number of these parallel cleavage-planes is altogether indefinite; so that the only limit that can be assigned to the divisibility of some minerals, as gypsum and mica, arises from the coarseness of our instruments.

These minima of coherence or cleavage-planes are always parallel to some face of the crystal, and similar equal minima occur parallel to every other face of the same form. Hence they are always equal in number to the faces of the form, and the figures produced by cleavage agree in every point with true crystals, except that they are artificial. They are thus most simply and conveniently described by the same terms and signs as the faces of crystals. Some minerals cleave in several directions parallel to the faces of different forms, but the cleavage is generally more easily obtained and more perfect in one direction than in the others. This complex cleavage is well seen in calc-spar, and fluor spar, and very remarkably in zinc-blende, where it takes place in no less than six directions. As in each of these the division may be indefinitely continued, it is clear that no lamellar structure in any proper sense can be assigned to the mineral. All that can be affirmed is, that contiguous atoms have less coherence in the normal of these planes than in other directions. When the cleavage takes place in three directions, it of course produces a perfect crystal form, from which the system of crystallization and angular dimensions of the species may be discovered, and is thus often of very great importance.

The common cleavage in the different systems is as follows, those of most frequent occurrence being put in italics:—(1.) In the tesseral, *Octahedric*, O, along the faces of the octahedron; *Hexahedric*, $\infty O\infty$, along those of the cube; and *Dodecahedric*, ∞O . (2.) In the tetragonal system, *Pyramidal*, P or $2P\infty$; *Prismatic*, ∞P or $\infty P\infty$; or *Basal*, OP. (3.) In the hexagonal system with holohedric forms, *Pyramidal*, P or P2; *Prismatic*, ∞P or $\infty P2$; or *Basal*, OP; with rhombohedral forms, *Rhombohedral*, R; *Prismatic*, ∞R ; or *Basal*, OR. (4.) In the rhombic sys-

tem, *Pyramidal*, P; *Prismatic*, ∞P ; *Makro* or *Brachydomatic*, $P\infty$ or $\bar{P}\infty$; *Basal*, OP; *Macrodiagonal*, $\infty \bar{P}\infty$; or *Brachydiagonal*, $\infty \bar{P}\infty$. (5.) In the monoclinohedric system, *Hemipyramidal*, P or $-P$; *Prismatic*, ∞P ; *Clinodomatic*, $(P\infty)$; *Hemidomatic*, $P\infty$ or $-P\infty$; *Basal*, OP; *Orthodiagonal*, $\infty P\infty$; or *Clinodiagonal*, $(\infty P\infty)$. (6.) In the triclinohedric system, *Hemiprismatic*, $\infty P'$ or $\infty \bar{P}$; *Hemidomatic* either along the macrodome or brachydome; *Basal*, OP; *Macrodiagonal*, $\infty \bar{P}\infty$; or *Brachydiagonal*, $\infty \bar{P}\infty$.

In some minerals the cleavage is readily procured; in others only with extreme difficulty. The planes produced also vary much in their degree of perfection, being *highly* perfect in some, as mica and gypsum; imperfect in others, as garnet and quartz. In a very few crystalline minerals cleavage-planes can hardly be said to exist. Cleavage must be carefully distinguished from the planes of union in twin crystals, and the division-planes in the laminar minerals.

Fracture surfaces are formed when a mineral breaks in a direction different from the cleavage-planes. They are consequently most readily observed when the cleavage is least perfect. The form of the fracture is named *conchoidal* when composed of concave and convex surfaces like shells, even when nearly free from inequalities. The character of the surface is *smooth*; or *splintery* when covered by small wedge-shaped splinters adhering by the thicker end; or *hackly* when covered by small slightly-bent inequalities, as in iron and other malleable bodies; or *earthy* when it shows only fine dust.

Hardness and Tenacity.

The hardness of minerals, or their power of resisting any attempt to separate their parts, is also an important character. As it differs considerably in the same species, according to the direction and the surface on which the trial is made, its accurate determination is difficult, and the utmost that can usually be obtained is a mere approximation found by comparing different minerals one with another. For this purpose Mohs has given the following scale:—

1. *Talc*, of a white or greenish colour.
2. *Rock-salt*, a pure cleavable variety, or semitransparent *uncrystallized gypsum*, the transparent and crystallized varieties being generally too soft.
3. *Calcareous spar*, a cleavable variety.
4. *Fluor spar*, in which the cleavage is distinct.
5. *Apatite*, the asparagus-stone, or phosphate of lime, from Saltzburg.
6. *Adularia felspar*, any cleavable variety.
7. *Rock-crystal*, a transparent variety.
8. *Prismatic topaz*, any simple variety.
9. *Corundum* from India, which affords smooth cleavage surfaces.
10. The *Diamond*.

Two other degrees are obtained by interposing foliated mica between 2 and 3, and scapolite, a crystalline variety, between 5 and 6. The former is numbered 2.5, the latter 5.5.

To ascertain the hardness of a mineral, first try which of the members of the scale is scratched by it, and in order to save the specimens, begin with the highest numbers, and proceed downwards, until reaching one which is scratched. Then take a fine hard file, and draw along its surface, with the least possible force, the specimen to be examined, and also that mineral in the scale whose hardness is immediately above the one which has been scratched. From the resistance they offer to the file, from the noise occasioned by their passing along it, and from the quantity of powder left on its surface, their relative hardness is deduced. When, after repeated trials, we are satisfied to which member of the scale of hardness the mineral is most nearly allied, we

Mineralogy.

Mineralogy.

say its hardness (suppose it to be felspar) is equal to 6, and write after it H.=6.0. If the mineral do not exactly correspond with any degree of the scale, but is found to be between two of them, it is marked by the lower with a decimal figure added. Thus, if more than 6 but less than 7, it is expressed H.=6.5. In these experiments we must be careful to employ specimens which nearly agree in form and size, and also as much as possible in the shape of their angles.

Where the scale of hardness is wanting, or for a first rough determination, the following experiments may serve:—

Every mineral that is scratched by the finger-nail has H.=2.5 or less.

Minerals that scratch copper have H.=3 or more.

Polished white iron has H.=4.5.

Window-glass has H.=5 to 5.5.

Steel point or file has H.=6 to 7.

Hence every mineral that will cut or scratch with a good pen-knife has H. less than 6.

Flint has H.=7 and only about a dozen minerals, including the precious stones or gems, are harder.

Closely allied to hardness is the **TENACITY** of minerals, of which the following varieties have been distinguished:—A mineral is said to be *brittle* when, as in quartz, on attempting to cut it with a knife, it emits a grating noise, and the particles fly away in the form of dust. It is *sectile* or *mild* when, as in galena and some varieties of mica, on cutting, the particles lose their connection in a considerable degree; but this takes place without noise, and they do not fly off, but remain on the knife. And a mineral is said to be *soft* or *ductile* when, like native gold or lead, it can be cut into slices with a knife, extended under the hammer, and drawn into wire. From tenacity it is usual to distinguish *frangibility*, or the resistance which minerals oppose when we attempt to break them into pieces or fragments. This property must not be confounded with hardness. Quartz is hard, and hornblende comparatively soft; yet the latter is more difficultly frangible than the former. *Flexibility*, again expresses the property possessed by some minerals of bending without breaking. They are *elastic*, like mica, if, when bent, they spring back again into their former direction; or merely flexible, when they can be bent in different directions without breaking, but remain in their new position, as gypsum, talc, asbestos, and all malleable minerals.

Specific Gravity.

The density or the relative weight of a mineral, compared with an equal volume of pure distilled water, is named its specific gravity. This is a most important character for distinguishing minerals, as it varies considerably in different species, and can be readily ascertained with much accuracy, and in many cases without at all injuring the specimen. The whole process consists in weighing the body, first in air, and then immersed in water, the difference in the weight being that of an equal bulk of the latter fluid. Hence, assuming, as is commonly done, the specific gravity of pure distilled water to be equal to 1 or unity, the specific gravity (G) of the other body is equal to its weight in air (*w*), divided by the loss or difference (d) of weight in water (or $G = \frac{w}{d}$).

A simple and portable instrument for finding the specific gravity is the arcometer of

Fig. 94.

Nicholson, fig. 94. A delicate hydrostatic balance gives the gravity with far more accuracy; and even a good common balance is often preferable. The mineral may be suspended from one arm or scale by a fine silk thread or hair, and its weight ascertained, first in the air, and then in water.

There are a few precautions necessary to insure accuracy. Thus, a pure specimen must be selected which is not intermixed with other substances, and when weighed in air it should be quite dry. It must also be free from cavities, and care must be taken that when weighed in water no globules of air adhere to its surface, which render it lighter. If the body imbibes moisture, it should be allowed to remain till fully saturated before determining its weight when immersed, and it is sometimes even necessary to boil the specimen in order to expel the air from its pores. Small crystals or fragments, whose freedom from mixture can be seen, are best adapted for this purpose. The specimen experimented on should not be too heavy; thirty grains being enough where the gravity is low, and even less where it is high. It is also of importance to repeat the trial, if possible with different specimens, which will show whether any cause of error exists, and to take the mean of the whole. A correction should be made for the variation of the temperature of the water from 60° Fahr., which is that usually chosen as the standard in mineralogical works. Where the difference, however, does not exceed ten or fifteen degrees this correction may be neglected, as it only affects the third or second decimal figure of the result.

Optical Properties of Minerals.

There are few more interesting departments of science than the relations of mineral bodies to light, and the modifications which it undergoes either when passing through them or when reflected from their surface. In this place, however, we can only notice these phenomena so far as they point out distinctions in the internal constitution of minerals, or furnish characters for distinguishing one species from another.

Minerals, and even different specimens of the same species, vary much in pellucidity or in the quantity of light which can pass through them. Some transmit so much light, that small objects can be clearly seen, or letters read when placed behind them, and are named *transparent*. They are *semitransparent* when the object is only seen dimly, as through a cloud; and *translucent* when the light that passes through it is so obscured that the objects can be no longer discerned. Some minerals are only thus *translucent on the thinnest edges*, and in others even these transmit no light, and the body is named *opaque* or *untransparent*. These degrees pass gradually into each other, and cannot be separated by any precise line; and this is also the case in nature, where some minerals pass through the whole scale, as quartz, from the fine transparent rock-crystal to opaque dark-black varieties. Such minerals may be described generally as *pellucid*. This change often arises from some mixture in their composition, especially of metallic substances. Perfect opacity is chiefly found in the metals or their compounds with sulphur, though even these seem to transmit light when reduced to laminæ of sufficient thinness.

Double Refraction.—When a ray of light passes obliquely from one medium into another of different density, it is bent or refracted from its former course. The line which it then follows forms an angle with the perpendicular, which in each body bears a certain proportion to that at which the ray fell upon it, or, as definitely stated, the sine of the angle of refraction has a fixed ratio to the sine of the angle of incidence, this ratio being named the index of refraction. This simple refraction is common to all trans-

Mineralogy.

Mineralogy.

parent bodies, whether crystalline, amorphous, or fluid; but some crystals produce a still more remarkable result. The ray of light which entered them as one is divided into two rays, each following different angles, or is doubly refracted. In minerals of the tesseral system this property does not exist, but it has been always observed in minerals belonging to the other systems, though in many only after they have been cut in a particular manner, or have been otherwise properly prepared. It is most distinctly seen in crystals of calc-spar, especially in the beautiful transparent variety from Iceland, in which it was first observed and described by Erasmus Bartholin in a work published at Copenhagen in 1669.

The subjoined figure will illustrate this singular property.

It represents a rhomb of Iceland spar, on the surface of which a ray of light Rr falls. As seen in the figure, this ray divides into two, one of which roo' follows the ordinary law of refraction, or the sines of the angles of incidence

and refraction maintain a constant ratio. This is named the ordinary ray O . The other, hence named the extraordinary ray E , does not obey the usual law of the sines, and has no general index of refraction. In the plane perpendicular to the axis it is most widely separated from the ordinary ray, but in others oblique to it approaches nearer to O , and in one at right angles coincides, or there is no double refraction. This plane, or rather direction, in which there is no double refraction, is named the optical axis of the crystal, or the axis of double refraction. Now, in certain minerals it is found that there is only one plane with this property, whereas in others there are two such planes, and they have in consequence been divided into monoaxial and binaxial. To the former (monoaxial) belong all crystals of the tetragonal and hexagonal systems; to the latter (binaxial) all those of the three other systems. In the former the optic axis coincides with, or is parallel to, the crystallographic chief axis. In some crystals the index of refraction for the extraordinary ray E is greater than for the ordinary ray O ; and in others it is smaller. The former are said to have positive (or attractive), the latter negative (or repulsive) double refraction. Quartz is an example of the former, the index of refraction, according to Malus, being for $O = 1.5464$, for $E = 1.5582$; and calc-spar of the latter, the index of O being 1.6543 , of $E = 1.4833$. The index of E is in both cases taken as its maximum.

It should be observed that the optic axes are not single lines, but directions parallel to a line, or innumerable parallel lines, passing through every atom of the crystal. It is also important to remark that this property divides the systems of crystallization into three precise groups,—the tesseral, with single refraction; the tetragonal and hexagonal, with double refraction, and monoaxial; the other three systems also double, but binaxial. It is therefore of use to determine the system to which a mineral belongs, but is not of great value as a character for distinguishing species.

Polarization of Light.—Intimately connected with this property is that of the polarization of light, which being more easily and precisely observable than double refraction, is in many cases of higher value as a mineralogical character. By this term is meant a peculiar modification which a ray of light undergoes, in consequence of which its capability of being transmitted or reflected towards particular sides is

either wholly or partially destroyed. Thus, if from a transparent prism of tourmaline two thin plates are cut parallel to its axis, they will transmit light, as well as the prism itself, when they are placed above each other with the chief axis of both in the same direction. But when the one slip of tourmaline is turned at right angles to the other, either no light at all or very little is transmitted, and the plates consequently appear black. Hence, in passing through the first slip the rays of light have acquired a peculiar property, which renders them incapable of being transmitted through the second, except in a parallel position, and they are then said to be polarized. The same property is acquired by a ray of light when reflected, at an angle of $35\frac{1}{2}^\circ$ (or angle of incidence $54\frac{1}{2}^\circ$), from a plate of glass, one side of which is blackened, or from some other non-metallic body. When such a ray falls on a second similar mirror at an equal angle, but so that the plane of reflection in the second is at right angles to that in the first, it is no longer reflected, but wholly absorbed. When, on the other hand, the planes of reflection are parallel, the ray is wholly and at any intermediate angle partially reflected. A ray of light polarized by reflection is also incapable of transmission through a tourmaline slip in one position, which, however, is at right angles to that in which a ray polarized by passing through another slip is not transmitted.

In order to observe the polarization of light, a very simple instrument will be found useful (fig. 96). At one end of a horizontal board B a black mirror a is fixed. In the middle is a pillar to which a tube cd is fastened, with its axis directed to the mirror at an angle of $35\frac{1}{2}^\circ$.

On the lower end is a cover c , with a small hole in the centre, and at the upper end another cover with a small black mirror m attached to it by two arms, as in the figure, and also at an angle of $35\frac{1}{2}^\circ$. With this instrument the mirror m can be so placed in relation to a that the planes of reflection shall have any desirable inclination to exhibit the simple polarization of light.

This instrument furnishes a simple test whether minerals that cleave readily into thin lamellæ are optically monoaxial or binaxial. Place the two mirrors with their polarization-planes at right angles, and fix a plate of the mineral with a little wax over the hole c , and then observe what takes place in the second mirror during the time that the cover c is turned round. If the mineral belongs to the binaxial system, the light from the first mirror a , in passing through it, is doubly refracted and has its polarization changed, and consequently can be again reflected from the second mirror m , and in each revolution of c will show four maxima and four minima of intensity. If, on the contrary, the mineral is monoaxial, the ray will pass through the lamina unaltered, and will not be reflected from the second mirror in any position of c .

Another beautiful phenomenon of polarized light, in like manner connected with the crystalline structure of minerals, is the coloured rings which laminae of the doubly-refracting species, when of a proper thickness, exhibit in certain positions. These rings are easily seen in the above apparatus by interposing a thin plate of gypsum or mica between the two mirrors. When the interposed plate belongs to a monoaxial mineral, there is seen in the second mirror a system of circular concentric coloured rings in-

Mineralogy.

Mineralogy.

intersected by a black cross (fig. 97). If the mineral is binaxial, one or two systems of elliptical coloured rings appear, each intersected by a black stripe (fig. 98). In certain cases this stripe is curved, or the two systems of rings unite in a lemniscoidal form (fig. 99). When the planes of polarization are parallel, the black cross and stripe appear white (fig. 100), showing that in this direction the crystals act like singly-refracting minerals.

Fig. 97.

Quartz, again, in close rela-

Fig. 98.

tion to its system of crystallization, exhibits a circular polarization of splendid prismatic colours, which on turning the plate change in each point in the order of the spectrum, from red to yellow, green, and blue. In order to produce these changes, however, in some specimens the plate must be turned to the right, in others to the left, showing a difference in the crystalline structure.

Fig. 99.

Fig. 100.

Pleochroism.—Closely connected with double refraction is that property of transparent minerals named pleochroism (many-coloured), in consequence of which they exhibit distinct colours when viewed by transmitted light in different directions. Crystals of the tesseral system do not show this property; whilst in those of the other systems it appears in more or less perfection; and in the tetragonal and hexagonal minerals as dichroism (two colours), in the rhombic and clinohedric systems as trichroism (three colours). In most cases these changes of colour are not very decided, and appear rather as different tints or shades than as distinct colours. The most remarkable of dichromatic minerals are the magnesian mica from Vesuvius, the tourmaline and ripidolite; of trichromatic, the iolite, the andalusite from Brazil, the diaspore from Schemnitz, and the axinite.

Some crystalline minerals exhibit a very lively play or change of colours from reflected light in certain directions. It is well seen in many various hues on the cleavage-planes of Labrador felspar, and seems produced by a multitude of very thin quadrangular pores, interposed in the mineral-like minute parallel laminae. On the cleavage-planes of the hypersthene it appears copper-red, and is occasioned by numerous small brown or black laminae of some foreign sub-

stance interposed in a parallel position between the planes of the hypersthene. The chatoyant, or changing colours of the sun-stone, arise from scales of iron glance similarly interposed. The play of colour in the noble opal seems to be produced very nearly in the same manner with that in the labradorite. A similar opalescence is seen in certain minerals when cut in particular forms. In the sapphire, cut hemispherically over the chief axis, it appears like a star with six rays; in certain varieties of chrysoberl and adularia it has a bluish tint; and is also very remarkable in the cat's-eye variety of quartz. Iridescence often arises from very fine fissures, producing semicircular arches of prismatic tints, which, like the colours of thin plates in general, are referred to the interference of light.

Mineralogy.

Lustre and Colour.

Though these properties admit of no precise or mathematical determination, they are of considerable value in mineralogy. One highly important distinction founded on them is that of minerals of metallic and non-metallic aspect or character. This distinction can hardly be described in words, and the student will best learn to distinguish metallic colours and lustre from non-metallic by observing them in nature. Transparency and opacity nearly coincide with this division, the metallic minerals being almost constantly opaque; the non-metallic more or less transparent. Minerals which are perfectly opaque, and show metallic colour and lustre, are named metallic; those with only two of these three properties, semi-metallic or metalloid; and those with the opposite properties non-metallic.

Lustre has reference to the intensity and quality of the reflected light, considered as distinct from colour. Several degrees in intensity have been named. (1.) *Splendent*, when a mineral reflects light so perfectly as to be visible at a great distance, and lively, well-defined images are formed in its faces, as galena, rock-crystal, or calc-spar. (2.) *Shining*, when the reflected light is weak, and only forms indistinct and cloudy images, as heavy spar. (3.) *Glistening*, when the reflected light is so feeble as not to be observable at a greater distance than arm's length, and the surface can no longer form an image. (4.) *Glimmering*, when the mineral held near the eye in full clear daylight presents only a number of small shining points, as red hematite and granular limestone. When, as in chalk, the lustre is so feeble as to be indiscernible, it is said to be *dull*.

In regard to the kind or quality of the lustre, the following varieties are distinguished:—(1.) The *metallic*, seen in much perfection in native metals and their compounds with sulphur, and imperfectly in glance coal. (2.) *Adamantine*, found in beautiful perfection in the diamond, and in some varieties of blende and carbonate of lead. (3.) *Vitreous* or glassy, seen in rock-crystal or common glass, or inclining to adamantine in flint-glass. (4.) *Resinous*, when the body appears as if smeared with oil, as in pitchstone and garnet. (5.) *Pearly*, like mother-of-pearl, seen in stilbite, gypsum, mica. (6.) *Silky*, the glimmering lustre seen on fine fibrous aggregates like amianthus.

Colour.—This property is not in all cases of equal value as a character. Thus some minerals are naturally coloured, showing in all modes of their occurrence one determinate colour, which is therefore essential, and forms a characteristic of the species. This class includes the metals, pyrites, blendes, with many metallic oxides and salts. A second class of minerals are colourless, their purest forms being white, or clear like water, as ice, calc-spar, quartz, adularia, and many silicates. But these minerals are occasionally coloured,—that is, accidentally tinged, sometimes from the chemical or mechanical admixture of some colouring substance, as a metallic oxide, carbon, or particles of coloured minerals; at other times from the substitution of

Mineralogy.

a coloured for an uncoloured isomorphous element. The colours of these minerals therefore vary indefinitely, and can never characterize the species, but only its varieties. Thus, quartz, calc-spar, fluor spar, gypsum, and felspar are often coloured accidentally by pigments mechanically mixed; and hornblende, augite, garnet, and other colourless silicates acquire green, brown, red, or black tints from the introduction of the isomorphous colouring elements.

Werner, who bestowed much attention on this portion of mineralogy, distinguished eight principal colours,—white, gray, black, blue, green, yellow, red, and brown,—each with several varieties or shades arising from intermixture with the other colours. He also divided them into metallic and non-metallic as follows:—

METALLIC COLOURS.

1. *White*.—(1.) Silver-white, as in leucopyrite and native silver.
- (2.) Tin-white; native antimony.
2. *Gray*.—(1.) Lead-gray; galena or lead glance.
- (2.) Steel-gray; native platina.
3. *Black*.—(1.) Iron-black; magnetite.
4. *Yellow*.—(1.) Brass-yellow; chalcopyrite.
- (2.) Bronze-yellow; iron pyrites.
- (3.) Gold yellow; native gold.
5. *Red*.—(1.) Copper-red; native copper and nickeline.

NON-METALLIC COLOURS.

1. *White*.—(1.) Snow-white; new fallen snow, Carrara marble, and common quartz.
- (2.) Reddish-white; heavy spar.
- (3.) Yellowish-white; chalk.
- (4.) Greyish-white; quartz.
- (5.) Greenish-white; amianthus.
- (6.) Milk-white; skimmed milk, chalcedony.
2. *Gray*.—(1.) Bluish-gray; limestone.
- (2.) Pearl-gray; porcelain jasper, and rarely quartz.
- (3.) Smoke-gray or brownish-gray; dense smoke, dark varieties of flint.
- (4.) Greenish-gray; clay-slate and whet-slate.
- (5.) Yellowish-gray; chalcedony.
- (6.) Ash-gray; wood-ashes, zoisite, zircon, and slate-clay.
3. *Black*.—(1.) Grayish-black; basalt, Lydian stone, and lucullite.
- (2.) Velvet-black; obsidian and schorl.
- (3.) Pitch-black or brownish-black; cobalt ochre, bituminous coal, and some varieties of mica.
- (4.) Greenish-black or raven-black; hornblende.
- (5.) Bluish-black; fluor spar.
4. *Blue*.—(1.) Blackish-blue; dark varieties of azurite.
- (2.) Azure-blue; bright varieties of azurite and Lapis lazuli.
- (3.) Violet-blue; amethyst and fluor spar.
- (4.) Lavender-blue; lithomarge and porcelain jasper.
- (5.) Plum-blue; spinel and fluor spar.
- (6.) Berlin-blue; sapphire, rock-salt, cyanite.
- (7.) Smalt-blue; pale-coloured smalt, gypsum.
- (8.) Duck-blue; talc and corundum.
- (9.) Indigo-blue; earthy-blue iron or vivianite.
- (10.) Skye-blue; lironite, some varieties of fluor spar and of blue spar.
5. *Green*.—(1.) Verdigris-green; amazon stone and lironite.
- (2.) Celandine-green; green earth, Siberian and Brazilian beryl.
- (3.) Mountain-green; beryl, aqua-marine topaz.
- (4.) Leek-green; common actynolite and prase.
- (5.) Emerald-green; emerald, and some varieties of green malachite.
- (6.) Apple-green; chrysoprase.
- (7.) Grass-green; uranite, smaragdite.
- (8.) Blackish-green; augite and precious serpentine.
- (9.) Pistachio-green; chrysolite and epidote.
- (10.) Asparagus-green; the apatite or asparagus-stone from Spain and Salzburg.
- (11.) Olive-green; garnet, pitch-stone, and olivine.
- (12.) Oil-green; olive-oil, blende, beryl.
- (13.) Siskin-green; uranite, and some varieties of pyromorphite.
6. *Yellow*.—(1.) Sulphur-yellow; native sulphur.
- (2.) Straw-yellow; pycnite and karpoholite.
- (3.) Wax-yellow; opal and wulfenite.
- (4.) Honey-yellow; dark honey, fluor spar, and beryl.
- (5.) Lemon-yellow; rind of ripe lemons, orpiment.
- (6.) Ochre-yellow; yellow-earth and jasper.
- (7.) Wine-yellow; Saxon and Brazilian topaz and fluor spar.
- (8.) Cream-yellow or Isabella-yellow; bole from Strigau, and compact limestone.
- (9.) Orange-yellow, rind of the ripe orange, uran-ochre, and some varieties of wulfenite.
7. *Red*.—(1.) Aurora, or morning-red; zealgar.
- (2.) Hyacinth-red; hyacinth or zircon, and garnet.
- (3.) Tile-red; fresh-burned bricks, porcelain-jasper, and heulandite.
- (4.) Scarlet-red; light-red cinnabar.
- (5.) Blood-red; blood, pyrope.
- (6.) Flesh-red; felspar and barytes.
- (7.) Carmine-red; carmine, spinel, particularly in thin splinters.
- (8.) Cochineal-red; cinnabar and certain garnets.
- (9.) Crimson-red; oriental ruby and erythrine.
- (10.) Columbine-red; precious garnet.
- (11.) Rose-red; diallogite and rose-quartz.
- (12.) Peach-blossom red; blossoms of the peach, red cobalt-ochre.
- (13.) Cherry-red; spinel, kermes, and precious garnet.
- (14.) Brownish-red; reddle and columnar-clay ironstone.
8. *Brown*.—(1.) Reddish-brown; brown blende from the Hartz, and zircon.
- (2.) Clove-brown; the clove, rock-crystal, and axinite.

Mineralogy.

- (3.) Hair-brown; wood-opal and limonite.
- (4.) Broccoli-brown; zircon.
- (5.) Chesnut-brown; Egyptian jasper.
- (6.) Yellowish-brown; iron-flint and jasper.
- (7.) Pinchbeck-brown; tarnished pinchbeck, mica.
- (8.) Wood-brown; mountain wood and old rotten wood.
- (9.) Liver-brown; boiled liver, common jasper.
- (10.) Blackish-brown; mineral pitch and brown coal.

The accidentally coloured minerals sometimes present two or more colours or tints, even on a single crystal; very remarkable examples occurring in fluor spar, apatite, sapphire, amethyst, tourmaline, and cyanite. This is still more common in compound minerals, on which the colours are variously arranged in points, streaks, clouds, veins, stripes, bands, or in brecciated and ruin-like forms. Some minerals again change their colour from exposure to the light, the air, or damp. Sometimes merely the surface is affected or *tarnished*, and then appears covered as with a thin film, producing in some minerals, as silver, arsenic, bismuth, only one colour; in others, as copper pyrites, hæmatite, stibine, and common coal, various or iridescent hues. Occasionally the change pervades the whole mineral, the colour sometimes becoming paler, or disappearing as in chrysoprase and rose-quartz; at other times darker, as in brown spar, siderite, and rhodonite. In a few minerals a complete change of colour takes place, as in the chlorophæite of the Western Isles, which, on exposure for a few hours, passes from a transparent yellow-green to black. These mutations seem generally connected with some chemical change. The tarnished colours sometimes only appear on certain faces of a crystal belonging to a peculiar form. Thus a crystal of copper pyrites (like fig. 35) has one face *P'* free from tarnish; the faces *b* and *c*, close to *P'*, are dark blue; the remainder of *c*, first violet, and then, close to *P*, gold-yellow. The colour of the powder formed when a mineral is scratched by a hard body is often different from that of the solid mass. This is named the *streak*, and is very characteristic of many minerals. It also often shows a peculiar lustre where the mineral is soft, as in talc and steatite.

Phosphorescence, Electricity, Magnetism.

Phosphorescence is the property possessed by particular minerals of producing light in certain circumstances without combustion or ignition. Thus some minerals appear luminous when taken into the dark after being for a time exposed to the sun's rays, or even to the ordinary daylight. Many diamonds and calcined barytes exhibit this property in a remarkable degree; less so, arragonite, calc-spar, and chalk; and in a still inferior degree, rock-salt, fibrous gypsum, and fluor spar. Many minerals, including the greater part of those thus rendered phosphorescent by the influence of the sun, also become so through heat. Thus some topazes, diamonds, and varieties of fluor spar become luminous by the heat of the hand; other varieties of fluor spar and the phosphorite require a temperature near that of boiling water; whilst calc-spar and many silicates are only phosphorescent at from 400° to 700° Fahr. Electricity produces it in some minerals, as in green fluor spar and calcined barytes. In others it is excited when they are struck, rubbed, split, or broken; as many varieties of zinc-blende and dolomite when scratched with a quill, pieces of quartz when rubbed on each other, and plates of mica when suddenly separated.

Friction, pressure, and heat also excite *electricity* in minerals. To observe this property delicate electrosopes are required, formed of a light needle, terminating at both ends in small balls, and suspended horizontally on a steel pivot by an agate cup. Such an instrument can be negatively electrified by touching it with a stick of sealing-wax, excited by rubbing, or positively when the wax is only brought so near as to attract the needle. When the instrument is in this state the mineral, if also rendered elec-

Mineralogy.

tric by heat or friction, will attract or repel the needle according as it has acquired electricity of an opposite or similar kind; but if the mineral is not electric, it will attract the needle in both conditions alike. Most precious stones become electrical from friction, and are either positive or negative according as their surface is smooth or rough. Pressure even between the fingers will excite distinct positive electricity in pieces of transparent double-refracting calc-spar. Topaz, arragonite, fluor spar, carbonate of lead, quartz, and other minerals show this property, but in a much smaller degree.

Heat or change of temperature excites electricity in many crystals, as in tourmaline, calamine, topaz, calc-spar, beryl, barytes, fluor spar, diamond, garnet, and others, which are hence said to be thermo- or pyro-electric. Some acquire polar pyro-electricity, or the two electricities appear in opposite parts of the crystal, which are named its electric poles. Each pole is alternately positive and negative,—the one when the mineral is heating, the other when it is cooling. The poles that become positive during an increase of temperature are named analogue; those that become negative in the same condition, antilogue poles, as shown in this table:—

Temperature.	Produces	Electricity.
+ or rising	in analogue	{ + or vitreous.
— or falling	poles	{ — or resinous.
+ or rising	in antilogue	{ — or resinous.
— or falling	poles	{ + or vitreous.

As already noticed, many polar electric minerals are also remarkable for their hemimorphic crystal forms. The number and distribution of the poles likewise vary. In many monoaxial minerals, as tourmaline and calamine, there are only two poles, one at each end of the chief axis; whereas boracite has eight poles corresponding to the angles of the cube. In prehnite and topaz, again, two antilogue poles occur on the obtuse lateral edges of the prism $\propto P$, and one analogue pole corresponding to the macrodiagonal chief section, or in the middle of the diagonal joining the obtuse edges.

Magnetism, or the power to act on the magnetic needle, is very characteristic of the few minerals in which it occurs, chiefly ores of iron or nickel. It is either simple, attracting both poles of the needle; or polar, when one part attracts, and another repels the same pole. Some magnetic iron ores, or natural magnets, possess polar magnetism; whilst the common varieties, meteoric iron, magnetic pyrites, precious garnet, and other minerals, are simply magnetic. Most minerals are only attracted by the magnet, but do not themselves attract iron.

Smell, taste, and touch furnish a few characters of minerals. Most have no smell, but some give out a peculiar odour when rubbed: as quartz an empyreumatic odour, or smell of burning; fluor spar of chlorine; clay of clay; some limestones and marls of bitumen, or a foetid odour. Aluminous minerals acquire a smell when breathed on. Other odours caused by heat, and often highly characteristic, are noticed under tests by the blow-pipe.

Taste is produced by all the salts soluble in water. Some are saline, like common salt; sweetish astringent, like alum; astringent, like blue vitriol; bitter, like epsom salt; cooling, like saltpetre; pungent, like sal-ammoniac; alkaline, like soda; acid or sour, like sassoline, &c.

Touch.—Some minerals are distinguished by a greasy feeling, like talc; others feel meagre, like clay; others cold. The last character readily distinguishes true gems from their imitations in glass.

CHAP. III.—CHEMICAL PROPERTIES OF MINERALS.

The consideration of the chemical nature of minerals,—that is, of the elements that enter into their composition,—of

the manner in which these elements combine, and the variations in proportion which they may undergo without destroying the identity of the species, forms an important branch of mineralogical science. The methods of detecting the different elements, and the characters which are thus furnished for the discrimination of minerals, are also of much value. This is especially true of the metallic ores and other substances, sought not as objects of curiosity, but for their economic qualities.

Mineralogy.

Composition of Minerals.

At present about sixty elements, or substances which have not been decomposed, are known. These are divided into metallic and non-metallic, a distinction of importance in mineralogy, though not always to be carried out with precision. The non-metallic elements are rarely of semimetallic aspect, and are bad conductors of heat and electricity. Some are commonly gaseous—oxygen, hydrogen, nitrogen, chlorine, and fluorine; one fluid—bromine; the others solid—carbon, phosphorus, sulphur, boron, selenium, and iodine. The metallic elements are, except mercury, solid at usual temperatures, have generally a metallic aspect, and are good conductors of heat and electricity. They are divided into light and heavy metals, the former with a specific gravity under 5, and a great affinity for oxygen, and again distinguished as either alkali-metals, potassium (or kalium), sodium (or natrium), lithium, barium, strontium, and calcium;—or earth-metals, magnesium, lanthanum, yttrium, glucinum, aluminium, zirconium, silicium. The heavy metals, with a specific gravity above 5, are divided into noble, which can be reduced, or separated from oxygen, by heat alone; and ignoble, whose affinity for oxygen renders them irreducible without other agents. Some of the latter are brittle and difficultly fusible,—thorium, titanium, tantalum (columbium), tungsten (wolframium), molybdenum, vanadium, chromium, uranium, manganese, and cerium; others are brittle and easily fusible or volatile—arsenic, antimony, tellurium, and bismuth; and others malleable—zinc, cadmium, tin, lead, iron, cobalt, nickel, and copper. The noble metals are,—quicksilver, silver, gold, platinum, palladium, rhodium, iridium, and osmium.

All the chemical combinations observed in the mineral kingdom follow the law of definite proportions; that is, two elements always combine either in the same proportion, or so that the quantity of the one is multiplied by two, three, four, or some other definite number seldom very large. As the same law prevails throughout the whole range of elements, by assuming any one, usually hydrogen or oxygen, as unity or 1, and determining from experiment the simple proportion in which the others combine with it, a series of numbers is obtained which also expresses the proportions in which all these elements combine with each other. These numbers, therefore, mark the combining proportions or equivalents, as they are named, of the elements. They are also named atomic weights, on the supposition that matter consists of definite atoms, and that its combinations consist of one atom (or sometimes two atoms) of one substance, with one, two, three, or more atoms of another. This theory is not free from difficulties, but the language is often convenient. To designate the elements chemists generally employ the first letter or letters of their Latin names. These signs also indicate one atom or equivalent of the element. Thus, O means oxygen in the proportion of one atom; H, hydrogen in the same proportion; N, an atom of nitrogen; Na, an equivalent proportion of sodium or sodium. These signs and the equivalent weights are given in the following table, in one column of which hydrogen is taken as unity, in the other oxygen. The elements are arranged according to Berzelius, beginning with the most electro-positive, and ending with the most electro-negative.

* Double atoms.

† L. Gmelin, who considers silica as composed of one atom base and two oxygen.

‡ Berzelius.

The above list includes ammonium, usually considered a compound body, and omits the two new metals, erbium and terbium.

All these elements occur in minerals, but not more than twenty are common, and only about twelve abundant. They are also very rare in their simple or uncombined state; only carbon in the diamond and graphite, sulphur, and about a dozen of the native metals, being thus known. More frequently minerals consist of two or more elements com-

bined in accordance with those laws which prevail in inorganic compounds. The most important of these laws is that the combinations are binary; that is, that the elements unite in pairs, which may again unite either with another compound of two, or with a single element. Inorganic compounds also are generally distinguished from organic by their greater simplicity.

The following principles are observed in designating the combinations of these elementary substances:—For those of the first order the signs of the two components are conjoined, and the number of atoms or equivalents of each expressed by a number following the sign like an algebraic exponent. Thus, SO, SO², SO³, are the combinations of one atom sulphur with one, two, and three atoms of oxygen; FeS, FeS², of one atom of iron with one or two of sulphur. But as combinations with oxygen and sulphur are very numerous in the mineral kingdom, Berzelius, to whom science is indebted for this system of signs, marks the atoms of oxygen by dots over the sign of the other element, and those of sulphur by an accent; the above compounds being then designated thus—S̄, S̄², S̄³, and Fe', Fe''. In some cases two atoms of a base combine with three or five of oxygen or sulphur, as Al²O³, Fe²S³. In such cases Berzelius marks the double atom by a line drawn through the sign of the single atom; thus, $\overline{\text{Al}}$ is two atoms aluminium with three of oxygen or alumina; $\overline{\text{Cu}}$, two of copper with one of oxygen or oxide of copper. Where a number is prefixed to the sign like a coefficient in algebra it includes both elements of the combination; thus H is one atom water, 2 H two; CaC is one atom carbonate of lime, 2 CaC two atoms, including of course two of calcium, two of carbon, and six of oxygen.

The most common and important binary compounds are those with oxygen, contained in the following table, with their signs, atomic numbers, and amount of oxygen in 100 parts. The more electro-negative are named acids, which are often soluble in water, and then render blue vegetable colours red. The more electro-positive are named oxides or bases, and show great affinity or attractive power for the former. The most powerful are the alkaline bases, which are colourless and soluble in water; less powerful are the earths, also colourless, but insoluble in water:—

Minera-
logy.

Mineralogy.

Similar to the compounds of oxygen are those with sulphur, usually named sulphurets, and considered analogous to the oxidized bases. A few of more electro-negative character, resembling acids, have been distinguished as sulphides. Some other compounds have been named haloid salts, and consist of certain electro-negative elements, combined with electro-positive ones, as bases.

Many of these combinations occur as independent species in the mineral kingdom, especially those with oxygen and sulphur. Thus the most abundant of all minerals, quartz, is an oxide, and corundum is of similar nature. Many oxides of the heavy metals, as of iron, tin, copper, and antimony; and some super-oxides, as of lead and manganese (pyrolusite),—are very common. Compounds with sulphur also abound, and either as sulphides, with the character of acids, like realgar, orpiment, and stibine; or as sulphurets, resembling bases, like galena, argentite, and pyrite. Less frequent are haloid salts, with chlorine and fluorine, as common salt and fluor spar; and still rarer those with iodine and bromine. On the other hand, metallic alloys, or combinations of electro-negative with electro-positive metals, are far from uncommon, especially those with arsenic, tellurium, or antimony.

Combinations of these binary compounds with each other are still more common, the greater number of minerals being composed of an acid and base. By far the greater number are oxygen-salts, distinguished by giving to the acid the termination *ate*; thus sulphate of lead, silicate of lime, and in like manner numerous carbonates, phosphates, arseniates, aluminates. The sulphur-salts (two metals combined with sulphur, and again combined with each other) are next in number, and perform a most important part in the mineral kingdom. The hydrates, or combinations of an oxide with water, are also common, and much resemble the oxygen salts, the water sometimes acting as an electro-positive, at other times as an electro-negative element. Combinations of a higher order are likewise common, especially the double salts, or the union of two salts into a new body; and even these again with water, as alum and many hydrous silicates. The chemical formula for these compound salts are formed by writing the signs of the simple salts with the sign of addition between them: thus $\text{Ca } \ddot{\text{C}} + \text{Mg } \ddot{\text{C}}$, *i.e.* carbonate of lime and carbonate of magnesia, or brown spar; $\text{Al } \ddot{\text{Si}}^3 + \text{K } \ddot{\text{Si}}^3$, or orthoclase; $3 \text{ Na } \text{F} + \text{Al } \text{F}^3$, or cryolite, composed of three compound atoms of fluorine and sodium united to one compound atom, consisting of three of fluorine and two of aluminium.

Influence of the Chemical Composition on the External Characters of Minerals.

That the characters of the compound must in some way or other depend on those of its component elements, seems, as a general proposition, to admit of no doubt. Hence it might be supposed possible, from a knowledge of the composition of a mineral, to draw conclusions in reference to its form and other properties; but practically this has not yet been effected. The distinction between the mineralizing and mineralizable, or the forming and formed, elements, lies at the foundation of all such inquiries. Certain elements in a compound apparently exert more than an equal share of influence in determining its physical properties. Thus the more important non-metallic elements, as oxygen, sulphur, chlorine, fluorine, are remarkable for the influence they exert on the character of the compound. The sulphurets, for example, have more similarity among themselves than the various compounds of one and the same metal with the non-metallic bodies. Still more generally it would appear that the electro-negative element in the compound is the most influential, or exerts the greatest degree of active forming power. After the non-metallic elements the brittle, easily fusible metals rank next in

Mineralogy.

power; then the ductile ignoble metals; then the noble metals; then the brittle, difficultly fusible; and last of all, the metals of the earths and alkalis.

It is sometimes stated that each particular substance can crystallize only in one particular form or series of forms. This is, however, only partially true; and sulphur, for instance, which usually crystallizes in the rhombic system, when melted may form monoclinohedric crystals. This property is named *dimorphism*; and hence the same chemical substance may form two, or even more, distinct bodies or mineral species. Thus carbon in one form is the diamond, in another graphite; carbonate of lime appears as calc-spar or arragonite; the bisulphuret of iron as pyrite and marcasite. An example of trimorphism occurs in the titanite acid, forming the three distinct species, anatase, rutile, and brookite. Even the temperature at which a substance crystallizes influences its forms, and so far its composition, as seen in arragonite, Glauber salt, natron, and borax.

Still more important is the doctrine of *isomorphism*, designating the fact that two or more simple or compound substances crystallize in one and the same form; or often in forms which, though not identical, yet approximate very closely. This similarity of form is generally combined with a similarity in other physical properties. Among minerals that crystallize in the tesseral form, isomorphism is of course common and perfect, there being no diversity in the dimensions of the primary form; but for this very reason it is of less interest. It is of more importance among mono-axial crystals, the various series of which are separated from each other by differences in the proportion of the primary form. In these perfect identity is seldom observed, but only very great similarity.

The more important isomorphous substances are the following:—

I. Simple substances:—

- (1.) Fluorine and chlorine.
- (2.) Sulphur and selenium.
- (3.) Arsenic, antimony, tellurium.
- (4.) Cobalt, iron, nickel.
- (5.) Copper, silver, quicksilver, gold (?)

II. Combinations with oxygen:—

- (1.) Of the formula $\ddot{\text{R}}$.
 - (a.) Lime, magnesia, protoxide of iron, protoxide of manganese, oxide of zinc, oxide of nickel, oxide of cobalt, potassa, soda.
 - (b.) Lime, baryta, strontia, lead-oxide.
- (2.) Of the formula $\ddot{\text{R}}^2$.
 - (a.) Alumina, peroxide of iron, peroxide of manganese, oxide of chromium.
 - (b.) Antimony oxide, arsenious acid.
- (3.) Formula $\ddot{\text{R}}$. Tin-oxide, titanium-oxide.
- (4.) Formula $\ddot{\text{R}}^2$. Phosphoric acid, arsenic acid.
- (5.) Formula $\ddot{\text{R}}$.
 - (a.) Sulphuric acid, selenic acid, chromic acid, manganese acid.
 - (b.) Tungstic acid, molybdic acid.

III. Combinations with sulphur:—

- (1.) Formula R' . Sulphuret of iron Fe' , and sulphuret of zinc Zn' .
- (2.) Formula R''' . Sulphuret of antimony Sb''' , and sulphuret of arsenic As''' .
- (3.) Formula R' . Sulphuret of copper Cu , and sulphuret of silver Ag' .

These substances are named vicarious, from the singular property that in chemical compounds they can mutually replace each other in indefinite proportions, and very often without producing any important change in the form or other physical properties. But there are numerous instances among the silicates, where the mutual replacement of the

Mineralogy.

isomorphic bodies, especially when the oxides of the heavy metals come in the room of the earths and alkalis, exerts a most essential influence on the external aspect of the species, particularly in regard to colour, specific gravity, and transparency. The varieties of hornblende, augite, garnet, epidote, and many other minerals, are remarkable proofs of this influence. This intermixture of isomorphic elements confers many valuable properties on minerals, and to it this department of nature owes much of its variety and beauty. Without the occasional presence of the colouring substances, especially the oxides of iron and manganese, the non-metallic combinations would have exhibited a very monotonous aspect. It is also remarkable that in some silicates the substitution of a certain portion of the metallic oxides for the earthy bases seems to be almost a regular occurrence; whilst in others, as the felspars and zeolites, this rarely happens. This fact is often of great economic importance, as drawing attention to important elements often combined with others of less value. Thus iron oxide and chrome oxide, sulphuret of copper and sulphuret of silver, nickel and cobalt, may be looked for in connection. The general chemical formula for such compounds is formed by writing R. (=radicle or basis) for the whole isomorphic elements; and in special instances to place their signs either one below the other, connected by a bracket, or, as is more convenient, to inclose them in brackets one after the other, separated by a comma. Thus the general sign for the garnet is $R^3 \text{Si}^2 + R \text{Si}$, which, when fully expressed, becomes $(\text{Ca}^3, \text{Fe}^3, \text{Mn}^3) \text{Si}^2 + (\text{Al}, \text{Fe}) \text{Si}$.

Chemical Reaction of Minerals.

The object of the chemical examination of minerals is the discovery of those elementary substances of which they consist. This examination is named *qualitative* when the nature of the elements alone, *quantitative* when also their relative amount, is sought to be determined. Mineralogists are in general content with such an examination as will discover the more important elements, and which can be carried on with a simple apparatus, and small quantities of the substance investigated. The indications thus furnished of the true character of the mineral are, however, frequently of high importance. Two methods of testing minerals are employed, the one by heat chiefly applied through the blowpipe, the second by acids and other reagents in solution.

Use of the Blowpipe.

The blowpipe in its simplest form is merely a conical tube of brass or other metal, curved round at the smaller extremity, and terminating in a minute circular aperture not larger than a fine needle. Other forms have been proposed, one of the most useful being a cone of tin open for the application of the mouth at the smaller end, and with a brass or platina beak projecting from the side near the other or broad end. With this instrument a stream of air is conveyed from the mouth to the flame of a lamp, or candle, so that this can be turned aside, concentrated, and directed upon any small object. The flame thus acted on consists of two parts,—the one nearest the beak of the blowpipe forming a blue obscure cone, the other external to this being of a shining yellow or reddish-yellow colour. The blue cone consists of the inflammable gases not yet fully incandescent, and the greatest heat is just beyond its point, where this is fully effected. The blue flame still needs oxygen for its support, and consequently tends to withdraw it from any body placed within its influence, and is named the *reducing flame*. At the extremity of the yellow cone, on the other hand, the whole gases being consumed, and the external air having free access, bodies are combined with oxygen, and this part is named the *oxidating flame*. Their action being so distinct, it is of great importance for the

Mineralogy.

student to learn to distinguish accurately these two portions of the flame. This is best done by experimenting on a piece of metallic tin, which can only be kept pure in a good reducing flame, and acquires a white crust when acted on by the oxidating flame.

The portion of the mineral to be examined should not be larger than a peppercorn, or a fine splinter a line or two long. It is supported in the flame either by a pair of fine pincers pointed with platinum, or on slips of platinum-foil, or on charcoal. Platinum is best for the siliceous minerals, whereas for metallic substances charcoal must be employed. For this purpose solid uniform pieces are chosen, and a small cavity formed in the surface in which the mineral to be tested can be deposited.

In examining a mineral by heat, it should be first tested alone, and then with various reagents. When placed alone in a matrass or tube of glass closed at one end, and heated over a spirit lamp, water or other volatile ingredients, mercury, arsenic, tellurium, often sulphur, may readily be detected, being deposited in the cooler part of the tube, or, like fluorine, acting on the glass. It may next be tried in an open tube of glass, through which a more or less strong current of air passes according to the inclination at which the tube is held, so that volatile oxides or acids may be formed; and in this way the chief combinations of sulphur, selenium, tellurium, and arsenic are detected. On charcoal, in the reducing flame, arsenic, and in the oxidating flame, selenium or sulphur, are shown by their peculiar odour; antimony, zinc, lead, and bismuth leave a mark or coloured ring on the charcoal; and other oxides and sulphurets are reduced to the pure metal. On charcoal or in the platinum pincers the fusibility of minerals is tested, and some other phenomena should be observed—as whether they intumesce (bubble up), effervesce, give out fumes, become shining, or impart a colour to the flame. The colour is seen when the assay is heated at the point of the inner flame, and is—

Reddish-yellow, from soda and its salts;
Violet, from potash and most of its salts;
Red, from lithia, strontia, and lime;
Green, from baryta, phosphoric acid, boracic acid, molybdic acid, copper oxide, and tellurium oxide;
Blue, from chloride of copper, bromide of copper, selenium, arsenic, antimony, and lead.

The fusibility, or ease with which a mineral is melted, should also be observed; and to render this character more precise, von Kobell has proposed this scale:—(1.) Antimony glance, which melts readily in the mere candle flame; (2.) Natrolite, which in fine needles also melts in the candle flame, and in large pieces readily before the blowpipe; (3.) Almandine (garnet from Zillerthal), which does not melt in the candle flame even in fine splinters, but in large pieces before the blowpipe; (4.) Strahlstein (hornblende from Zillerthal) melts with some difficulty, but still more readily than (5.) Orthoclase (or adularia felspar); and (6.) Bronzite or diallage, of which only the finest fibres can be rounded by the blowpipe. In employing this scale, fine fragments of the test minerals and of that to be tried, and nearly of equal size, should be exposed at the same time to the flame. A more common mode of expressing fusibility is to state whether it is observable in large or small grains, in fine splinters, or only on sharp angles. The result or product of fusion also yields important characters, being sometimes a glass, clear, opaque, or coloured; at other times an enamel, or a mere slag.

The most important reagents for testing minerals with the blowpipe are the following:—(1.) Soda (the carbonate), acting as a flux for quartz and many silicates, and especially for reducing the metallic oxides. For the latter purpose, the assay (or mineral to be tried) is reduced to powder, kneaded up with moist soda into a small ball, and placed in

Mineralogy.

a cavity of the charcoal. Very often both the soda and assay sink into the charcoal, but by continuing the operation they either again appear on the surface, or, when it is completed, the charcoal containing the mass is finely pounded and washed away with water, when the reduced metal is found in the bottom of the vessel. (2.) Borax (biborate of soda) serves as a flux for many minerals, which are best fused in small splinters on platina wire. The borax when first exposed to the flame swells up or intumesces greatly, and it should therefore be first melted into a small bead, in which the assay is placed. During the process the student should observe whether the assay melts easily or difficultly, with or without effervescence, what colour it imparts to the product both when warm and when cold, and also the effect both of the oxidating and reducing flames. (3.) Microcosmic salt, or salt of phosphorus (phosphate of soda and ammonia) is specially important as a test for metallic oxides, which exhibit far more decided colours with it than with borax. It is also a useful reagent for many silicates, whose silica is separated from the base and remains undissolved in the melted salt. (4.) Solution of cobalt (nitrate of cobalt dissolved in water), or dry oxalate of cobalt, serve as tests of alumina, magnesia, and zinc oxide.

In examining minerals in the moist way, the first point to be considered is their solubility, of which three degrees may be noted: (1) minerals soluble in water; (2) minerals soluble in hydrochloric or nitric acid; and (3) those unaffected by any of these fluids. The minerals soluble in water are either acids (almost only the boracic acid or sassolin and the arsenious acid), or oxygen or haloid salts. These are easily tested, one part of the solution being employed to find the electro-positive element or basis, the other the electro-negative or acid.

Minerals insoluble in water may next be tested with the above acids; the nitric acid being preferable when it is probable, from the aspect of the mineral or its conduct before the blowpipe, that it contains an alloy, a sulphuret, or arseniate of some metal. In this manner the carbonic, phosphoric, arsenic, and chromic acid salts, many hydrous and anhydrous silicates, many sulphurets, arseniates, and other metallic compounds, are dissolved, so that further tests may be employed.

The minerals insoluble either in water or these acids are sulphur, graphite, cinnabar, some metallic oxides, some sulphates, and compounds with chlorine and fluorine, and especially quartz, and various silicates. For many of these no test is required, or those furnished by the blowpipe are sufficient. The silicates and others may be fused with four times their weight of anhydrous carbonate of soda when they are rendered soluble, so that further tests may be applied.

Chemical Reaction of the more Important Elements.

It is not intended in this place to describe the chemical nature of the elementary substances, and still less to enumerate the whole of those marks by which the chemist can detect their presence. Our object is limited principally to the conduct of minerals before the blowpipe, and to a few simple tests by which their more important constituents may be discovered by the student.

I.—NON-METALLIC ELEMENTS, AND THEIR COMBINATIONS WITH OXYGEN.

Nitric Acid.—Most of its salts detonate when heated on charcoal. In the closed tube they form nitrous acid, easily known by its orange colour and smell; a test more clearly exhibited when the salt is mixed with copper filings and treated with concentrated sulphuric acid. When to the solution of a nitrate, a fourth part of sulphuric acid is added,

and a fragment of green vitriol placed in it, the surrounding fluid becomes of a dark brown colour.

Sulphur and its compounds, in the glass tube or on charcoal, form sulphurous acid, easily known by its smell. The minutest amount of sulphur or sulphuric acid may be detected by melting the pulverized assay with two parts soda and one part borax, and placing the bead moistened with water on a plate of clean silver, which is then stained brown or black. Solutions of sulphuric acid give with chloride of barium a heavy white precipitate, insoluble in acids.

Phosphoric Acid.—Most combinations with this acid tinge the blowpipe flame green, especially if previously moistened with sulphuric acid. The experiment must be performed in the dark, when even three per cent. of the acid may be detected. If the assay is melted with six parts of soda, digested in water, filtered, and neutralized with acetic acid, the solution forms an orange-yellow layer round a crystal of nitrate of silver. This solution, with muriate of magnesia, forms a white crystalline precipitate.

Selenium and **Selenic Acid** are readily detected by the strong smell of decayed horse-radish, and leave a gray deposit with a metallic lustre on the charcoal.

Chlorine and its salts. When oxide of copper is melted with salt of phosphorus into a very dark-green bead, and an assay containing chlorine fused with this, the flame is tinged of a beautiful reddish blue colour, till all the chlorine is driven off. If very little chlorine is present, the assay is dissolved in nitric acid (if not soluble it must first be melted with soda on platinum wire), and the diluted solution gives, with nitrate of silver, a precipitate of chloride of silver, which is first white, but on exposure to the light becomes gradually brown, and at length black.

Iodine and its salts, treated like chlorine, impart a very beautiful bright-green colour to the flame; and heated in the closed tube with sulphate of potash, yield violet-coloured vapours. In solution it gives, with nitrate of silver, a precipitate similar to chlorine, but which is very difficultly soluble in ammonia. Its surest test is the blue colour it imparts to starch, best seen by pouring concentrated sulphuric acid over the mineral in a test tube which has a piece of paper or cotton covered with moist starch over its mouth.

Bromine and its salts, treated in the same manner with salt of phosphorus and oxide of copper, colour the blowpipe flame greenish-blue. In the closed tube with nitrate of potassa they yield bromine vapours, known by their yellow colour and peculiar disagreeable smell. Treated with sulphuric acid, bromine in a few hours colours starch pomegranate-yellow.

Fluorine is shown by heating the assay with sulphate of potassa, in a closed tube with a strip of logwood paper in the open end. The paper becomes straw-yellow, and the glass is corroded. Another test is to heat the pulverized mineral with concentrated sulphuric acid in a shallow dish of platinum (or lead), over which a plate of glass covered with a coat of wax, through which lines have been drawn with a piece of sharp-pointed wood, is placed. If fluorine is present the glass is etched where exposed.

Boracic Acid.—The mineral alone, or moistened with sulphuric acid when melting, colours the flame momentarily green. If the assay be heated with sulphuric acid, and alcohol added, and set on fire, the flame is coloured green from the vapours of the boracic acid.

Carbon, pulverized and heated with saltpetre, detonates, leaving carbonate of potassa. Carbonic acid is not easily discovered with the blowpipe, but the minerals containing it effervesce in hydrochloric acid, and the colourless gas that escapes renders litmus paper red. In solution it forms a precipitate with lime-water, which is again dissolved with effervescence in acids.

Silica, before the blowpipe, alone is unchanged; is very

Mineralogy.

Mineralogy.

slowly acted on by borax, very little by salt of phosphorus, but with soda melts entirely with a brisk effervescence into a clear glass. The silicates are decomposed by salt of phosphorus, the silica being left in the bead as a powder or a skeleton. Most of them melt with soda to a transparent glass. Some silicates are dissolved in hydrochloric acid, and this the more readily the more powerful the basis, the less proportion of silica, and the greater the amount of water they contain. Sometimes the acid only extracts the basis, leaving the silica as a powder or jelly; or the silica too is dissolved, and only gelatinizes on evaporation. The insoluble silicates may be first melted with some carbonate of an alkali, when the solution gelatinizes, and finally leaves a dry residuum of which the part insoluble in warm hydrochloric acid has all the properties of silica.

II.—THE ALKALIES AND EARTHS.

Ammonia, heated with soda in a closed tube, is readily known by its smell. Its salts, heated with solution of potassa, also yield the vapour, known from its smell, its action on turmeric paper, and the white fumes that rise from a glass tube tipped in hydrochloric acid held over it.

Soda imparts a reddish-yellow colour to the external flame when the assay is fused or kept at a strong red heat. In solution it yields no precipitate with chloride of platinum or sulphate of alumina.

Lithia is best recognised by the beautiful carmine-red colour it imparts to the flame during the fusion of a mineral containing it in considerable amount. Where the proportion is small, the colour appears if the assay be mixed with 1 part fluor spar and $1\frac{1}{2}$ parts sulphate of potassa. In concentrated solutions it forms a precipitate with the phosphate and carbonate of soda, but none with bichloride of platinum, sulphate of alumina, or acetic acid.

Potassa gives a violet colour to the external cone, when the assay is heated at the extremity of the oxidating flame. The presence of lithia or soda, however, disturbs this reaction. It may still be discovered by melting the assay in borax glass coloured brown by nickel oxide, which is changed to blue by the potassa. In concentrated solutions of potassa the bichloride of platinum gives a citron-yellow precipitate; acetic acid a white, granular precipitate; and sulphate of alumina, after some time, a deposit of alum-crystals.

Baryta.—The carbonate of this earth melts easily to a clear glass, milk-white when cold; the sulphate is very difficultly fusible. Both strongly heated at the point of the blue flame impart a green tinge to the outer flame. When combined with silica it cannot be well discovered by the blowpipe. In solution, salts of baryta yield, with sulphuric acid or solution of sulphate of lime, *immediately* a fine white precipitate insoluble in acids or alkalies.

Strontia, the carbonate, even in thin plates, only melts on the edges, and forms cauliflower-like projections of dazzling brightness; the sulphate melts easily in the oxidating flame, and in the reducing flame is changed into sulphuret of strontium, which, dissolved in hydrochloric acid, and evaporated to dryness, gives a fine carmine-red colour to the flame of alcohol. Strontia in solution gives a precipitate with sulphuric acid, or with sulphate of lime, but not *immediately*.

Lime.—The carbonate is rendered caustic by heat, when it has alkaline properties, and readily absorbs water. The sulphate in the reducing flame changes to the sulphuret of calcium, which is also alkaline. Sulphuric acid precipitates lime only from very concentrated solutions; oxalic acid even from very weak ones; and silico-hydrofluoric acid not at all. As baryta and strontia also form precipitates with the first two reagents, they must previously be separated by sulphate of potassa. Chloride of calcium tinges the flame of alcohol yellowish-red.

rated by sulphate of potassa. Chloride of calcium tinges the flame of alcohol yellowish-red.

Magnesia, alone, or as a hydrate, a carbonate, and in some other combinations, when ignited with solution of cobalt, or the oxalate of cobalt, assumes a light-red tint. It is not precipitated from a solution either by sulphuric acid, oxalic acid, or silico-hydrofluoric acid; but phosphoric acid, with ammonia, throws down a white crystalline precipitate of phosphate of ammonia and magnesia.

Alumina alone is infusible. In many combinations, when ignited with solution of cobalt, it assumes a fine blue colour. It is thrown down by potassa or soda as a white voluminous precipitate, which in excess of the alkali is easily and completely soluble, but is again precipitated by muriate of ammonia. Carbonate of ammonia also produces a precipitate which is not soluble in excess.

Glucina, *Yttria*, *Zirconia*, and *Thorina* are not properly distinguished by blowpipe tests, though the minerals in which they occur are well marked in this way. In solution glucina acts with potassa like alumina; but the precipitate with carbonate of ammonia is again soluble, with excess of the alkali, and the two earths may thus be separated. Yttria is precipitated by potassa, but is not again dissolved by excess of the alkali. With carbonate of ammonia it acts like glucina. It must be observed, however, that the substance formerly named yttria is now considered a mixture of this earth with the oxides of erbium, terbium, and lanthanum. Zirconia acts with potassa like yttria, and with carbonate of ammonia like glucina. Concentrated sulphate of potassa throws down a double salt of zirconia and potassa, which is very little soluble in pure water.

III.—THE METALS.

Arsenic and its sulphuret on charcoal yield fumes, with a smell like garlic, and sublime in the closed tube. The greater number of alloys of arsenic in the reducing flame leave a white deposit on the charcoal; or where it is in larger proportion, give out grayish-white fumes with a smell of garlic. Some alloys also yield metallic arsenic in the closed tube. In the open tube all of them yield arsenious acid, and those containing sulphur also sulphurous fumes. Many arsenic acid salts emit evident odours of arsenic when heated on charcoal with soda; and some sublime metallic arsenic when heated with pulverized charcoal in the closed tube.

Antimony melts easily on charcoal, emitting dense white fumes, and leaving a ring of white crystalline oxide on the support. In the closed tube it does not sublime, but burns in the open tube with white smoke, leaving a sublimate on the glass, which is easily driven from place to place by heat. Most of its compounds, with sulphur or with the other metals, show similar reaction. Antimony oxide on charcoal melts easily, fumes, and is reduced, colouring the flame pale greenish-blue.

Bismuth melts easily, fumes, and leaves a yellow oxide on the charcoal. In the closed tube it does not sublime, and in the open tube scarcely fumes, but is surrounded by the fused oxide, dark-brown when warm, and bright-yellow when cold. Its oxides are easily reduced. A great addition of water produces a white precipitate from its solution in nitric acid.

Tellurium fumes on charcoal, and becomes surrounded by a white mark with a reddish border, which, when the reducing flame is turned on it, disappears with a bluish-green light. In the closed tube tellurium gives a sublimate of the gray metal; and in the open tube produces copious fumes, and a white powder which can be melted into small clear drops.

Mercury in all its combinations is volatile, and yields a

Mineralogy.

Mineralogy.

metallic sublimate when heated alone, or with tin or soda in the closed tube.

Zinc, when heated with soda on charcoal, forms a deposit, which, when warm, is yellow; when cold, white; is tinged of a fine green by solution of cobalt, and is not further volatile in the oxidating flame. In solution zinc is precipitated by potassa as a white gelatinous hydrate, easily redissolved in the excess of the alkali.

Tin forms a white deposit on the charcoal behind the assay, which takes a bluish-green colour with the solution of cobalt. The oxide is easily reduced by soda.

Lead forms a sulphur-yellow deposit with a white border on the charcoal when heated in the oxidating flame, and with soda is easily reduced. The solutions of its salts are colourless, but give a black precipitate with sulphuretted hydrogen; with sulphuric acid a white, and with chromate of potassa a yellow, precipitate.

Cadmium produces, with soda, a reddish-brown or orange-yellow ring, with iridescent border on the charcoal, and also on platinum-foil.

Manganese alone, melted with borax or salt of phosphorus on the platinum wire in the oxidating flame, forms a fine amethystine glass, which becomes colourless in the reducing flame. In combination with other metals, the pulverized assay mixed with two or three times as much soda, and melted in the oxidating flame on platinum-foil, forms a bluish-green glass. Potassa or ammonia throws down from solutions of its salts a white hydrate, which in the air becomes gradually dark-brown.

Cobalt, melted with borax in the oxidating flame, gives a beautiful blue glass. Minerals of metallic aspect must be first roasted on charcoal. The salts of protoxide of cobalt form bright-red solutions, from which potassa throws down a blue flaky hydrate, which becomes olive-green in the air.

Nickel, the assay, first roasted in the open tube and on charcoal, produces in the oxidating flame, with borax, a glass, which hot, is reddish or violet-brown; when cold, yellowish or dark red; and by the addition of saltpetre changes to blue. In the reducing flame the glass appears gray. With salt of phosphorus the reaction is similar, but the glass is almost colourless when cold. The salts in solution have a bright-green colour, and with potassa form a green precipitate of hydrated nickel-oxide, which is unchanged in the air.

Copper may in most cases be discovered by melting the assay (if apparently metallic, first roasted) with borax or salt of phosphorus in the oxidating flame, when an opaque reddish-brown glass is produced, a small addition of tin aiding in the result. In the reducing flame the glass, when warm, is green; when cold, blue. With soda metallic copper is produced. A small proportion of copper may often be detected by heating the assay, moistened with hydrochloric acid, in the oxidating flame, which is then tinged of a beautiful green colour. Solutions of its salts are blue or green, and produce a brownish-black precipitate, with sulphuretted hydrogen. Ammonia at first throws down a pale-green, or blue precipitate, but in excess produces a very fine blue colour.

Silver in the metallic state is at once known, and from many combinations can be readily extracted on charcoal with soda. From its solution in nitric acid silver is thrown down by hydrochloric acid as a white chloride, which in the light soon becomes black, is soluble in ammonia, and can again be precipitated from this solution by nitric acid as chloride of silver.

Gold, when pure, is readily known, and is easily separated from its combinations with tellurium on charcoal. If the grain is white, it contains more silver than gold, and must then be heated in a porcelain capsule with nitric acid, which gives it a black colour, and gradually removes the silver, if

the gold is only a fourth part or less. If the proportion of gold is greater, the nitro-chloric acid must be used, which then removes the gold. From its solution in this acid the protochloride of tin throws down a purple precipitate (*purple of Cassius*), and the sulphate of iron, metallic gold.

Platinum, and the metals usually found with it, cannot be separated from each other by heat. Only the *Osmium-iridium* strongly heated in the closed tube with saltpetre is decomposed, forming osmium acid, known from its peculiar pungent odour. The usual mixture of platinum grains is soluble in nitro-chloric acid, leaving osmium-iridium. From this solution the *platinum* is thrown down by sal-ammonia as a double chloride of platinum and ammonium. From the solution evaporated, and again diluted, with cyanide of mercury, the *palladium* separates as cyanide of palladium. The *rhodium* may be separated by its property of combining with fused bisulphate of potassa, which is not the case with platinum or iridium.

Cerium, when no iron-oxide is present, produces, with borax and salt of phosphorus, in the oxidating flame, a red or dark-yellow glass, which becomes very pale when cold, and colourless in the reducing flame. *Lanthanum* oxide forms a white colourless glass; *didymium* a dark amethystine glass.

Iron, the peroxide and hydrated peroxide, become black and magnetic before the blowpipe, and form, with borax or salt of phosphorus, in the oxidating flame, a dark-red glass, becoming bright-yellow when cold; and in the reducing flame, especially on adding tin, an olive-green or mountain-green glass. The peroxide colours a bead of borax containing copper oxide bluish-green; the protoxide produces red spots. Salts of protoxide of iron form a green solution, from which potassa or ammonia throws down the protoxide as a hydrate, which is first white, then dirty-green, and finally yellowish-brown. Carbonate of lime produces no precipitate. The salts of the peroxide, on the other hand, form yellow solutions from which the peroxide is thrown down by potassa or ammonia as a flaky-brown hydrate. Carbonate of lime also causes a precipitate.

Chromium forms, with borax or salt of phosphorus, a glass, fine emerald-green when cold, though when hot often yellowish or reddish. Its solutions are usually green, and the metal is thrown down by potassa as a bluish-green hydrate, again dissolved in excess of the alkali. The chrome in many minerals is very certainly discovered by melting the assay with three times its bulk of saltpetre, which, dissolved in water, gives with acetate of lead a yellow precipitate.

Vanadium, melted on platinum wire with borax or salt of phosphorus, gives a fine green glass in the reducing flame, which becomes yellow or brown in the oxidating flame, distinguishing it from chrome.

Uranium, with salt of phosphorus, forms in the oxidating flame a clear yellow; in the reducing flame a fine green glass. With borax its reaction is similar to that of iron.

Molybdenum forms in the reducing flame, with salt of phosphorus, a green; with borax, a brown glass.

Tungsten or *Wolfram* forms, with salt of phosphorus, in the oxidating flame, a colourless or yellow, in the reducing flame, a very beautiful blue glass, which appears green when warm. When accompanied by iron the glass is blood-red, not blue. Or melt the assay with five times as much soda in a platinum spoon, dissolve it in water, filter, and decompose the result with hydrochloric acid, which throws down the tungstic acid, which is white when cold, but citron-yellow when heated.

Tantalum, as tantalic acid, is readily dissolved by salt of phosphorus, and in large quantity into a colourless glass, which does not become opaque in cooling, and does not acquire a blue colour from solution of cobalt. Or fuse the assay with two times as much saltpetre, and three times as

Mineralogy.

Mineralogy.

much soda, in a platinum spoon; dissolve this, filter, and decompose the fluid by hydrochloric acid: the tantalic acid separates as a white powder, which does *not* become yellow when heated.

Titanium in anatase, rutile, brookite, and titanite, is shown by the assay forming, with salt of phosphorus, in the oxidating flame, a glass which is and remains colourless; in the reducing flame, a glass which appears yellow when hot, and whilst cooling passes through red into a beautiful violet. When iron is present, however, the glass is blood-red, but is changed to violet by adding tin. When titanate of iron is dissolved in hydrochloric acid, and the solution boiled with a little tin, it acquires a violet colour from the oxide of titanium. Heated with concentrated sulphuric acid, the titanate of iron produces a blue colour.

CHAP. IV.—CLASSIFICATION OF MINERALS.

A mineral species was formerly defined as a natural inorganic body, possessing a definite chemical composition and peculiar external form. The account given of these properties shows that the form of a mineral species comprehends not only the primary or fundamental figure, but all those that may be derived from it by the laws of crystallography. Irregularities of form arising from accidental causes, or that absence of form which results from the limited space in which the mineral has been produced, do not destroy the identity of the species. Even amorphous masses, when the chemical composition remains unaltered, are properly classed under the same species, as the perfect crystal.

The definite chemical composition of mineral species must be taken with equal latitude. Pure substances, such as they are described in works on chemistry, are very rare in the mineral kingdom. In the most transparent quartz crystals traces of alumina and iron oxide can be detected; the purest spinel contains a small amount of silica, and the most brilliant diamond, consumed by the solar rays, leaves some ash behind. Such non-essential mixtures must be neglected, or each individual crystal would form a distinct mineral species. The isomorphous elements introduce a wider range of varieties, and render the limitation of species more difficult. Carbonate of lime, for instance, becomes mixed with carbonate of magnesia or of iron in almost innumerable proportions; and the latter substances also with the former. Where these mixtures are small in amount, variable in different specimens, and do not greatly affect the form or physical characters of the predominant element, they may safely be neglected, and the mineral reckoned to that species with which it most closely agrees. Where, however, the mixture is greater, and the two substances are frequently found in definite chemical proportions, these compounds must be considered as distinct species, especially should they also show differences in form and other external characters.

Amorphous minerals with definite composition must also be considered as true species. But when they show no definite composition, as in many substances classed as clays and ochres, they cannot be accounted true mineral species, and properly ought not to be included in a treatise on mineralogy. Some of them, however, from their importance in the arts, others from other circumstances, have received distinct names and a kind of prescriptive right to a place in mineralogical works, from which they can now scarcely be banished. Many of them are properly rocks, or indefinite combinations of two or more minerals; others are the mere products of the decomposition of such bodies. Their number is of course indefinite, and their introduction tends much to render mineralogy more complex and difficult, and to destroy its scientific character.

Mineralogy.

In collecting the species into higher groups, and arranging them in a system, several methods have been pursued. Some, like Mohs, have looked only at the external characters, and asserted that they alone were sufficient for all the purposes of arranging and classifying minerals. Others, led by Berzelius, have, on the contrary, taken chemistry as the foundation of mineralogy, and classed the species by their composition, without reference to form or physical characters.

Neither system can be exclusively adopted, and a natural classification of minerals should take into account all their characters, and that in proportion to their relative importance. Among these the chemical composition undoubtedly holds a high rank, as being that on which the other properties will probably be ultimately found to depend. Next in order is their crystalline form, especially as exhibited in cleavage; and then their other characters of gravity, hardness, and tenacity. But the properties of minerals are as yet far from showing that subordination and co-relation which has been observed in the organic world, where the external forms and structures have a direct reference to the functions of the living being. Hence even when all the characters are taken into account, there is not that facility in classifying the mineral that is presented by the other kingdoms of nature. Many, or rather most, of the species stand so isolated that it is scarcely possible to find any general principle on which to collect them into larger groups, especially such groups as, like the natural families of plants and animals, present important features of general resemblance, and admit of being described by common characteristics. Certain groups of species are indeed united by such evident characters, that they are found together in almost every method; but other species are not thus united, and the general order of arrangement is very uncertain. Hence, though some classifications of very considerable merit have been proposed, no natural system of minerals commanding general assent has yet appeared.

The arrangement followed in this treatise is chiefly founded on that proposed by Professor Weiss of Berlin. We have, however, made considerable changes, which the progress of the science and the more accurate knowledge of many species require. This classification appears to us to come nearer than any other we have seen to a natural system, which in arranging and combining objects takes account of all their characters, and assigns them their place, from a due consideration of their whole nature, and is thus distinguished from artificial systems, which classify objects with reference only to one character.

Besides species, two higher grades in classification seem sufficient at once to exhibit the natural relations, and to facilitate an easy and complete review of the species composing the mineral kingdom. These are families and orders. In forming the families those minerals are first selected which occupy the more important place in the composition of rocks, and consequently in the crust of the globe. Thus quartz, felspar, mica, hornblende, garnet, among siliceous minerals; calc-spar, gypsum, rock-salt, less so fluor spar and heavy spar, among those of saline composition, stand out prominently as the natural centres or representatives of so many distinct families. To these certain metallic minerals, as iron pyrites, lead-glance or galena, blende, magnetic iron ore, the sparry iron ore, and a few more, are readily associated as important families. But the minerals thus geologically distinguished are not sufficient to divide the whole mineral kingdom into convenient sections, and additional groups must be selected from the peculiarity of their natural-historical or chemical properties. Thus the zeolites are easily seen to form such a natural group. The precious stones or gems also, notwithstanding their diverse chemical composition, must ever appear a highly natural

Mineralogy.

family, when regarded as individual objects. Their great hardness, tenacity, high specific gravity without the metallic aspect, their brilliant lustre, transparent purity, and vivid colours,—all mark them out as a peculiar group. Only the diamond, which might naturally seem to take the chief place in this class, differs so much, not only in elementary composition, but in physical properties, that it must be assigned to a diverse place.

Round these species thus selected the other less important minerals are arranged in groups or families. It is evident that no precise definition of these families can be given, as the connection is one of resemblance in many points, not of identity in any single character. In other words, it is a classification rather according to types than from definitions, as every true natural classification must be. The same cause, however, leaves the extent of the families somewhat undefined, and also permits considerable license in the arrangement of species. But both circumstances are rather of advantage in the present state of the science, as allowing more freedom in the grouping of species than could be obtained in a more rigid system of classification.

In collecting the families into orders, the guidance of chemistry is followed rather than of natural history, though the latter is also taken into consideration. Chemical names are assigned to the orders, but still regarded as *names* derived from the prevailing chemical characters, and *not as definitions*. Hence it must not be considered an error should two or three mineral species be found in an order with whose name, viewed as a definition, they may not agree.

Guided by these, and similar considerations, minerals may be divided into the following orders and families:—

ORDER I.—THE OXIDIZED STONES.

- | | |
|------------------------------|----------------------|
| <i>Families</i> :—1. Quartz. | 8. Serpentine. |
| 2. Felspar. | 9. Hornblende. |
| 3. Scapolite. | 10. Clays. |
| 4. Haloid stones. | 11. Garnet. |
| 5. Leucite. | 12. Gems. |
| 6. Zeolite. | 13. Metallic stones. |
| 7. Mica. | |

ORDER II.—SALINE STONES.

- | | |
|---------------------------------|---------------|
| <i>Families</i> :—1. Calc spar. | 4. Gypsum. |
| 2. Fluor spar. | 5. Rock salt. |
| 3. Heavy spar. | |

ORDER III.—SALINE ORES.

- | | |
|--|------------------|
| <i>Families</i> :—1. Sparry iron ores. | 3. Copper salts. |
| 2. Iron salts. | 4. Lead salts. |

PART II.—DESCRIPTION OF MINERAL SPECIES.

ORDER I.—THE OXIDIZED STONES.

The minerals contained in this order are either simple oxides, or compounds of oxides. Oxides of the true metals are not abundant, and occur generally as isomorphous with, or replacing, the earths and alkalis which compose the greater number. They have all a stony character, non-metallic lustre and colours, and are often white and more or less translucent, except the family of the Metallic Stones, which forms a transition group to the following order.

** FAMILY I.—QUARTZ.

Contains only one true species, and hence no general characteristic. Quartz is the true type or representative of the mineral kingdom.

**1.—QUARTZ.— Si , or Si .

ORDER IV.—OXIDIZED ORES.

- | | |
|---------------------------------|-------------------------|
| <i>Families</i> :—1. Iron ores. | 4. Red copper ores. |
| 2. Tinstone. | 5. White antimony ores. |
| 3. Manganese ores. | |

ORDER V.—NATIVE METALS.

Form only one family.

ORDER VI.—SULPHURETTED METALS.

- | | |
|------------------------------------|---------------------|
| <i>Families</i> :—1. Iron pyrites. | 4. Gray copper ore. |
| 2. Galena. | 5. Blende. |
| 3. Gray antimony ore. | 6. Ruby-blende. |

ORDER VII.—THE INFLAMMABLES.

- | | |
|-------------------------------|-----------------------|
| <i>Families</i> :—1. Sulphur. | 4. Mineral resins. |
| 2. Diamond. | 5. Combustible salts. |
| 3. Coal. | |

Mineralogy.

In describing the species we have followed this general plan. First, that name which it seems most expedient to adopt is given, with the principal synonyms, followed in the same line by the probable chemical formula. In these, silica is commonly assumed as Si ; but we have given also the formula with Si for the more important species. In the descriptions the system of crystallization is noted, and the mineral more precisely characterized, by enumerating some of its more common forms and combinations with their characteristic angles. The physical characters of the species, its state of aggregation, cleavage, fracture, hardness (H.), and specific gravity (G.), follow; then its lustre, pellucidity, colour, and any other marked peculiarities. Next come its chemical characters, or its conduct before the blowpipe (B.B.), and the effect of acids, specially the hydrochloric (h.), nitric (n.), and sulphuric (s.). The chemical composition, or the amount of the different elements in 100 parts, generally deduced from the formula, but with notices of the more important variations indicated by the best analyses either from the substitution of isomorphous elements or other substances, are then noted. The principal localities where each species occurs, especially in our own country, with certain miscellaneous particulars, conclude the description.

We have also given similar characters of the orders and families, so far as this was possible. These, of course, apply chiefly to the more important and better marked or typical species (indicated by one or two asterisks [* or **] prefixed to the name), but in many points are also descriptive of the others. The possibility of forming such general characters is the best proof that the groups are so far natural, and that the object of a scientific classification has been partially at least attained.

Hexagonal; the purest varieties tetartohedral. The primary pyramid P has the middle edge $=103^{\circ} 34'$, and the polar edges $=133^{\circ} 44'$, and is often perfect. Very frequently it appears as a rhombohedron R. (or $\frac{1}{2}$ P), with polar edges $=94^{\circ} 15'$. Crystals often of $\infty P.P$; $\infty P.P.4P$, the forms ∞P and $4P$ being combined in an oscillatory manner, producing striæ on the face of the prism; $\infty P.P.\frac{1}{2}(2P2)$ (fig. 101), the last face appearing as a rhomb replacing the angles between the two other forms. They are prismatic, or pyramidal, or rhombohedral when P is divided into R and \bar{R} ; the latter very often wanting.

Fig. 101.

Mineralogy.

Twins or macles common, with parallel axes, and either merely in juxtaposition (see fig. 80), or interpenetrating. The crystals occur either single, attached, or imbedded, or in groups and druses. Most frequently granular, massive, fibrous, or columnar; also in pseudomorphs, petrifications, and other forms. Cleavage, rhombohedral along R very imperfect; prismatic along ∞P still more imperfect. Fracture conchoidal, uneven, or splintery. $H=7$; $G=2.5 \dots 2.8$, or 2.65 in the purest varieties. Colourless, but more often white, gray, yellow, brown, red, blue, green, or even black. Lustre vitreous, inclining to resinous; transparent or translucent, sometimes almost opaque. B.B. infusible alone; with soda effervesces and melts into a clear glass; insoluble in acids, except the fluoric; when pulverized, slightly soluble in solution of potash. Chem. com. 48.04 silicium and 51.96 oxygen, but frequently a small amount of the oxides of iron or titanium, of lime, alumina, and other substances.

Varieties are,—*Rock-crystal*, highly transparent and colourless; Dauphiné, Switzerland, Tyrol, Hungary, Madagascar, and Ceylon. *Amethyst*, violet-blue (from iron peroxide or manganese), and often marked by zig-zag or undulating lines, and the colour disposed in clouds; Siberia, Persia, India, Ceylon, Brazil (white or yellow named topaz), Hungary, Siebenburg, Ireland, near Cork, and Aberdeenshire. Wine yellow, or *citrin* and *gold topaz*; the brown or *smoky quartz*; and the black or *morion*; Siberia, Bohemia, Pennsylvania, and other places. *Cairngorm stone*, brown or yellow; Aberdeenshire mountains. The above are valued as ornamental stones; less so:—

Rose-quartz, red inclining to violet-blue; Ben Macdhui, and Rabenstein in Bavaria. *Milk-quartz*, milk-white and slightly opalescent; Greenland. *Prase*, leek, and other shades of green; Saxony and Cedar Mountain in South Africa. *Cat's-eye*, greenish-white or gray, olive-green, red, brown, or yellow; Ceylon and Malabar. *Avanturine*, yellow, red, or brown; India, Spain, and Scotland. *Siderite*, indigo or Berlin blue; Golling in Salzburg.

Common quartz, crystallized or massive, white or gray, also red, brown, &c., is a frequent constituent in many rocks. Some varieties are so impure as to be properly rocks, as—

(1.) *Ferruginous quartz*, or iron-flint, red, yellow, or brown, often associated with iron ores.

(2.) *Jasper*, red, yellow, or brown, but also green, gray, white, and black alone, or in spots, veins, and bands (*Ribbon* or *Egyptian jasper*); the Ural, Tuscan Apennines, the Harz, and many parts of Scotland.

(3.) *Lydian stone*, or *flinty slate*, black, gray, or white; has a splintery or conchoidal fracture, breaks into irregular fragments, and passes by many transitions into clay slate, of which it is often merely an altered portion, as in Scotland; used as a touchstone for gold, and at Elfdal manufactured into ornaments.

(4.) *Hornstone* or *chert*, compact, conchoidal splintery fracture; translucent on the edges, and dirty gray, red, yellow, green, or brown; passes into flint, flinty slate, or common quartz; common in the mountain limestone, oolite, and greensand formations; and often contains petrifications, as shells, madrepores, and wood.

Other siliceous minerals seem intermediate between quartz and opal, as,—*Flint*, grayish-white, gray, or grayish-black, also yellow, red, or brown; sometimes in clouds, spots, or stripes; semitransparent; lustre dull; fracture flat conchoidal; occurs chiefly in the chalk formation of England, North Ireland, Aberdeenshire, France, Germany, and other countries; sometimes in beds or vertical veins, oftener in irregular lumps or concretions, inclosing petrifications, as sponges, echinites, shells, or siliceous infusoria. The colour is partly derived from carbon or organic matter. It is used for gun-flints, and for the manufacture of glass and pottery, and cut into cameos or other ornaments.

Mineralogy.

Calcedony, semitransparent or translucent; white, gray, blue, green, yellow, or brown; stalactitic, reniform, or botryoidal, and in pseudomorphs or petrifications; Trevascus mine in Cornwall, Scotland, Hungary, Tyrol, Bohemia, Oberstein. *Carnelian*, chiefly blood-red, but also yellow, brown, or almost black; India, Arabia, Surinam, and Siberia; also Bohemia, Saxony, and Scotland (Perthshire). *Plasma*, leek or grass-green, and waxy lustre; Olympus, Schwarzwald, India, and China. *Chrysoprase*, apple-green; Silesia, and Vermont in North America. *Heliotrope* or *bloodstone*, dark-green, sprinkled with deep-red spots; Siberia, Bohemia, the Fassa Valley, the Island of Rum and other parts of Scotland. *Agates*, mixtures chiefly of calcedony in layers, with jasper, amethyst, or common quartz, abound in the amygdaloids of our own and other countries. *Onyx*, alternate layers of white, brown, or black, was much used in ancient times for cameos.

Some crystals are remarkable for their great size, as one in the Museum at Paris, measuring 3 feet in diameter, and weighing nearly 8 cwt. Other specimens contain cavities inclosing various substances, more than 24 known, as silver, iron pyrites, rutile, magnetite, tremolite, amianthus, mica, tourmaline, topaz; also air, water, naphtha, or other fluids.

*2. OPAL.—Si, H.

Amorphous; fracture conchoidal; very brittle. $H. = 5.5 \dots 6.5$; $G. = 2 \dots 2.2$. Transparent to opaque; vitreous, inclining to resinous. Colourless, but often white, yellow, red, brown, green, or gray, with a beautiful play of colours. B.B. decrepitates and becomes opaque, but is infusible; in the closed tube yields water; almost wholly soluble in solution of potash. Chem. com., silica, with 5 to 13 per cent. water; or probably a mere hardened natural gelatine of silica with water as an accidental mixture.

Varieties are,—(1.) *Hyalite*, *glassy opal*, or *Muller's glass*, transparent, colourless, very glassy; small botryoidal or incrusting; Frankfort on the Maine, Kaiserstuhl in the Breisgau, Schemnitz in Hungary, in Silesia, Moravia, Mexico, and other places. (2.) *Fire-opal* or *girasol*, transparent, brilliant vitreous lustre; bright hyacinth red or yellow; Zimapan in Mexico, and the Faroe Islands. (3.) *Noble opal*, semitransparent or translucent; resinous inclining to vitreous; bluish or yellowish-white, with brilliant prismatic colours; in irregular masses or veins at Czernewitz near Eperies in Hungary, Frankfort, and Gracios a Dios in Honduras. (4.) *Common opal*, semitransparent, vitreous; white, yellow, green, red, or brown; Hungary, also Faroe, Iceland, the Giant's Causeway, and the Western Isles of Scotland. (5.) *Semi-opal*, duller and less pellucid. *Wood-opal* or *lithoxylon*, with the form and texture of wood distinctly seen; Hungary, also Bohemia, and near Hobart's Town in Tasmania. (6.) *Menilite*, compact, reniform; opaque and brown or bluish-gray; Mont Menil near Paris. (7.) *Opal jasper*, blood-red, brown, or yellow. (8.) *Cacholong*, opaque, dull, glimmering, or pearly, and yellowish or rarely reddish-white; in veins or reniform and incrusting; Faroe, Iceland, the Giant's Causeway, and in Bucharia. One variety is named *Hydrophane*, from imbibing water and becoming translucent. (9.) *Siliceous sinter*, deposited from the Geyser and other hot springs near volcanoes; and *Pearl sinter*, incrusting volcanic tufa at Santa Fiora in Tuscany (*Fiorite*), in Italy, and in Auvergne. That from the Geyser contains 84.4 silica, 3.1 alumina, 1.9 peroxide of iron, 1.1 magnesia, 0.7 lime, 0.9 potash and soda, and 7.9 water.

2 b. EARTHY SILICA.—(a.) *Spongiform quartz*, coarse earthy, soft and often friable, and yellow or grayish-white; porous, and swims on water till saturated; St Ouen near Paris. (b.) *Tripoli*, coarse or fine earthy; white, gray, or yellow; near Tripoli in Africa, Corfu, Bohemia, Saxony, and Bavaria. (c.) *Polishing slate* (*Polirschiefer*), white or yellow; slaty texture, opaque, brittle, and swims on water; at Bilin

Minera-
logy.

family, when regarded as individual objects. Their great hardness, tenacity, high specific gravity without the metallic aspect, their brilliant lustre, transparent purity, and vivid colours,—all mark them out as a peculiar group. Only the diamond, which might naturally seem to take the chief place in this class, differs so much, not only in elementary composition, but in physical properties, that it must be assigned to a diverse place.

Round these species thus selected the other less important minerals are arranged in groups or families. It is evident that no precise definition of these families can be given, as the connection is one of resemblance in many points, not of identity in any single character. In other words, it is a classification rather according to types than from definitions, as every true natural classification must be. The same cause, however, leaves the extent of the families somewhat undefined, and also permits considerable license in the arrangement of species. But both circumstances are rather of advantage in the present state of the science, as allowing more freedom in the grouping of species than could be obtained in a more rigid system of classification.

In collecting the families into orders, the guidance of chemistry is followed rather than of natural history, though the latter is also taken into consideration. Chemical names are assigned to the orders, but still regarded *as names* derived from the prevailing chemical characters, and *not as definitions*. Hence it must not be considered an error should two or three mineral species be found in an order with whose name, viewed as a definition, they may not agree.

Guided by these, and similar considerations, minerals may be divided into the following orders and families:—

ORDER I.—THE OXIDIZED STONES.

- | | |
|------------------------------|----------------------|
| <i>Families</i> :—1. Quartz. | 8. Serpentine. |
| 2. Felspar. | 9. Hornblende. |
| 3. Scapolite. | 10. Clays. |
| 4. Haloid stones. | 11. Garnet. |
| 5. Leucite. | 12. Gems. |
| 6. Zeolite. | 13. Metallic stones. |
| 7. Mica. | |

ORDER II.—SALINE STONES.

- | | |
|---------------------------------|---------------|
| <i>Families</i> :—1. Calc spar. | 4. Gypsum. |
| 2. Fluor spar. | 5. Rock salt. |
| 3. Heavy spar. | |

ORDER III.—SALINE ORES.

- | | |
|--|------------------|
| <i>Families</i> :—1. Sparry iron ores. | 3. Copper salts. |
| 2. Iron salts. | 4. Lead salts. |

ORDER IV.—OXIDIZED ORES.

Minera-
logy.

In describing the species we have followed this general plan. First, that name which it seems most expedient to adopt is given, with the principal synonyms, followed in the same line by the probable chemical formula. In these, silica is commonly assumed as Si ; but we have given also the formula with $\ddot{\text{Si}}$ for the more important species. In the descriptions the system of crystallization is noted, and the mineral more precisely characterized, by enumerating some of its more common forms and combinations with their characteristic angles. The physical characters of the species, its state of aggregation, cleavage, fracture, hardness (H.), and specific gravity (G.), follow; then its lustre, pellucidity, colour, and any other marked peculiarities. Next come its chemical characters, or its conduct before the blowpipe (B.B.), and the effect of acids, specially the hydrochloric (*h.*), nitric (*n.*), and sulphuric (*s.*). The chemical composition, or the amount of the different elements in 100 parts, generally deduced from the formula, but with notices of the more important variations indicated by the best analyses either from the substitution of isomorphous elements or other substances, are then noted. The principal localities where each species occurs, especially in our own country, with certain miscellaneous particulars, conclude the description.

We have also given similar characters of the orders and families, so far as this was possible. These, of course, apply chiefly to the more important and better marked or typical species (indicated by one or two asterisks [*** or ****] prefixed to the name), but in many points are also descriptive of the others. The possibility of forming such general characters is the best proof that the groups are so far natural, and that the object of a scientific classification has been partially at least attained.

PART II.—DESCRIPTION OF MINERAL SPECIES.

ORDER I.—THE OXIDIZED STONES.

The minerals contained in this order are either simple oxides, or compounds of oxides. Oxides of the true metals are not abundant, and occur generally as isomorphous with, or replacing, the earths and alkalies which compose the greater number. They have all a stony character, non-metallic lustre and colours, and are often white and more or less translucent, except the family of the Metallic Stones, which forms a transition group to the following order.

**** FAMILY I.—QUARTZ.**

Contains only one true species, and hence no general characteristic. Quartz is the true type or representative of the mineral kingdom.

****1.—QUARTZ.**— $\ddot{\text{Si}}$, or $\ddot{\text{Si}}$.

Hexagonal; the purest varieties tetartohedral. The primary pyramid P has the middle edge $=103^{\circ}34'$, and the polar edges $=133^{\circ}44'$, and is often perfect. Very frequently it appears as a rhombohedron R. (or $\frac{1}{2}$ P), with polar edges $=94^{\circ}15'$. Crystals often of ∞ P . P; ∞ P . P . 4 P, the forms ∞ P and 4 P being combined in an oscillatory manner, producing striae on the face of the prism; ∞ P . P . $\frac{1}{2}$ (2 P 2) (fig. 101), the last face appearing as a rhomb replacing the angles between the two other forms. They are prismatic, or pyramidal, or rhombohedral when P is divided into R and $\bar{\text{R}}$; the latter very often wanting.

Fig. 101.

Mineralogy.

Twins or macles common, with parallel axes, and either merely in juxtaposition (see fig. 80), or interpenetrating. The crystals occur either single, attached, or imbedded, or in groups and druses. Most frequently granular, massive, fibrous, or columnar; also in pseudomorphs, petrifications, and other forms. Cleavage, rhombohedral along R very imperfect; prismatic along ∞P still more imperfect. Fracture conchoidal, uneven, or splintery. $H=7$; $G=2.5 \dots 2.8$, or 2.65 in the purest varieties. Colourless, but more often white, gray, yellow, brown, red, blue, green, or even black. Lustre vitreous, inclining to resinous; transparent or translucent, sometimes almost opaque. B.B. infusible alone; with soda effervesces and melts into a clear glass; insoluble in acids, except the fluoric; when pulverized, slightly soluble in solution of potash. Chem. com. 48.04 silicium and 51.96 oxygen, but frequently a small amount of the oxides of iron or titanium, of lime, alumina, and other substances.

Varieties are,—*Rock-crystal*, highly transparent and colourless; Dauphiné, Switzerland, Tyrol, Hungary, Madagascar, and Ceylon. *Amethyst*, violet-blue (from iron peroxide or manganese), and often marked by zig-zag or undulating lines, and the colour disposed in clouds; Siberia, Persia, India, Ceylon, Brazil (white or yellow named topaz), Hungary, Siebenburg, Ireland, near Cork, and Aberdeenshire. Wine yellow, or *citrin* and *gold topaz*; the brown or *smoky quartz*; and the black or *morion*; Siberia, Bohemia, Pennsylvania, and other places. *Cairngorm stone*, brown or yellow; Aberdeenshire mountains. The above are valued as ornamental stones; less so:—

Rose-quartz, red inclining to violet-blue; Ben Macdhui, and Rabenstein in Bavaria. *Milk-quartz*, milk-white and slightly opalescent; Greenland. *Prase*, leek, and other shades of green; Saxony and Cedar Mountain in South Africa. *Cat's-eye*, greenish-white or gray, olive-green, red, brown, or yellow; Ceylon and Malabar. *Avanturine*, yellow, red, or brown; India, Spain, and Scotland. *Siderite*, indigo or Berlin blue; Golling in Salzburg.

Common quartz, crystallized or massive, white or gray, also red, brown, &c., is a frequent constituent in many rocks. Some varieties are so impure as to be properly rocks, as—

(1.) *Ferruginous quartz*, or iron-flint, red, yellow, or brown, often associated with iron ores.

(2.) *Jasper*, red, yellow, or brown, but also green, gray, white, and black alone, or in spots, veins, and bands (*Ribbon* or *Egyptian jasper*); the Ural, Tuscan Apennines, the Harz, and many parts of Scotland.

(3.) *Lydian stone*, or *flinty slate*, black, gray, or white; has a splintery or conchoidal fracture, breaks into irregular fragments, and passes by many transitions into clay slate, of which it is often merely an altered portion, as in Scotland; used as a touchstone for gold, and at Elfdal manufactured into ornaments.

(4.) *Hornstone* or *chert*, compact, conchoidal splintery fracture; translucent on the edges, and dirty gray, red, yellow, green, or brown; passes into flint, flinty slate, or common quartz; common in the mountain limestone, oolite, and greensand formations; and often contains petrifications, as shells, madrepores, and wood.

Other siliceous minerals seem intermediate between quartz and opal, as,—*Flint*, grayish-white, gray, or grayish-black, also yellow, red, or brown; sometimes in clouds, spots, or stripes; semitransparent; lustre dull; fracture flat conchoidal; occurs chiefly in the chalk formation of England, North Ireland, Aberdeenshire, France, Germany, and other countries; sometimes in beds or vertical veins, oftener in irregular lumps or concretions, inclosing petrifications, as sponges, echinites, shells, or siliceous infusoria. The colour is partly derived from carbon or organic matter. It is used for gun-flints, and for the manufacture of glass and pottery, and cut into cameos or other ornaments.

Calcedony, semitransparent or translucent; white, gray, blue, green, yellow, or brown; stalactitic, reniform, or botryoidal, and in pseudomorphs or petrifications; Trevascus mine in Cornwall, Scotland, Hungary, Tyrol, Bohemia, Oberstein. *Carnelian*, chiefly blood-red, but also yellow, brown, or almost black; India, Arabia, Surinam, and Siberia; also Bohemia, Saxony, and Scotland (Perthshire). *Plasma*, leek or grass-green, and waxy lustre; Olympus, Schwarzwald, India, and China. *Chrysoprase*, apple-green; Silesia, and Vermont in North America. *Heliotrope* or *bloodstone*, dark-green, sprinkled with deep-red spots; Siberia, Bohemia, the Fassa Valley, the Island of Rum and other parts of Scotland. *Agates*, mixtures chiefly of calcedony in layers, with jasper, amethyst, or common quartz, abound in the amygdaloids of our own and other countries. *Onyx*, alternate layers of white, brown, or black, was much used in ancient times for cameos.

Some crystals are remarkable for their great size, as one in the Museum at Paris, measuring 3 feet in diameter, and weighing nearly 8 cwt. Other specimens contain cavities inclosing various substances, more than 24 known, as silver, iron pyrites, rutile, magnetite, tremolite, amianthus, mica, tourmaline, topaz; also air, water, naphtha, or other fluids.

*2. OPAL.— Si , H .

Amorphous; fracture conchoidal; very brittle. $H=5.5 \dots 6.5$; $G=2 \dots 2.2$. Transparent to opaque; vitreous, inclining to resinous. Colourless, but often white, yellow, red, brown, green, or gray, with a beautiful play of colours. B.B. decrepitates and becomes opaque, but is infusible; in the closed tube yields water; almost wholly soluble in solution of potash. Chem. com., silica, with 5 to 13 per cent. water; or probably a mere hardened natural gelatine of silica with water as an accidental mixture.

Varieties are,—(1.) *Hyalite*, *glassy-opal*, or *Muller's glass*, transparent, colourless, very glassy; small botryoidal or incrusting; Frankfort on the Maine, Kaiserstuhl in the Breisgau, Schemnitz in Hungary, in Silesia, Moravia, Mexico, and other places. (2.) *Fire-opal* or *girasol*, transparent, brilliant vitreous lustre; bright hyacinth red or yellow; Zimapan in Mexico, and the Faroe Islands. (3.) *Noble opal*, semitransparent or translucent; resinous inclining to vitreous; bluish or yellowish-white, with brilliant prismatic colours; in irregular masses or veins at Czernewitz near Eperies in Hungary, Frankfort, and Gracios a Dios in Honduras. (4.) *Common opal*, semitransparent, vitreous; white, yellow, green, red, or brown; Hungary, also Faroe, Iceland, the Giant's Causeway, and the Western Isles of Scotland. (5.) *Semi-opal*, duller and less pellucid. *Wood-opal* or *lithoxylon*, with the form and texture of wood distinctly seen; Hungary, also Bohemia, and near Hobart's Town in Tasmania. (6.) *Menilite*, compact, reniform; opaque and brown or bluish-gray; Mont Menil near Paris. (7.) *Opal jasper*, blood-red, brown, or yellow. (8.) *Cacholong*, opaque, dull, glimmering, or pearly, and yellowish or rarely reddish-white; in veins or reniform and incrusting; Faroe, Iceland, the Giant's Causeway, and in Bucharra. One variety is named *Hydrophane*, from imbibing water and becoming translucent. (9.) *Siliceous sinter*, deposited from the Geyser and other hot springs near volcanoes; and *Pearl sinter*, incrusting volcanic tufa at Santa Fiora in Tuscany (*Fiorite*), in Italy, and in Auvergne. That from the Geyser contains 84.4 silica, 3.1 alumina, 1.9 peroxide of iron, 1.1 magnesia, 0.7 lime, 0.9 potash and soda, and 7.9 water.

2 b. EARTHY SILICA.—(a.) *Spongiform quartz*, coarse earthy, soft and often friable, and yellow or grayish-white; porous, and swims on water till saturated; St Ouen near Paris. (b.) *Tripoli*, coarse or fine earthy; white, gray, or yellow; near Tripoli in Africa, Corfu, Bohemia, Saxony, and Bavaria. (c.) *Polishing slate* (*Polirschiefer*), white or yellow; slaty texture, opaque, brittle, and swims on water; at Bilin

Mineralogy.

Mineralogy.

in Bohemia; consists of the siliceous remains of animals or plants (*Diatomaceæ*). (d.) *Adhesive slate*, from Montmartre near Paris; and (e.) *Mountain meal*, snow-white, pearly, gray, or greenish; have a similar origin; Santa Fiora in Tuscany, Oberolie in Hanover, Kymmenegard in Sweden (where used as food), in Bohemia, and the Isle of France.

** FAMILY II.—FELSPAR.

Crystallization monoclinohedric or triclinohedric, both very similar in aspect and angles. Cleavage very distinct, especially the basal *P*; less so the clino- or brachy-diagonal *M*. $G = 2.4 \dots 3.2$, but mostly $2.5 \dots 2.8$; $H = 6$, or a little more. Slightly or not at all soluble in acids. B.B. fusible, but often with difficulty. Translucent, pure varieties highly transparent. Colourless, white, or shades of red; less common, green or yellow. Chem. com. anhydrous silicates of alumina, and of an alkali or lime.

The feldspars are very important constituents of the earth's crust, occurring in nearly all the igneous rocks, and in many of the stratified crystalline schists. In true strata, they are found chiefly as fragments or decomposed, and in the latter state form a large part of most soils and clays. In the older mineralogists and popular language many species are conjoined under the common name of feldspar, which are now considered as distinct, each of them having not only its peculiar physical and chemical characters, but also geognostic position and associated group of minerals. Thus orthoclase, and the other more siliceous feldspars with potash, abound in granite and the plutonic rocks; the less siliceous, with soda and lime, characterize the volcanic rocks—as labradorite the basaltic group, glassy feldspar the trachytic. Orthoclase occurs with quartz, hornblende, and mica; glassy feldspar only with hornblende and mica, or only with augite; labradorite only with augite, rarely if ever with quartz or hornblende.

The feldspars are best known from similar minerals by their hardness (scarce scratch with a good knife), difficult fusibility, and unequal cleavages. The following marks may aid the student in distinguishing the more common species. If the basal cleavage plane is turned to the spectator, then in orthoclase it forms a right angle with the clinodiagonal cleavage planes *M* on both hands; in albite, oligoclase, and petalite it forms an obtuse angle with *M* on his right hand; and in labradorite and anorthite on his left hand. Orthoclase, albite, andesin, and oligoclase are insoluble in acids; ryacolite, labradorite, and anorthite more or less soluble.

S. von Waltershausen states that the feldspars form a series with the oxygen of the silica, alumina, and $R = x : 3 : 1$, in which x ranges from 24 to 4. Baulite (with 80 silica), albite (69 silica), and anorthite (44 silica), being the three true species, of which the others are mixtures, according to a peculiar law (isomorphism of groups).

** 3. ORTHOCLASE.— $\text{Al Si}^3 + \text{K Si}^3$, or $\text{Al Si}^3 + \text{K Si}$. Monoclinohedric; $C = 65^\circ 47'$, $\infty P 118^\circ 50'$, $P \infty 63^\circ 53'$, ($2P \infty$) 90° , $2P \infty 35^\circ 12'$. Crystals often of $\infty P \cdot OP$. $P \infty$; or ($\infty P \infty$). (*M*). ∞P (*T*, *l*) $\cdot OP$ (*P*). $2P \infty$ (*y*), (fig. 102), are short rhombic prisms, when ∞P predominates; or tabular when ($\infty P \infty$); or short hexagonal prismatic when ∞P and ($\infty P \infty$); or rectangular prismatic when OP and ($\infty P \infty$) predominate; and occur single, attached, or in druses. Macles are frequent, especially with the twin axis parallel to the chief axis, and often partially interpenetrating as in fig. 103; also massive and coarse or fine granular. Cleavage, basal (*P*) very perfect; clinodiagonal (*M*) perfect (*P* to *M* = 90°);

Fig. 102.

and hemiprismatic ∞P in traces. Fracture conchoidal or uneven and splintery. $H = 6$; $G = 2.53 \dots 2.58$. Transparent to translucent on the edges; vitreous, but often pearly on the more perfect cleavage; and also opalescent, with bluish or changing colours. Colourless, but generally red, yellow, gray, or green. B.B. fuses with difficulty to an opaque vesicular glass; not affected by acids. Chem. com. 65.4 silica, 18 alumina, and 16.6 potash, but generally 10 to 14 potash, 1 to 4 soda, 0 to 1.3 lime, 0 to 2 iron peroxide.

Fig. 103.

Varieties are,—(1.) *Adularia* and *Ice-spar*, transparent or translucent, splendid, and almost or wholly colourless. Some with a bluish opalescence are named *Moonstone*; St Gotthardt, Mont Blanc, Dauphiné, Arendal, Southern Norway, Greenland, and Ceylon.

(2.) *Common feldspar*, less splendid and transparent, and generally white or red, especially flesh-red, is a very common constituent of many rocks. Crystals at Baveno on Lago Maggiore, Lomnitz in Silesia, Mourne Mountains and Wicklow in Ireland, Aberdeenshire (at Rubislaw, 4 or 5 inches long) in Scotland, and at Carlsbad and Elnbogen in Bohemia. *Amazon stone*, verdigris-green, from Lake Ilmen; and *Murchisonite*, golden or grayish-yellow, from Arran and Dawlish, seem varieties.

(3.) The *Glassy feldspar* or *sanadine* ($C = 63^\circ 55'$, $\infty P 119^\circ 13'$), contains 3 to 12 potash, 3 to 10 soda, 0 to 3 lime, and 0 to 2 magnesia. Crystals imbedded, yellowish-white or gray; vitreous; transparent or translucent, and often much cracked;

Macles of common Feldspar.

RIGHT.

Fig. 104.

LEFT.

Drachenfels on the Rhine, Mont d'Or and other parts of Auvergne, Hungary, Italy, Iceland, Mexico, Chili, and other countries; also in Arran, Rum, and other parts of Scotland. *Ryacolite*, from Vesuvius and Lake Laach, is only a variety—the specimen analysed, having been impure. *Loxoclase*, from Hammond, New York, also a variety with much soda. *Baulite* and *Krabbite* from Iceland, probably mixtures with quartz.

Orthoclase occurs in granite, gneiss, and porphyry in many countries. It is commonly associated with quartz, sometimes, as in the graphic granite of Portsoy and Aberdeenshire, in regular combinations. It is very liable to decomposition, when it is converted especially into kaolin, used for manufacturing porcelain and stoneware. The adularia or moonstone, and the green amazon stone are cut as ornamental stones.

Compact feldspar, or *feldstein*, a mixture of orthoclase and quartz, often harder than the pure mineral. $G = 2.59 \dots 3$. White, gray, red, or yellow, sometimes in spots or bands. The softer varieties, or *claystones*, often bluish or purplish. $G = 2.21$. B.B. most melt with difficulty to a white enamel (hornstone is infusible). Common in the porphyry rocks of many countries, as in Scotland (Cheviots,

Mineralogy.

Mineralogy.

Pentland, and Ochil Hills), and Sweden (*leelite* from Grythyttan).

**** 4. ALBITE.**— $\text{Al Si}^3 + \text{Na Si}^3$, or $\text{Al Si}^3 + \text{Na Si}$.

Triclinohedric; $\text{OP} (P)$ to $\infty P \infty (M) = 86^\circ 24'$, $\infty P' (l)$ to $\infty P (T) = 122^\circ 15'$. Crystals, generally like those of orthoclase, are tabular or prismatic (fig. 105). Macles very

Fig. 105.

common, especially united by a face of $\infty P \infty$ (fig. 106), the re-entering angle between the faces of $\text{OP} (P$ and $P' = 172^\circ 48')$ being very characteristic. Fig. 107 is another macle common in pericline. Also massive and foliated or radiating. Cleavage, basal and brachydiagonal almost equally perfect, prismatic along ∞P imperfect; fracture

Fig. 106.

Fig. 107.

conchoidal or uneven. $H. = 6 \dots 6.5$; $G. = 2.6 \dots 2.67$. Rarely transparent, usually translucent or only on the edges; vitreous, inclining to pearly on the cleavage. Colourless, but generally white, gray, green, red, or yellow; streak white. B.B. difficultly fusible, tinging the flame yellow, to a white semi-opaque glass; not affected by acids. Chem. com. 69.3 silica, 19.1 alumina with 0.1 to 1 iron peroxide and 11.6 soda with 0.3 to 4 lime, 0 to 2.5 potash, and 0 to 0.5 magnesia. Hence albite and orthoclase both contain soda and potash, only in different proportions. Albite is best marked by the frequent re-entering angles, its more easy fusibility, and the obliquity ($93^\circ 36'$) of its cleavage planes. *Pericline*, with $G. = 2.54 \dots 2.6$, and slight diversity in angles, is only a variety.

Albite is a constituent of many greenstones (Edinburgh), of granite (Aberdeenshire), syenite, gneiss, porphyry, and trachyte; also in beds and veins; crystals at Barèges in the Pyrenees, Bourg d'Oisans in Dauphiné, St Gotthardt, the Tyrol, Salzburg, and Arendal. *Adinole* is a compact gray or red mixture of albite and quartz.

5. ANDESIN.— $\text{Al Si}^2 + (\text{Na}, \text{Ca}) \text{Si}$.

Triclinohedric; crystals and physical properties similar to albite, but the cleavage less distinct. $G. = 2.67 \dots 2.73$. B.B. more easily fusible (like oligoclase) to a milky somewhat porous glass. Chem. com. 60 silica, 25 alumina, 7 soda, 6 lime, 1 potash, and 1 magnesia. Cordilleras, in andesite or diorite porphyry; Vosges Mountains, near Dresden, and Iceland.

Saccharite, compact, or fine granular; white or apple-green; Frankenstein, Silesia, and Canada; seems a variety.

**** 6. LABRADORITE.**— $\text{Al Si}^2 + (\text{Ca}, \text{Na}) \text{Si}$, or $\text{Al Si} + \text{R Si}$.

Triclinohedric; $\text{OP} : \infty P \infty = 86^\circ 25'$, $\text{OP} : \infty P' = 114^\circ 26'$. Crystals rare; mostly massive and granular; macles like

those of pericline (fig. 107). Cleavage basal, very perfect, brachydiagonal less so; both usually striated. $H. = 6$; $G. = 2.68 \dots 2.74$. Translucent, or only on the edges; vitreous, on the cleavage pearly or resinous. Gray, passing into white, green, yellow, or red. The faces of $\infty P \infty$ often exhibit very beautiful changing colours,—blue, green, yellow, red, or brown,—sometimes in bands intersecting at certain angles. B.B. fuses more readily than orthoclase to a compact colourless glass; soluble when pulverized in n. acid. Chem. com. 53.7 silica, 29.7 alumina with 1 to 2 iron peroxide, 12.1 lime, and 4.5 soda with 0.3 to 2 potash, 0.1 to 2 magnesia, and 1 to 3 water—the latter probably not essential.

Common constituent of dolerite, greenstone, the gabbro, and hypersthene rocks. Labrador, Finland, Harz, Meissner, Tyrol, Mourne Mountains, Campsie and Milngavie near Glasgow, and Skye; also Etna and Vesuvius, and in meteoric stones.

Scolexerose, from Pargas, is a pure lime-labradorite. *Glaucolite*, from Lake Baikal, pale blue or greenish, with traces of cleavage in two directions, and $G. = 2.72 \dots 3.2$, is not distinct. *Saussurite*, compact, dull, subtranslucent; gray, inclining to blue, green, or red; B.B. fuses to a gray or greenish-white enamel, and is not acted on by acids; is merely an impure labradorite. Alps near Geneva, Harz, Styria, Apennines, and Corsica.

7. COUZERANITE.— $2 \text{Al Si}^2 + 3 (\text{Ca}, \text{K}, \text{Na}, \text{Mg}) \text{Si}$.

Monoclinohedric; $C = 87^\circ$, $\infty P = 96^\circ$. Cleavage clinodagonal. $H. = 6$; $G. = 2.69$. Opaque, vitreous, or resinous. Pitch-black, blackish-blue, or gray. B.B. melts to a white enamel; not affected by acids. Chem. com. by Dufresnoy's analysis, 52.37 silica, 24.02 alumina, 11.85 lime, 1.40 magnesia, 5.52 potash, and 3.96 soda. Couzerans in the Pyrenees.

8. ANORTHITE, Christianite.— $\text{Al Si} + \text{Ca Si}$, or $3 \text{Al Si} + \text{R}^3 \text{Si}$.

Triclinohedric; $\text{OP} : \infty P \infty = 85^\circ 48'$; $\infty P' : \infty P = 120^\circ 30'$. Crystals and macles like albite, with angle between P and $P' = 188^\circ 24'$. Cleavage, basal and brachydiagonal perfect. $H. = 6$; $G. = 2.7 \dots 2.76$. Transparent or translucent; vitreous. Colourless or white. B.B. fuses to a clear glass; soluble without gelatinizing in con. h. acid. Chem. com. 43.9 silica, 36.3 alumina, and 19.8 lime with 1 to 5 magnesia, 0.3 to 8 soda, 0.2 to 1 potash, and 0.1 to 2 iron peroxide. Monte Somma, Iceland, Java.

Amphodelite has the same composition and a close resemblance in crystalline forms, cleavage, and macles; is reddish-gray, or dirty peach-blossom red. Lojo in Finland, and Tunaberg in Sweden. *Indianite* from the Carnatic; gelatinizes with acids; and B.B. is infusible.

*** 9. OLIGOCLASE.**— $2 \text{Al Si}^3 + \text{Na}^2 \text{Si}^3$, or $\text{Al Si}^2 + \text{Na Si}$.

Triclinohedric; $\text{OP} : \infty P \infty = 86^\circ 45'$; $\infty P' : \infty P$ about 120° . Crystals rather rare, and macles resemble albite. Cleavage, basal perfect; brachydiagonal less perfect; $\infty P'$ imperfect. $H. = 6$; $G. = 2.64 \dots 2.68$. More or less translucent; vitreous, pearly or resinous on the cleavage. White, with a tinge of green, gray, or red. B.B. melts easier than orthoclase or albite to a clear glass; not affected by acids. Chem. com. 63 silica, 23 alumina, and 14 soda; but 20 to 24 alumina, 7 to 12 soda, 1 to 4 potash, 5 to 4 lime, 0 to 1 magnesia, and 0 to 4 iron peroxide. Scotland, Scandinavia, Ural, Harz, and Morea. The *Sunstone* or *Aventurine felspar* from Tvedestrand, Norway, Lake Baikal, and Ceylon, with a fine play of colour, belongs to this species. *Hafnefordite*, in lava, Hafneford, Iceland; $G. = 2.729$; is a lime-oligoclase.

10. LATROBITE.— $4 \text{Al} (\text{Mn}) \text{Si} + 3 (\text{Ca}, \text{Mg}, \text{K}) \text{Si}^2 (?)$.

Diploite.— } Triclinohedric; crystals indistinct, prismatic; mostly

Mineralogy.

Mineralogy.

Indigo, smalt, or other shades of blue inclining to green or white; streak white. In closed tube yields water and loses its colour. B.B. intumesces, but does not melt. With cobalt solution assumes a fine blue colour. Scarcely affected by acids till after ignition, when almost wholly soluble. Chem. com. 44.1 phosphoric acid, 31.7 alumina, 9 to 12 magnesia, 2 to 10 iron protoxide, 1 to 4 lime, and 5.7 water. Werfen in Salzburg, Vorau (*Voraulite*) and Krieglach in Styria, Tijuco in Brazil, and Lincoln county in North Carolina.

30. CALAITE, Turquoise.— $\ddot{\text{Al}}^2 \ddot{\text{P}} + 5 \text{ H}$.

Reniform; stalactitic or incrusting. Fracture conchoidal. H.=6; G.=2.6...2.8. Opaque or translucent on the edges; dull or waxy. Sky-blue, greenish-blue, rarely green; streak greenish-white. In the closed tube yields water, decrepitates violently, and becomes black. B.B. infusible, but colours the flame green. Soluble in acids. Chem. com. 46.89 alumina, 32.57 phosphoric acid, and 20.54 water, but mixed with phosphate of iron and copper. Silesia, Lausitz, and Voigtland. Oriental turquoise, in veins, at Meschid near Herat; in pebbles in Khorazan, Bucharia, and Syrian desert. Takes a fine polish, and is valued as an ornamental stone.

31. FISCHERITE.— $\ddot{\text{Al}} \ddot{\text{P}} + 8 \text{ H}$.

Rhombic; $\infty \text{P } 118^\circ 32'$, mostly in crusts or indistinct six-sided prisms. H.=5; G.=2.46. Transparent; vitreous; green. Slightly soluble in h. or n., wholly in s. acid, and on heating becomes white or partly black. Chem. com. 42 alumina, 29 phosphoric acid, 29 water, with a little lime and copper oxide. Nischnei Tagilsk.

Peganite.—Probably rhombic, $\infty \text{P } 127^\circ$ nearly; in very small prismatic crystals or thin crusts. Emerald, grass-green, or white. H.=3...4; G.=2.49...2.54. Chem. com. like Fischerite, but 6 H. Strigis in Saxony.

Variscite.—Reniform; incrusting; weak resinous; greasy feel; green. G.=2.34...2.38; H.=5. In the closed tube it yields much water, and assumes a rose-red colour. Chem. com. chiefly phosphate of alumina, with water, magnesia, protoxide of iron, and chrome-oxide. Plauen in the Voigtland.

*32. WAVELLITE, Lasionite.— $\ddot{\text{Al}}^3 \ddot{\text{P}}^2 + 12 \text{ H}$.

Rhombic, $\infty \text{P } 126^\circ 25'$, $\bar{\text{P}} \infty 106^\circ 46'$; crystals $\infty \text{P} \infty$ (P). ∞P (d). $\bar{\text{P}} \infty$ (o) (fig. 109); but generally small, acicular, and in hemispherical radiated fibrous masses. Cleavage, along ∞P and $\bar{\text{P}} \infty$ rather perfect. H.=3.5...4; G.=2.3...2.5. Translucent; vitreous. Colourless, but generally yellowish or grayish, sometimes green or blue. In closed tube yields water. B.B. in the forceps colours the flame weak bluish-green; on charcoal intumesces, and becomes snow-white. Soluble in acids. Chem. com. 38.0 alumina, 35.3 phosphoric acid, and 26.7 water; but generally traces of fluoric acid (2 per cent.). Beraun in Bohemia, Amberg in Bavaria, Frankenberg in Saxony, Tanne in the Harz, Barnstaple in Devonshire, St Austle in Cornwall, near Clonmel, Cork, and Portrush, Ireland, and in the Shiant Isles in Scotland; also in New Hampshire and Tennessee.

33. WAGNERITE.— $\ddot{\text{Mg}}^3 \ddot{\text{P}} + \text{Mg F}$.

Monoclinohedric; C=63° 25', $\infty \text{P } 57^\circ 35'$, $\text{P} \infty 71^\circ 53'$. Cleavage, prismatic and orthodiagonal imperfect. Fracture conchoidal or splintery. H.=5...5.5; G.=3.0...3.1. Translucent or transparent; resinous. Wine-yellow, honey-yellow, and white. B.B. fuses with great difficulty in thin splinters to a dark greenish-gray glass. Chem. com. 43.32 phosphoric acid, 11.35 fluorine, 37.64 magnesia, and 7.69 magnesium; but with 3 to 4.5 iron protoxide, and 1 to 4 lime. Very rare; Werfen in Salzburg.

34. AMBLYGONITE. $\left\{ \begin{array}{l} \ddot{\text{Al}}^5 \ddot{\text{P}}^3 + (\text{Li}, \text{Na})^5 \ddot{\text{P}} + \text{Al F}^3 \\ + (\text{Li}, \text{Na}) \text{ F} \end{array} \right.$

Rhombic; coarse granular. Cleavage, $\infty \text{P } 106^\circ 10'$, tolerably perfect. Fracture uneven and splintery. H.=6; G.=3...3.1. Translucent; vitreous; pearly on ∞P . Grayish or greenish-white to pale mountain-green. In closed tube yields water, sometimes corroding the glass. B.B. fuses very readily to a transparent glass, opaque when cold. Finely pulverized it is slowly soluble in acids. Chem. com. 47.9 phosphoric acid, 34.5 alumina, 6.9 lithia, 6 soda, and 8.3 fluorine. Penig in Saxony.

FAMILY V.—LEUCITE.

Tesseral. H.=5...6; G.=2.2...2.5. All fusible except leucite, and all soluble and mostly gelatinize in hydrochloric acid. They are mostly silicates of alumina and of alkalis (or lime), often with chlorine, sulphur, or sulphuric acid. Their colours are white, gray, or often blue. They are mostly found imbedded in volcanic rocks.

35. LEUCITE.— $(\ddot{\text{Al}} \ddot{\text{Si}}^3 + \ddot{\text{K}} \ddot{\text{Si}}, \text{ or } 3 \ddot{\text{Al}} \ddot{\text{Si}}^2 + \ddot{\text{K}}^3 \ddot{\text{Si}}^2)$

Tesseral; only 202 (fig. 6). The crystals generally single. Cleavage, hexahedral very imperfect. Fracture conchoidal. H.=5.5...6; G.=2.4...2.5. Transparent to translucent on the edges; vitreous, inclining to resinous. Colourless, but grayish, yellowish, or reddish-white, or gray; streak white. B.B. infusible; with cobalt solution becomes blue. Soluble in h. acid, without gelatinizing. Chem. com. 55.7 silica, 23.1 alumina, and 21.2 potash. Abundant in the lavas of Vesuvius, the tufas near Rome, and the peperino of Albano; also at the Kaiserstuhl, and near Lake Laach. Readily distinguished from Analcime by its infusibility and by never showing faces of the cube.

36. PORCELAIN SPAR.— $3 \ddot{\text{Al}} \ddot{\text{Si}}^2 + (\ddot{\text{Ca}} \ddot{\text{Na}})^4 \ddot{\text{Si}}^3 + \frac{1}{2} \text{K Cl}$.

Rhombic; $\infty \text{P } 92^\circ$ nearly. Massive and coarse granular. Fracture uneven. H.=5.5; G.=2.67...2.68. Translucent, or only on the edges; vitreous or pearly. Yellowish or bluish-white, or pale gray. B.B. fuses easily with intumescence to a colourless vesicular glass. Soluble without gelatinizing in con. h. acid. Chem. com. 49.55 silica, 27.40 alumina, 15.62 lime, 4.75 soda, 1.39 potassium, and 1.29 chlorine. Oberzell near Passau (*Passauite*), forming porcelain earth when decomposed.

37. SODALITE.— $3 (\ddot{\text{Al}} \ddot{\text{Si}} + \ddot{\text{Na}} \ddot{\text{Si}}) + \text{Na Cl}$.

Tesseral; ∞O (fig. 3); massive and granular. Cleavage, ∞O more or less perfect. Fracture conchoidal or uneven. H.=5.5; G.=2.28...2.29. Translucent; vitreous, inclining to resinous. White, gray, green, and rarely blue. B.B. becomes white and fuses easily alone, sometimes intumescing to a clear glass; with difficulty in borax. Gelatinizes with acids. Chem. com. 37.8 silica, 31.3 alumina, 25.3 soda, and 5.6 chlorine. Greenland, Vesuvius, Valle di Noto in Sicily, Lake Laach, Ilmen Hills, Fredriksvärn in Norway, and Litchfield in Maine.

*38. HAUYNE.— $3 (\ddot{\text{Al}} \ddot{\text{Si}} + \ddot{\text{Na}} \ddot{\text{Si}}) + 2 \text{ Ca } \ddot{\text{S}}$.

Tesseral chiefly ∞O , but more common in grains. Cleavage ∞O more or less perfect. H.=5...5.5; G.=2.4...2.5. Semi-transparent or translucent; vitreous or resinous. Azure or sky blue; streak bluish-white. B.B. decrepitates violently, and melts to a bluish-green vesicular glass. Soluble, and gelatinizes in h. acid. Chem. com. 32.5 silica, 27.1 alumina, 16.4 soda, 9.9 lime, and 14.1 sulphuric acid. Vesuvius, Mount Vultur near Melfi, the Campagna of Rome, and Niedermendig near Andernach.

39. NOSEAN.— $3 (\ddot{\text{Al}} \ddot{\text{Si}} + \ddot{\text{Na}} \ddot{\text{Si}}) + \ddot{\text{Na}} \ddot{\text{S}}$.

Tesseral, like Hauyne, but oftener granular. H.=5.5; G.=2.25...2.27. Translucent; vitreous to resinous. Ash or yellowish gray, sometimes blue, brown, or black. B.B. becomes paler, and melts to a vesicular glass. Soluble in acids. Chem. com. 36.65 silica, 30.59 alumina, 24.82 soda,

Mineralogy.

Fig. 109.

Mineralogy.

and 7.94 sulphuric acid; but with 1 to 1.5 lime and 0.6 chlorine. Lake Laach and Rieden, near Andernach, on the Rhine. *Skolopsite*, granular, smoke-gray and reddish-white; $G.=2.53$; is very similar. Kaiserstuhl in the Breisgau.

40. ITTNERITE.— $\ddot{Al} \ddot{Si} + (\ddot{Na}, \ddot{Ca}) \ddot{Si} + 2 \ddot{H}$.

Tesseral, but only coarse granular. Cleavage, dodecahedral distinct; fracture imperfect conchoidal. $H.=5.5$; $G.=2.37 \dots 2.40$. Translucent; resinous. Smoke, ash or dark bluish-gray. In the closed tube yields much water. B.B. fuses, with much effervescence and sulphureous smell, to a vesicular opaque glass. Soluble, and gelatinizes in con. h. acid. Chem. com. by Whitney's analysis, 35.69 silica, 29.14 alumina, 5.64 lime, 12.57 soda, 1.20 potash, 4.62 sulphuric acid, 1.25 chlorine, 9.83 water and loss. Kaiserstuhl near Freiburg.

*41. LAPIS-LAZULI, Lasurstein.

Tesseral; ∞O , but rarely distinct; generally massive and fine granular. Imperfect dodecahedral cleavage. $H.=5.5$; $G.=2.38 \dots 2.42$. Translucent on the edges; dull resinous or vitreous. Ultra-marine or azure blue; streak light-blue. B.B. fuses readily to a white porous glass. In h. acid the powder is dissolved and gelatinizes, evolving sulphuretted hydrogen. Chem. com. by Varrentrapp's analysis, 45.50 silica, 5.89 sulphuric acid, 31.76 alumina, 9.09 soda, 8.52 lime, 0.86 iron, 0.42 chlorine, 0.95 sulphur, 0.12 water. Near Lake Baikal, China, Thibet, and Tartary. It is used for ornamental purposes, and the preparation of ultramarine-blue. The colour both in it and the Hauyne seems caused by some compound of sulphur, probably with iron. A mode of preparing the artificial colour was discovered by Chr. Gmelin.

42. EUDIALITE.— $[\ddot{Zr} \ddot{Si} + 2 (\ddot{Na}, \ddot{Ca}, \ddot{Fe}) \ddot{Si}]$, Na Cl.

Rhombohedral; $R 73^\circ 30'$; also massive and granular. Cleavage, basal distinct. $H.=5 \dots 5.5$; $G.=2.84 \dots 2.95$. Semitranslucent or opaque; vitreous. Peach-blossom to brownish-red; streak white. B.B. fuses easily to a light-green opaque glass. Gelatinizes in hydrochloric acid. Chem. com. by Rammelsberg's analysis, 49.92 silica, 16.88 zirconia, 11.11 lime, 12.28 soda, 6.97 iron protoxide, 1.15 manganese protoxide, 1.19 chlorine, with 0.65 potash, and 0.3 water. Greenland.

**FAMILY VI.—ZEOLITES.

Crystallization chiefly rhombic and monoclinohedric; also tetragonal and tesseral. $H.=3.5 \dots 6$, or mostly scratched by steel; $G.=2 \dots 3$. Mostly hyaline, and white or red, gray or yellow coloured. Cleavage generally distinct. All yield water in closed tube; all fusible B.B.; all soluble in acids, and mostly gelatinize or deposit silica. They are hydrated silicates of alkalis, or alkaline earths, mostly with silicates of alumina, but rarely contain magnesia. They are generally found in amygdaloidal cavities or fissures of trap or plutonic rocks, apparently as deposits from water percolating through them. Also in veins, but rare.

*43. ANALCIME. $\left\{ \begin{array}{l} \ddot{Al} \ddot{Si} + \ddot{Na} \ddot{Si} + 2 \ddot{H}, \text{ or} \\ 3 \ddot{Al} \ddot{Si} + \ddot{Na}^3 \ddot{Si}^3 + 6 \ddot{H}. \end{array} \right.$

Tesseral; crystals 202, seldomer $\infty O \infty$. 202 (fig. 115), in druses; also granular. Cleavage hexahedral, very imperfect; fracture uneven. $H.=5.5$; $G.=2.1 \dots 2.25$. Transparent to translucent on the edges; vitreous. White, grayish, greenish, yellowish, or reddish white; also flesh-red, and very rarely leek-green. B.B. melts quietly to a clear glass. Completely soluble and gelatinizes in h. acid. Chem. com. 55.2 silica, 22.9 alumina, 13.9 soda, and 8 water, with occasionally a little potash or lime. Seisser Alp in

Fig. 110.

Tyrol, Dumbarton in Scotland, and in Siebenburg; Cyclopean Islands, Sicily; the Vicentine, Norway, Faroe, Iceland, Nova Scotia; also Giant's Causeway; and the Hebrides, Glenfarg, Salisbury Crags, and other parts of Scotland. *Sarcolite*, *Cuboit*, and the *Cluthalite*, from near Dumbarton, are varieties.

*44. NATROLITE, Mesotype. $\left\{ \begin{array}{l} \ddot{Al} \ddot{Si} + \ddot{Na} \ddot{Si} + 2 \ddot{H}, \text{ or} \\ \ddot{Al} \ddot{Si} + \ddot{Na} \ddot{Si} + 2 \ddot{H}. \end{array} \right.$

Rhombic; $\infty P 91^\circ$, P polar edges $143^\circ 20'$, and $142^\circ 40'$, middle edges $53^\circ 20'$; crystals, $\infty P.P$ (fig. 111), fine prismatic, acicular or fibrous, and radiating. Cleavage, ∞P perfect. $H.=5 \dots 5.5$; $G.=2.17 \dots 2.26$. Pellucid; vitreous. Colourless or grayish-white, but sometimes bluish or yellow, seldom red or brown. Is not pyroelectric. B.B. becomes obscure and melts quietly to a clear glass. Gelatinizes in h. acid. Chem. com. 48 silica, 26.6 alumina, 16.1 soda, and 9.3 water, with a little lime and iron oxides. Clermont in Auvergne, Alpstein in Hessa, Hohentwiel in Swabia, Norway; in Scotland, as in Mull, Canna, and near Tantallan Castle; and in Ireland, Nova Scotia, and other countries. *Bergmannite* and *Radiolite* are varieties. *Gallactite*, $H.=4.5$, with 4 lime and 10.5 water. Glenfarg, Kilpatrick, and Bishopstoun, probably distinct.

Fig. 111.

*45. SCOLEZITE, Needlestone. $\left\{ \begin{array}{l} \ddot{Al} \ddot{Si} + \ddot{Ca} \ddot{Si} + 3 \ddot{H}, \text{ or} \\ \ddot{Al} \ddot{Si} + \ddot{Ca} \ddot{Si} + 3 \ddot{H}. \end{array} \right.$

Monoclinohedric; $C=89^\circ 6'$, $\infty P 91^\circ 35'$, $P 144^\circ 20'$; crystals, $\infty P.P.P.$ —P, prismatic or acicular. Twin crystals very common, united by a face of $\infty P \infty$, and one face with feathery striæ (fig. 112); also massive and radiating. Cleavage, ∞P rather perfect. $H.=5 \dots 5.5$; $G.=2.2 \dots 2.3$. Pellucid; vitreous, fibrous varieties silky. Snow-white, grayish, yellowish, and reddish white. Distinctly pyroelectric. B.B. bends and twists in a vermicular manner, and melts easily to a porous glass. In h. acid dissolves and gelatinizes. Chem. com. 46.6 silica, 25.8 alumina, 14 lime, and 13.6 water. Very fine on Staffa; at Beruford in Iceland; in Faroe, Greenland; and the Vendyah Mountains in India; also in Tyrol, Ireland, &c.

Fig. 112.

The following are either varieties of, or closely allied to, Scolezite or Natrolite:—

Mesolite, with 4 to 5 soda; Staffa, Antrim, and Iceland. *Caporcianite*, reddish-gray, radiating fibrous; Caporciano, Tuscany. *Lehuntite*, fine scaly, flesh-red. $G.=1.953$; $H.=3.75$. Glenarm, Ireland. *Poonahite*, rhombic prisms of $92^\circ 20'$, otherwise like Scolezite, from Poonah in Hindustan. *Brevicite*, radiated, massive, white, reddish-gray, or dark-red; Brevig. *Harringtonite*, compact, earthy, snow-white; Portrush in Ireland. *Antrimolite*, white, fibrous, and opaque. $G.=2.096$; $H.=3.75$. Antrim. *Stellite*, fine rhombic prisms grouped in concentric stars. White, translucent, silky. $H.=3 \dots 3.5$; $G.=2.612$. Kilsyth, Scotland. *Mesole* or *Faröelite*, radiating, fibrous; transparent, pearly; white, yellow, or gray. $H. 3.5$. Chem. com. 41.3 silica, 28.4 alumina, 11.5 lime, 5.7 soda, and 13.2 water. Faroe, Schonen; Storr, Uig, and Portree, in Skye. The last is perhaps a distinct species.

*46. THOMSONITE, Comp. $\left\{ \begin{array}{l} 3 \ddot{Al} \ddot{Si} + 3 \ddot{Ca} \ddot{Si} + 7 \ddot{H}, \text{ or} \\ 3 \ddot{Al} \ddot{Si} + \ddot{R}^3 \ddot{Si}^3 + 7 \ddot{H}. \end{array} \right.$ tonite.

Rhombic; $\infty P 90^\circ 40'$, usually like fig. 113, terminating in an extremely obtuse dome of $177^\circ 35'$, like the basis with the plane broken. In druses, fan-shaped or radiated. Cleavage, macrodiagonal and brachydiagonal equally perfect. $H.=5 \dots 5.5$; $G.=2.3 \dots 2.4$. Translucent, but often obscure; vitreous, sometimes pearly. White. B.B. intumescs, becomes opaque, and fuses with difficulty to a white enamel.

Fig. 113.

Mineralogy.

Mineralogy.

Soluble, and gelatinizes in h. acid. Chem. com. 38.2 silica, 31.6 alumina, 17.2 lime, with 1 to 8 soda, and 13 water. Vesuvius, Sicily, Bohemia, Tyrol, Iceland, Faroe, Scotland (Lochwinnoch, Kilpatrick Hills), and Nova Scotia. *Chalilite*, a compact variety; Antrim.

Rhombic; P polar edges, $119^\circ 16'$, and 114° ; crystals, $\infty P \infty (M) . \infty P \infty (T) . P (r) . OP (P)$, (fig. 114), broad pyramidal, very often fascicular or diverging; also radiating or broad columnar, or macled. Cleavage, macrodiagonal very perfect. $H. = 3.5 \dots 4$; $G. = 2.1 \dots 2.2$. Translucent, or only on the edges; vitreous; pearly on $\infty P \infty$. White, red, gray, yellow, and brown. B.B. intumesces greatly, and melts with difficulty to a white enamel. Decomposed by c. h. acid, leaving slimy silica. Chem. com. 58.2 silica, 16 alumina, 8.8 lime, with 1 to 3 soda or potash, and 17 water. Andreasberg in the Harz, Kongsberg and Arendal, Iceland, Faroe, and the Vendayah Mountains in Hindostan; in Scotland, in Skye, Kilpatrick, Kilmaccolm, and Arran. *Sphaerostilbite* and *Hypostilbite* are related species. *Ædelforsite*; fibrous or columnar; $H. = 6$; $G. = 2.6$; is a stilbite with two atoms less water, or a laumontite mixed with quartz. *Ædelfors* in Sweden.

Fig. 114.

Monoclinohedric; $C = 63^\circ 40'$, $P \infty 50^\circ 20'$; crystals ($\infty P \infty$). $\infty P \infty . P \infty . OP$ (fig. 115); mostly tabular, rarely prismatic in druses or radiated lamellar. Cleavage, clinodiagonal very perfect; brittle. $H. = 3.5 \dots 4$; $G. = 2.1 \dots 2.2$. Transparent to translucent on the edges; vitreous or pearly. White, but often flesh or brick-red, and yellowish or hair-brown. B.B. exfoliates, intumesces, and melts to a white enamel. Soluble in h. acid, leaving slimy silica. Chem. com. 59.9 silica, 16.7 alumina, 9 lime, and 14.5 water. Arendal, Kongsberg, Andreasberg, Fassa Valley, Iceland, Faroe, Nova Scotia, New Jersey, and the Vendayah Mountains, Hindostan; at Campsie, in Skye, and other parts of Scotland. *Beaumontite* is the same; Baltimore.

Fig. 115.

49. BREWSTERITE. $\text{Al Si}^3 + (\frac{2}{3} \text{Sr} + \frac{1}{3} \text{Ba}) \text{Si}^3 + 5 \text{H}$. Monoclinohedric; $C. = 86^\circ 20'$; crystals short prismatic, of several vertical prisms, bounded by an extremely obtuse clinodome (172°) (fig. 116), are mostly small. Cleavage, clinodiagonal very perfect. $H. = 5 \dots 5.5$; $G. = 2.12 \dots 2.2$. Pellucid; vitreous or pearly. White, gray, yellow, brown, or green. B.B. froths, intumesces, and fuses to a porous glass. Soluble in h. acid, and gelatinizes. Chem. com. 54.3 silica, 15.0 alumina, 10.1 strontia, 7.4 baryta with 1.3 lime, and 13.1 water; and thus with all the three alkaline earths. Strontian in Scotland, Giants' Causeway, Freiburg in the Breisgau, and the Pyrenees.

Fig. 116.

Rhombic; $\infty P 135^\circ 10'$, $P \infty 109^\circ 46'$, $P \infty 147^\circ 40'$; in long prismatic crystals (fig. 117). Macles united by a face of ∞P are more common; also massive and granular. Cleavage, brachydiagonal very perfect. $H. = 3.5 \dots 4$; $G. = 2.3 \dots 2.4$. Pellucid; vitreous or pearly. Colourless or white. B.B. melts with intumescence to a porous enamel. Soluble without gelatinizing, but after ignition is insoluble. Chem. com. 59 silica, 17.5 alumina,

Fig. 117.

9 lime, with 1.5 soda, and 14.5 water, or like Heulandite. Iceland and Faroe; also, it is said, in Skye, and at Portrush in Ireland.

Tetragonal; $P 121^\circ 4'$; crystals, $P . \infty P \infty (m)$ (fig. 118) and OP , are pyramidal, or short prismatic, or tabular; usually in druses or lamellar. Cleavage, basal perfect; $\infty P \infty$ imperfect; brittle. $H. = 4.5 \dots 5$; $G. = 2.3 \dots 2.4$. Pellucid; vitreous; on OP pearly (*ichthyophthalm*). Colourless, but yellowish, grayish, or reddish white, to rose or flesh red. B.B. exfoliates, intumesces, and melts easily to a white enamel. Powder readily soluble in h. acid, leaving slimy silica. Chem. com. 52.8 silica, 25.4 lime, 5.3 potash, and 16.5 water; in some with 0.24 to 1.54 fluorine. Occurs at Utö in Sweden, Aussig in Bohemia, the Seisser Alp in Tyrol, St Andreasberg in the Harz, Nertschinsk in Siberia, in Greenland, Iceland, Faroe, and Raith in Fife.

Fig. 118.

Gyrolite, spherical radiated concretions, with 50.7 silica, 1.48 alumina, 33.24 lime, 0.18 magnesia, and 14.18 water, seems a variety; Storr in Skye. Also *Xylochor*, from Iceland.

Rhombic; $\infty P 122^\circ 19'$; usually fine columnar or fibrous. $H. = 5$; $G. = 2.28 \dots 2.36$. Pellucid; slightly pearly. Yellowish to bluish-white. B.B. froths up and melts to an enamel. In powder easily soluble in h. acid, leaving gelatinous flakes; after ignition insoluble. Chem. com. 57 silica, 26 lime, and 17 water. On Disco Island, Greenland, Faroe, and Iceland.

53. PECTOLITE. $8 \text{Ca Si} + \text{Na}^2 \text{Si}^3 + 3 \text{H}$, or $6 \text{R Si} + \text{H}$. Monoclinohedric (?), but only spheroidal, radiating, and columnar. $H. = 5$; $G. = 2.69 \dots 2.74$. Translucent on the edges; slightly pearly. Grayish-white or yellowish. B.B. melts easily to a white enamel-like glass. Soluble in h. acid, leaving flaky silica; after ignition gelatinizes perfectly. Chem. com. 52.1 silica, 34.2 lime, 9.5 soda, with 0.6 to 1.6 potash and 4.2 water. Monte Baldo, Monte Monzoni in Tyrol, Kilsyth (*Wollastonite*), Ratho, Corstorphine near Edinburgh, and Storr in Skye.

Rhombohedral; $R 79^\circ 29'$; crystals, OR. R. $-\frac{1}{2}R$, thick tabular, in perfect intersecting macles (fig. 119). $H. = 4$; $G. = 2.1 \dots 2.2$. Chem. com. 44.5 silica, 23.8 alumina, 10.7 lime, 1.6 potash, 1.4 soda, and 17.4 water. Otherwise like chabasite. Faroe, Glenarm, Skye, and Hartfield Moss in Renfrewshire.

Fig. 119.

55. CHABASITE, Lime-Ch. $\text{Al Si}^3 + \text{Ca} (\text{Na}, \text{K}) \text{Si} + 6 \text{H}$. Rhombohedral; $R 94^\circ 46'$; R mostly alone, but also with $-\frac{1}{2}R$ and $-2R$. Intersecting macles very common; crystals in druses and striated. Cleavage, R rather perfect. $H. = 4 \dots 4.5$; $G. = 2 \dots 2.2$. Transparent to translucent; vitreous. Colourless, grayish, yellowish, reddish to flesh-red. B.B. fuses to a finely porous enamel. Soluble in h. acid, leaving slimy silica. Chem. com. 48.2 silica, 20 alumina, 10.8 lime, with 0 to 2.5 soda, and 0.2 to 3 potash, and 21 water. Faroe, Iceland, Greenland, Aussig in Bohemia, Giants' Causeway, Kilmaccolm in Renfrewshire, in Skye, and other places in Scotland. *Phacolite*, with rather less silica and more alumina, is a variety; Leipa in Bohemia.

Hexagonal; $P 80^\circ 8'$; crystals $P . OP . \infty P$ (fig. 120). The faces of P striated parallel to their polar edge;

Mineralogy.

Minera-
logy.

those of the prism horizontally. Cleavage, ∞P distinct. Gelatinizes with h. acid; otherwise like chabasite. Chem. com. 47.6 silica, 19.7 alumina, 12 soda, with 3 to 5 lime, and 0.4 to 2 potash, and 20.7 water. Glenarm in Antrim, Vicenza (*Sarcolite*). *Lederite*, with only 9 per cent. water, seems a variety; Cape Blomidon, Nova Scotia.

Fig. 120.

57. FAUJASITE.— $2 \text{Al} \text{Si}^3 + (\text{Ca}, \text{Na})^3 \text{Si}^3 + 18 \text{H}$. Tetragonal; $P 105^\circ 30'$. Fracture uneven; brittle. Scratches glass. $G.=1.923$. Transparent; vitreous or adamantine. White or brown. B.B. intumesces and fuses to a white enamel. Soluble in h. acid. Chem. com. 46 silica, 17 alumina, 5 lime, 5 soda, and 27 water. Kaiserstuhl.

58. EDINGTONITE.— $4 \text{Al} \text{Si}^3 + 3 \text{Ba} \text{Si} + 12 \text{H}$. Tetragonal, hemihedric; $P 87^\circ 9'$; formed as a sphenoid (P), with polar edges $92^\circ 51'$; also $\frac{1}{2}P$ (n), polar edges $129^\circ 8'$, and ∞P (m) (fig. 121). Cleavage, ∞P , perfect. $H.=4.4 \dots 4.5$; $G.=2.7 \dots 2.75$. Translucent; vitreous. Grayish-white. B.B. fuses difficultly to a colourless glass. Chem. com. 37.3 silica, 23.7 alumina, 26.5 baryta, and 12.5 water (*analysis*). Kilpatrick Hills, Dumbartonshire.

Fig. 121.

*59. HARMOTOME, Cross-stone.— $\text{Al} \text{Si}^3 + \text{Ba} \text{Si}^2 + 5 \text{H}$. Rhombic; P polar edges $119^\circ 4'$, and $121^\circ 6'$, and $\infty P 88^\circ 14'$; crystals, $\infty P \infty$ (q). $\infty P \infty$ (o). $P. P \infty$, short prismatic. Generally in perfectly intersecting macles (fig. 122). Cleavage, brachydiagonal imperfect, macrodiagonal less distinct; brittle; fracture uneven. $H.=4.5$; $G.=2.3 \dots 2.5$. Translucent; vitreous. Colourless, but white, gray, yellow, brown, or red. B.B. fuses rather difficultly but quietly to a clear glass. Soluble, but not readily, in h. acid, with deposition of silica. Chem. com. 47.25 silica, 15.67 alumina, 23.39 baryta (with 1 to 3 lime and 1 to 2.5 potash), and 13.76 water. Andreasberg, Kongsberg, Oberstein; Dumbartonshire and Strontian (*Morvenite*), Scotland.

Fig. 122.

60. PHILLIPSITE.— $\text{Al} \text{Si}^3 + (\text{Ca}, \text{K}) \text{Si} + 5 \text{H}$. Rhombic; P polar edges $119^\circ 18'$ and $120^\circ 42'$. Forms, macles, and other characters like harmotome. $G.=2.15 \dots 2.20$. B.B. fuses easily with slight intumescence; gelatinizes in h. acid. Chem. com. 48.6 silica, 20.2 alumina, 7.3 lime, 6.2 potash, and 17.7 water. Giessen, Marburg, Casel, Iceland, and the Giants' Causeway.

61. HERSCHELITE.— $\text{Al} \text{Si}^3 + (\text{Na}, \text{K}, \text{Ca}) \text{Si} + 3 \text{H}$. Hexagonal; P polar edges, $124^\circ 45'$; crystals $\infty P. \infty P$. $H.=4.5$; $G.=2.06$. Translucent; pearly; white. B.B. fuses readily to a white enamel. Chem. com. 48.5 silica, 20.1 alumina, 9.2 soda, 4.6 potash (with 0.2 to 5 lime), and 17.6 water. Aci Reale and Palagonia in Sicily.

62. ZEAGONITE.— $2 \text{Al} \text{Si}^3 + 2 (\text{Ca}, \text{K}) \text{Si} + 7 \text{H}$. Rhombic; P polar edges $120^\circ 37'$ and $121^\circ 44'$; crystals single or in groups. $H.=5$, on angles and edges $=7$ or more; $G.=2.213$. Transparent; vitreous. Colourless, white, or bluish. B.B. becomes white, falls down, shines, and melts to a clear glass. Capo di Bove. Variety of Phillipsite (?).

63. GISMONDINE, Abrazite.— $\text{Al} \text{Si}^3 + \text{Ca} (\text{K}) \text{Si} + 4 \text{H}$. Tetragonal (or rhombic?); $P 92^\circ 30'$; crystals, P or with $\infty P \infty$, in groups. Cleavage, P imperfect. $H.=5$, on edges and angles $=6$; $G.=2.265$. Semitransparent to translucent; vitreous. Grayish-white to pale-red. B.B. intumesces, shines, and melts to a white enamel. Chem. com. 35 silica, 29 alumina, 15.7 lime (with 2.8 potash), and 20.3 water. Vesuvius, Aci Castello, and Capo di Bove.

64. LAUMONITE.— $\text{Al} \text{Si}^3 + \text{Ca} \text{Si} + 4 \text{H}$.

Monoclinohedric; $C=68^\circ 40'$, $\infty P 86^\circ 15'$, $\infty P:2 P \infty 113^\circ 30'$; crystals prismatic, also columnar. Cleavage, prismatic perfect; clinodiagonal in traces; rather brittle. $H.=3 \dots 3.5$ (when fresh $=5 \dots 6$?); $G.=2.2 \dots 2.3$. Pellucid; vitreous; on cleavage pearly. White, grayish, yellowish, and reddish. In the air soon decomposed. B.B. intumesces and melts easily to a white enamel, which becomes clear in a stronger heat. Soluble and gelatinizes in h. acid. Chem. com. 51.8 silica, 21.5 alumina, 11.3 lime, and 15.4 water. Huelgoët in Brittany, Eule near Prague, Fahlun, Iceland, Faroe, Snizort and Storr in Skye, Dumbarton, and other parts of Scotland, and in North America.

65. LEONHARDITE.— $4 \text{Al} \text{Si}^3 + 3 \text{Ca} \text{Si} + 12 \text{H}$.

Monoclinohedric; $\infty P 83^\circ 30'$, $\infty P:OP 114^\circ$; crystals, $\infty P. \infty P$, prismatic, and grouped in bundles; also granular or columnar. Cleavage, ∞P very perfect, basal imperfect. Very friable. $H.=3 \dots 3.5$; $G.=2.25$. Translucent on the edges; pearly; yellowish-white. B.B. exfoliates, froths, and melts easily to a white enamel. Becomes opaque, and decomposes quickly in the air. Chem. com. 53.9 silica, 23.8 alumina, 9.8 lime, and 12.5 water. Schernnitz.

66. GLOTTALITE.— $\text{Al} \text{Si}^3 + 3 \text{Ca} \text{Si} + 8 \text{H}$.

Tesseral; O and $\infty O \infty$; in druses. $H.=3 \dots 4$; $G.=2.18$. Highly translucent; vitreous. Colourless or white. B.B. melts with intumescence to a white enamel. Chem. com. 37.4 silica, 15.6 alumina, 25.3 lime, and 21.7 water. Near Port-Glasgow. Probably chabasite.

FAMILY VII.—MICA.

Crystallization monoclinohedric or rhombic, and hexagonal or rhombohedric. Cleavage mostly very perfect in one direction (basal), and thin laminae flexible. Pellucid, with a strong, often semimetallic lustre. $H.=2 \dots 3$, more rarely $1 \dots 6$; $G.=2.5 \dots 3$. B.B. mostly fusible. Are silicates of alumina, with silicates of potash, magnesia, lithia, and protoxides of iron and manganese, with or without water. They are mostly constituents of the plutonic or volcanic rocks.¹

**67. POTASH-MICA, Muscovite, $\{ 3 \text{Al} \text{Si} + \text{K} \text{Si}^3$, or
Phengite, Binaxial-Mica. $\{ 3 \text{Al} \text{Si} + \text{K} \text{Si}$.

Monoclinohedric, or probably rhombic. Crystals chiefly rhombic or six-sided tables, with $\infty P 120^\circ$ and 60° nearly. Imbedded, or in druses; also scaly, foliated, or lamellar. Macles rather rare. Cleavage, basal highly perfect; sectile, and in thin laminae elastic. $H.=2 \dots 3$; $G.=2.8 \dots 3.1$. Pellucid in various degrees; optically binaxial; metallic-pearly, on some faces vitreous. Colourless, but white, gray, green, red, brown, black, and rarely yellow. In closed tube usually yields water, with traces of fluorine. B.B. loses its transparency, and fuses to an obscure glass or white enamel. Not affected by h. or s. acids. Chem. com. very variable, but nearly 48 silica, 39.8 alumina, and 12.2 potash; but analyses give 40 to 48 silica, 32 to 37 (rarely 9 to 10) alumina, 3 to 9 (or 36) peroxide of iron, 1 to 2 peroxide of manganese, 5 to 10 potash, 1 to 3 protoxide of iron (with traces of lime, magnesia, and soda), and most 1 to 4 water and 1 to 3 fluorine. The green micas (*Fuchsite*) also 4 to 6 chrome oxide. Abundant as a constituent of granite, gneiss, mica-slate, and other rocks. Large plates in Norway, Sweden, and especially in

¹ Neither the optical nor crystallographical characters of the micas, Nos. 67 to 71, are well determined. The magnesia micas were formerly regarded as monoaxial and hexagonal, but now appear to be binaxial, with the angle between the axes small; in biotite under 5° , often 0° to 1° or 2° ; in phlogopite, 5° to 20° . The crystallization of the potash mica and lepidolite is more probably rhombic. The chem. com. also cannot be represented by any general formula.

Minera-
logy.

Minera-
logy.

Siberia, often a yard in diameter, and used for windows, but become white on exposure. Fine crystals, Vesuvius, St Gotthardt, Pargas, Arendal, Utoe, Fahlun, Kimito, Cornwall, and Aberdeenshire.

68. DAMOURITE.— $3\text{Al}\text{Si} + \text{K}\text{Si}^3 + 2\text{H}$.

Fine foliated. $H.=1.5$; $G.=2.7\dots 28$. Translucent on the edges; pearly; yellowish-white. B.B. yields water, intumesces, becomes milk-white, and melts with difficulty to a white enamel. Soluble in sulphuric (not in h.) acid, leaving silica. Chem. com. 45.7 silica, 38.1 alumina, 11.7 potash, and 4.5 water. Pontivy in Brittany. The mica slate of St Gotthardt (*Paragonite*) is similar externally, but contains 50.20 silica, 35.90 alumina, 2.36 iron peroxide, 8.45 soda, and 2.45 water; and is infusible B.B. *Didrimite* from Zillerthal, and *Margarodite* from Connecticut, are similar hydrous micas.

*69. LITHIA-MICA, } $3\text{Al}\text{Si}^2 + 2\text{Li}\text{Si} + (\text{KF}, \text{Si F}^3)$.
Lepidolite. }

Crystallization and physical characters like potash-mica, but colour often rose or peach-blossom red. In the closed tube shows evident fluorine reaction. B.B. melts *very easily* with effervescence to a colourless, brown, or rarely black magnetic glass, colouring the flame *red*. Imperfectly soluble in acids, wholly so after fusion. Chem. com. 51.6 silica, 28.5 alumina, 8.7 potash, 5.3 lithia, and 5.9 fluoric acid; analyses give 46 to 52 silica, 20 to 29 alumina, 0 to 18 iron peroxide, 0 to 5 manganese peroxide, 5 to 10 potash, 2 to 6 lithia, 4 to 6 fluorine, and 0 to 15 soda. Cornwall, Bohemia, Saxony; and also at Portsoy (serpentine), Loch Fine, and Balmahulish (limestone), in Scotland. It is sometimes used as an ornamental stone.

**70. BIOTITE, Magnesia- } $\text{Al}\text{Si} + (\text{Mg}, \text{K}, \text{Fe})^3\text{Si}$, or
Mica. } $\text{Al}\text{Si} + \text{R}^3\text{Si}$.

Rhombohedral; $R\ 71^\circ 4'$ to about 73° (but perhaps rhombic); crystals mostly tabular, rarely short prisms. Cleavage, basal very perfect; sectile; in thin plates elastic. $H.=2.5\dots 3$; $G.=2.85\dots 2.9$. Transparent, but often only in very thin plates (and generally mono-axial?); metallic pearly. Usually dark-green, brown, or black; streak greenish-gray or white. B.B. difficultly fusible to a gray or black glass. Completely soluble in con. s. acid, leaving white pearly plates of silica. Chem. com. very variable, but analyses give 40 to 42 silica, 13 to 16 alumina, 0 to 20 iron peroxide, 0 to 20 iron protoxide, 10 to 25 magnesia, 4 to 10 potash, 0 to 2 fluorine, and 1 to 3 water. Pargas, Bodenmais, Monroe in New York, Greenland, near Aberdeen, and in other parts of Scotland. *Rubellan*, brownish-red, Bohemia and Saxony, seems a variety.

*71. PHLOGOPITE.— $\text{Al}\text{Si} + (\text{Mg}, \text{K}, \text{Na})^3\text{Si}^2$.

Rhombic (or rhombohedral?), in rhombic or hexagonal prisms. Cleavage, basal. Yellow or copper-red; also colourless, white, and brown. B.B. fuses to a white enamel. Chem. com. 38 to 42 silica, 13 to 20 alumina, 2 to 7 iron oxides, 25 to 30 magnesia, 6 to 10 potash, 1 to 5 soda, and 0.2 to 4 fluorine. In limestones, New York, Vosges Mountains, Sala.

72. LEPIDOMELANE.— $(\text{Al}, \text{Fe})\text{Si} + (\text{Fe}, \text{K})\text{Si}$.

Hexagonal, small six-sided tables. Cleavage, basal perfect; rather brittle. $H.=3$; $G.=3.0$. Highly vitreous; opaque and raven-black; or translucent and leek-green; streak mountain-green. B.B. becomes brown, and fuses to a black magnetic bead. Soluble in h. acid, leaving pearly scales of silica. Chem. com. 37.4 silica, 11.6 alumina, 27.7 iron peroxide, 12.4 iron protoxide, 9.2 potash, with 0.6 magnesia and lime. Persberg, Sweden.

*73. CHLORITOM.— $\text{Al}^2\text{Si} + (\text{Fe}, \text{Mg})\text{Si}$.

Granular, foliated. Cleavage, in one direction perfect; brittle. $H.=5.5\dots 6$; $G.=3.55$. Opaque; weak pearly. Blackish-green; streak greenish-white. B.B. infusible, but becomes darker and magnetic. Not affected by acids.

Chem. com. 26.2 silica, 43.4 alumina, and 30.4 iron protoxide, with 0 to 4 magnesia, and mostly 6 to 7 water. Kosobrod in the Ural, Tyrol. *Sismondine*, St Marcel in Piedmont, is similar; and *Masonite*, from Rhode Island.

74. OTTRELITE.— $\text{Al}^2\text{Si}^3 + 3(\text{Fe}, \text{Mn})\text{Si} + 3\text{H}$.

Thin hexagonal tables. Cleavage, parallel to the lateral faces, rather perfect. Scratches glass. $G.=4.4$. Translucent; vitreous. Greenish or blackish-gray. B.B. melts difficultly on the edges to a black magnetic globule. Powder soluble in warm s. acid. Chem. com. 43.9 silica, 24.3 alumina, 17.0 iron protoxide, 8.5 manganese protoxide, and 6.3 water. In gray clay-slate at Ottrez in Belgium.

**75. CHLORITE (Ripi- } $2\text{R}\text{Si} + \text{R}^2\text{Al} + 3\text{H}$, or
dolite, *G. Rose*.) } $3\text{R}^3\text{Si} + \text{R}^2\text{Si} + 9\text{H}$ (*Rams.*)

Hexagonal; $P\ 106^\circ 50'$; crystals tabular of OP. ∞P , or OP. P, (fig. 123), often in comb-like or other groups; generally foliated and scaly. Cleavage, basal perfect; laminæ flexible, but not elastic.

Fig. 123.

$H.=1\dots 1.5$; $G.=2.78\dots 2.96$. Thin plates transparent or translucent; pearly. Leek to blackish green, often red transverse to the chief axis; streak greenish-gray. In the closed tube yields water. B.B. difficultly fusible on thin edges; soluble in con. sul. acid. Chem. com. when 4R

$=3\text{Mg} + \text{Fe}$, $=26.3\text{ sil.}$, 21.8 al. , 25.5 mag. , 15.0 Fe , and 11.5 water.
 $=2\text{Mg} + 2\text{Fe}$, $=24.6\dots 20.1\dots 15.9\dots 28.5\dots 10.9\dots$

but the analyses variable. Common in the Alps, Scandinavia, the Ural, the Harz, Cornwall, and many parts of Scotland.

76. RIPIDOLITE, Pennine } $3\text{Mg}\text{Si} + \text{Mg}^2\text{Al} + 4\text{H}$, or
(Chlorite, *G. Rose*.) } $3\text{R}^3\text{Si} + \text{R}^2\text{Si} + 9\text{H}$ (*Rams.*)

Rhombohedral (?); $R\ 63^\circ 15'$; crystals chiefly tabular, in comb-like or fan-shaped groups. Cleavage, basal very perfect; sectile and flexible, but not elastic. $H.=2\dots 3$; $G.=2.6\dots 2.77$. Translucent, in thin leaves transparent; pearly. Green, but red by light transmitted transverse to the axis; streak greenish-white. B.B. exfoliates, becomes white, and fuses on the edges to a white enamel. Completely soluble in warm s. acid. Chem. com. 33.2 silica, 18.3 alumina, 35.7 magnesia, and 13.8 water, but with 1 to 7 peroxide, and 1 to 6 protoxide of iron. Zermatt in Valais, Schwarzenstein in Tyrol, and Mauleon in the Pyrenees. *Leuchtenbergite*, yellowish-white, from Slatoust, is the same.

N.B.—Chlorite and Ripidolite may be regarded as one species, with the formula $\text{R}^3(\text{Si}, \text{Al})^3 + 3\text{H}$ (*Rams.*)

77. CLINOCHLORE.

Monoclinohedric; $C=76^\circ 4'$; OP: P $113^\circ 59'$, OP: $\infty P\ 102^\circ 8'$. Macles common; also in groups and druses. Other characters and chem. com. like ripidolite, and the two probably identical. West Chester in Pennsylvania, Achmatowsk in Ural, and Leugast in Bavaria (massive).

Epichlorite, *Metachlorite*, *Helminth*, *Delessite*, and *Grensesite* are other chlorite-like minerals.

**78. TALC.— $\text{Mg}^4\text{Si}^5 + \text{H}$, or $\text{Mg}^6\text{Si}^5 + 2\text{H}$.

Monoclinohedric; $\infty P2=105^\circ 50'$. Rarely found in six-sided or rhombic tables. Generally massive, granular, or scaly. Cleavage, basal very perfect. Soft, sectile, and flexible, in thin plates. $H.=1$; $G.=2.68\dots 2.80$. Transparent in thin plates, and optically binaxial; pearly or resinous. Colourless, but generally greenish or yellowish-white, to apple, leek, or olive green. Feels very greasy. B.B. emits a bright light, exfoliates, and hardens ($H.=6$), but is infusible. Not soluble in h. or s. acid before or after ignition. Chem. com. 62.5 silica, 33.9 magnesia, and 3.6 water; but analyses give 57 to 63 silica, 0 to 4.7 alumina, 30 to 35 magnesia, 0 to 2.3 iron protoxide, with traces of lime and nickel oxide, and 2 to 6 water. Greiner in Tyrol, Sala, Fahlun, the Pyrenees, Unst in Zetland, and many parts

Minera-
logy.

Mineralogy.

of the Scottish Highlands (talc-slate). Used as crayons; also for forming crucibles and porcelain.

Steatite.—Massive. Gray, red, yellow, or green. B.B. melts in fine splinters to a white enamel; but in other respects acts like talc, of which it seems only a compact variety. Briançon, Wunsiedel, the Lizard Point, Cornwall, and near Kirkcaldy, Scotland. Savage nations cut the steatite into culinary utensils. *Potstone* is a mixture of talc, chlorite, and other minerals. Steatite and talc are apparently altered forms of other minerals, chiefly augite and hornblende.

79. **SCHILLERSPAR.**— $\text{Mg}(\text{Fe}, \text{Ca}), \text{Si}(\text{Al}, \text{Cr}, \text{Fe}) + \text{H}$. Mono- or tri-clinohedric; only granular and foliated. Cleavage very perfect in one direction, less so in another, meeting at 87° ; fracture uneven, splintery. $H.=3.5\ldots4$; $G.=2.6\ldots2.8$. Translucent on thin edges; metallic pearly. Olive or pistacio green, yellow, brown, or black; streak greenish white. Imperfectly soluble in h., wholly in s. acid. B.B. becomes magnetic, and fuses in thin splinters on the edges. With borax traces of iron when hot, of chrome when cold. Chem. com. 43 silica, 26 magnesia, 2.7 lime, 7.4 iron protoxide, 3.3 iron peroxide, 2.4 chrome-oxide, 1.7 alumina, and 12.4 water. Baste in the Harz; other localities uncertain. Probably an altered augite.

Metaxite, massive, asbestiform, weak pearly, and greenish-white; $H.=2\ldots2.5$ nearly; $G.=2.52$; Schwarzenberg; is closely related.

80. **PYROSMAILITE.** $\left\{ \begin{array}{l} 15 \text{ Fe Si} + 15 \text{ Mn Si} + 3 \text{ Fe H} \\ + \text{Fe}^2 \text{ Cl}^3 \end{array} \right.$

Hexagonal; $P 101^\circ 34'$; crystals ∞P . OP, tabular; also granular. Cleavage, basal perfect, ∞P imperfect; brittle. $H.=4\ldots4.5$; $G.=3.0\ldots3.2$. Translucent to opaque; resinous, or metallic pearly. Liver-brown to olive-green. B.B. fuses to a black magnetic globule. Wholly soluble in c. n. acid. Chem. com. 38.5 silica, 22 iron protoxide, 22 manganese protoxide, 13 iron peroxide, 3.4 hydrochloric acid, and 1.1 water. Nordmark in Sweden.

81. **CRONSTEDTITE,** $\left\{ \begin{array}{l} \text{Chloromelan.} \\ \text{Fe}^2 \text{ Si} + 2 (\text{Fe}, \text{Mg})^2 \text{ Si} + 5 \text{ H.} \end{array} \right.$

Rhombohedral, chiefly radiated, columnar. Cleavage, basal perfect; thin laminæ elastic. $H.=2.5$; $G.=3.3\ldots3.5$. Opaque or translucent; highly vitreous. Raven-black; streak dark-green. B.B. intumesces, and melts on the edges slowly to a steel-gray globule. Gelatinizes with h. or s. acid. Chem. com. 21.8 silica, 37.6 iron peroxide (with 2.9 manganese peroxide), 25.4 iron protoxide, 4.7 magnesia, and 10.5 water. Przibram in Bohemia; Huel Maudlin, Cornwall; and Conghonas do Campo in Brazil (*Sideroschistolite*).

82. **STILPNOMELAN.**— $(\text{Fe}, \text{Mg})^2 (\text{Si}, \text{Al})^3 + 2 \text{ H}$.

Massive or radiating-foliated. Cleavage in one direction very perfect; rather brittle. $H.=3\ldots4$; $G.=3\ldots3.4$. Opaque; vitreous, inclining to pearly. Greenish-black; streak greenish. B.B. fuses with difficulty to a black shining globule. Imperfectly decomposed by acids. Chem. com. 45.3 silica, 6.9 alumina, 38.3 iron protoxide (with 2 to 3 magnesia), and 9.5 water. Zuckmantel in Silesia, and Wielburg in Nassau.

83. **CLINTONITE, Seybertite, Holme-** $\left\{ \begin{array}{l} \text{Si, Al, Mg, Ca,} \\ \text{site, Xanthophyllite, Chrysophane.} \end{array} \right.$ $\left\{ \begin{array}{l} \text{Fe, Na, H.} \end{array} \right.$

Hexagonal tables, or massive and foliated. Cleavage very perfect in one direction, traces in another. $H.=4.5\ldots6$; $G.=3$ to 3.16. Translucent; pearly on the cleavage planes. Wax-yellow, yellowish, or reddish-brown. Soluble in concentrated acids. B.B. infusible alone, but some become white and colour the flame yellow. Chem. com. uncertain. Amity, New York; Slatoust in the Ural.

Disterrite, Brandisite, from Monzoni, in Tyrol; $H.=5$ on basis, $6\ldots6.5$ on the prism; when fresh blackish-green, but reddish-brown after exposure; is closely allied.

Groppite.—Coarse foliated. $H.=2.5$, $G.=2.73$. Rose or brown-red. Gropp in Sweden.

84. **MARGARITE, Pearl-** $\left\{ \begin{array}{l} \text{Mica, Emerylite.} \end{array} \right.$ $\left\{ \begin{array}{l} \text{Al}^2 \text{ Si} + (\text{Ca}, \text{Na}, \text{Mg}) \text{ Si} + \text{H.} \end{array} \right.$

Rhombic; rarely in six-sided tables; generally granular foliated. Cleavage, basal very perfect. Thin plates slightly elastic. $H.=3.5\ldots4.5$; $G.=3.032$. Translucent; vitreous, or pearly. Snow-white, reddish-white, or pearl-gray. B.B. intumesces and difficultly fusible. Soluble in acids. Chem. com. 30.1 silica, 51.2 alumina, 11.6 lime, 2.6 soda, 0.5 to 3 magnesia, and 4.5 water. Sterzing in Tyrol; Asia Minor and Greece, with emery; and in Pennsylvania. **Diphanite**, in hexagonal prisms, bluish-white; B.B. fuses to an enamel; from the Ural; is nearly allied.

Euphyllite.—Like mica, but less readily cleavable. $H.=4$; $G.=3$. Pellucid; bright pearly; colourless. B.B. exfoliates with a bright light, and fuses on the edges. Contains 40 silica, 42 alumina, 1.4 iron peroxide, 1.4 lime, 3.3 potash, 5 soda, and 5.5 water. Unionville, Pennsylvania.

85. **PYROPHYLLITE.**— $\text{Al}^2 \text{ Si}^4 + \text{H}$.

Rhombic(?), but radiated, columnar, or foliated. Cleavage very perfect; flexible; sectile. $H.=1$; $G.=2.7\ldots2.8$. Translucent; pearly. Light verdigris-green to yellowish-white. B.B. swells up with many twistings to a white infusible mass. Partially soluble in sulphuric acid. Chem. com. 67 silica, 28.1 alumina, and 4.9 water, with 0.1 to 4 magnesia and lime. Ural, Spaa, Morbihan, and Westana in Sweden.

86. **ANAUXTITE.**

Granular, with a very perfect cleavage in one direction. $H.=2\ldots3$; $G.=2.26$. Translucent on the edges; pearly. Greenish-white. B.B. becomes white and fuses on thin edges. Chem. com. 55.7 silica, much alumina, a little magnesia, iron protoxide, and 11.5 water. Bilin in Bohemia.

87. **PHOLERITE, Nacrite.**— $\text{Al}^2 \text{ Si}^3 + 4 \text{ H}$.

Fine scaly. $H.=0.5\ldots1$; $G.=2.35\ldots2.57$. Glimmering or pearly. Snow or yellowish white. B.B. infusible. Chem. com. 40 silica, 44.4 alumina, and 15.6 water. Fins in the Allier dept., Mons, Freiberg, and Naxos.

88. **ROSELLAN, Polyar-** $\left\{ \begin{array}{l} \text{gite, Rosite.} \end{array} \right.$ $\left\{ \begin{array}{l} \text{Al}^2 \text{ Si}^3 + (\text{K}, \text{Ca}, \text{Mg}) \text{ Si} + 2 \text{ H.} \end{array} \right.$

Small grains, with perfect cleavage. $H.=2.5$; $G.=2.72$. Translucent; splendent; fine rose-red. B.B. fuses with difficulty to a white slag. Chem. com. 45 silica, 35 alumina, 6.6 potash, 3.6 lime, 2.45 magnesia, and 6.5 water. Aker and Tunaberg in Sweden.

** FAMILY VIII.—SERPENTINE.

Massive or rhombic. $H.=1\ldots4$, rarely more; $G.=2.3\ldots3$. Often compact or fibrous. B.B. infusible or difficultly. Mostly soluble in acids. Colour often green. Chem. com. generally hydrated silicates of magnesia, partly replaced by protoxide of iron or lime, occasionally also with silicate of alumina or iron peroxide. Occur in plutonic or altered rocks; the serpentine often in large masses or beds.

89. **SERPENTINE.— $\text{Mg}^2 \text{ Si}^2 + 2 \text{ H}$, or $\text{Mg}^2 \text{ Si}^4 + 6 \text{ H}$.

Crystallization uncertain; generally massive, and granular or fibrous. Fracture flat-conchoidal, uneven, or splintery. Sectile and slightly brittle. $H.=3\ldots3.5$; $G.=2.5\ldots2.6$. Translucent to opaque; dull resinous. Green, gray, yellow, red, or brown, often in spots, stripes, or veins; streak white, shining. Feels greasy. In the closed tube yields water and becomes black. B.B. becomes white, and fuses with much difficulty on thin edges. Soluble in h. or easier in s. acid. Chem. com. 43.35 silica, 43.78 magnesia, and 12.87 water, but with 1 to 8 iron protoxide, and also carbonic acid, bitumen, and chrome oxide.

Mineralogy.

Mineralogy.

Varieties are,—1st, Noble Serpentine; 2d, Marmolite or foliated; 3d, Picrolite or fibrous ($H.=3.5...4.5$); 4th, Common or compact Serpentine; 5th, *Chrysotile* (*Baltimorite*, *Metaxite*), in fine asbestiform fibres, easily separated, with a metallic or silky lustre. $G.=2.219$. Common in Norway, Sweden, North America, the Lizard Point in Cornwall, in Shetland, Portsoy, and many parts of Scotland. The chrysotile, at Reichenstein in Silesia, the Vosges Mountains, and North America.

90. ANTIGORITE.— $(Mg, Fe)^4 \ddot{Si}^3 + H$ (?).

Very thin, straight, slaty laminae. $H.=2.5$; $G.=2.62$. Transparent or translucent. Dull or blackish leek-green, in some parts with brown spots; streak white. B.B. very thin edges fuse to a yellowish-brown enamel. Chem. com. 46 silica, 2 alumina, 13 iron protoxide, 35 magnesia, and 3.7 water (but others 13 water). Antigorio in Piedmont.

91. HYDROPHITE.— $(Mg, Fe)^4 \ddot{Si}^3 + 4 H$.

Massive or fibrous. Fracture uneven. $H.=3...4$; $G.=2.65$. Mountain-green; streak lighter. B.B. infusible. Chem. com. 36.19 silica, 22.73 iron protoxide, 1.66 manganese protoxide, 21.08 magnesia, 2.89 alumina, 0.12 vanadic acid, 16.08 water. Taberg in Sweden, and New York.

92. PICROSMINE.— $2 Mg \ddot{Si} + H$.

Rhombic, but massive. Cleavage, $\infty P \infty$ perfect; less so in other directions. Very sectile. $H.=2.5...3$; $G.=2.5...2.7$. Translucent or opaque; vitreous, but pearly on $\infty P \infty$. Greenish-white, gray, or blackish-green; streak colourless. Yields a bitter odour when breathed on (hence the name). In closed tube gives water and blackens. B.B. becomes white, and hard ($=5$). Chem. com. 55.8 silica, 36.1 magnesia, and 8.1 water. Presnitz in Bohemia, and the Greiner in Tyrol.

Monradite.—Massive, foliated, translucent, and yellowish-gray. $H.=6$; $G.=3.267$. Has nearly the same composition, but with half the water. B.B. infusible. Bergen, Norway.

Picrophyll.—Dark-green, foliated. $G.=2.73$; $H.=2.5$. B.B. infusible, but becoming white. Is also nearly related. Sala.

93. VILLARSITE.— $2 Mg^2 \ddot{Si} + H$.

Rhombic; crystals $\infty P.P$. OP, with $\infty P=119^\circ 59$ (?); also granular. Fracture uneven. $H.=3$; $G.=2.9...3$. Translucent. Greenish or grayish-yellow. B.B. infusible; decomposed by acids. Chem. com. 41 silica, 53 magnesia, with 34 iron protoxide and 23 manganese protoxide, and 6 water. Probably a pseudomorph of Olivine. Traversella in Piemont.

94. SPADAITE.— $Mg^5 \ddot{Si}^6 + 4 H$.

Only massive, with splintery fracture. Sectile. $H.=2.5$. Translucent; weak resinous. Red; streak white. B.B. fuses to an enamel-like glass; soluble in con. h. acid, leaving slimy silica. Chem. com. 57 silica, 32 magnesia, and 11 water. Capo di Bove, near Rome.

95. GYMNITE, Deweylite.— $Mg^4 \ddot{Si}^3 + 5 H$.

Only massive. $H.=2...3$; $G.=2.2...2.4$. Semi-translucent; resinous. Pale or dirty orange-yellow. B.B. becomes dark-brown, and fuses on very thin edges. Chem. com. 42.1 silica, 37 magnesia, and 20.9 water. Bare Hills near Baltimore, and Tyrol.

96. CHONKRITE.— $3 (Mg, Ca, Fe) (\ddot{Si}, \ddot{Al}) + 2 H$.

Massive. Fracture uneven. Sectile. $H.=2.5...3$; $G.=2.91$. Translucent; dull or glimmering. Snow, yellowish, or grayish-white. B.B. melts with ebullition to a grayish-white glass; soluble with deposition of silica in h. acid. Chem. com. 35.7 silica, 17.1 alumina, 22.5 magnesia, 12.6 lime, 1.5 iron protoxide, and 9 water. Elba.

97. PYROSCLERITE.— $3 Mg^2 \ddot{Si} + \ddot{Al} \ddot{Si} + 4 H$.

Massive. Cleavage, in two directions at right angles, the one perfect, the other imperfect; fracture uneven; splintery. Sectile. $H.=3$; $G.=2.7...2.8$. Translucent; dull,

or weak pearly. Apple, emerald, or grayish green. B.B. fuses with difficulty to a gray glass. With borax forms a chrome-green glass. The powder soluble in c. h. acid, leaving silica. Chem. com. 36.8 silica, 15.2 alumina (with 1.5 chrome-oxide), 33.7 magnesia, 3.5 iron protoxide, and 10.7 water. Elba, Aker in Södermanland.

98. KAMMERERITE.— $3 Mg^2 \ddot{Si} + \ddot{Al} \ddot{Si} + 5 H$.

Hexagonal; OP. ∞P tabular and prismatic; but usually massive and foliated. Cleavage, basal perfect. Sectile; flexible. $H.=1.5...2$; $G.=2.76$. Translucent; pearly. Violet-blue, reddish, or greenish. Feels greasy. B.B. exfoliates without fusing. Chem. com. 37.0 silica, 14.2 alumina, 1.0 chrome-oxide, 31.5 magnesia, 1.5 lime, 1.5 iron protoxide, and 13.0 water. Bissersk in Siberia.

Rhodochrome.—Massive, fine scaly, splintery fracture. $H.=2.5...3$; $G.=2.668$. Greenish-black, in fine splinters peach-blossom red. Tino in Greece, the Ural, Styria, and near Baltimore.

Tabergite, from Taberg; *Vermiculite*, in fine scales, twisting up, B.B., from Millbury, Mass.; and *Loganite*, from Canada, are closely allied.

99. BRUCITE, Nematite.— $Mg H$.

Rhombohedral; $R. 82^\circ 15'$; crystals OR, ∞R ; also foliated or columnar. Cleavage, basal very perfect. Sectile; fine laminae flexible. $H.=2$; $G.=2.3...2.4$. Translucent; pearly. Colourless, or grayish and greenish-white. B.B. infusible; easily soluble in acids. Chem. com. 69 magnesia, and 31 water, but after exposure often contains carbonic acid and effervesces. *Nematite* is the fine fibrous varieties with silky lustre. Swinans in Unst, Hoboken in New Jersey, and Beresowsk in the Ural.

** FAMILY IX.—HORNBLLENDE.

Monoclinohedric mostly. Distinct cleavage in several directions. $H.=4...6$, but generally 5, or scratch with knife; $G.=2.5...4$, but mostly high. Mostly coloured, ranging from white, through green (rarely brown), to black. Lustre sometimes silky or metallic pearly. Soluble, but not very readily, in acids; and more or less easily fusible. Chem. com. anhydrous silicates and aluminates of lime, magnesia, iron protoxide, more sparingly of soda, yttria, and manganese protoxide. The chief species are essential constituents of the igneous rocks, and form by their decomposition highly fertile soils.

N.B.—Hornblende and Augite rather represent groups of mineral substances than single species.

**100. HORNBLLENDE, $\{ R^5 \ddot{Si}^6 = (Mg, Ca, Fe)^5 (\ddot{Si} \ddot{Al})^4, \text{ or } \ddot{R}^4 \ddot{Si}^3 \}$.

Monoclinohedric; $C=75^\circ 10'$, $\infty P 124^\circ 30'$, $P 148^\circ 30'$. The crystals short and thick, or long and thin prismatic, formed especially by $\infty P (M)$ and $(\infty P \infty) (x)$, and bounded on the ends chiefly by OP and P (r) (fig. 123).

Macles common, with the chief axis the twin axis. Very often radiated, fibrous or columnar, or granular. Cleavage, prismatic along $\infty P 124^\circ$, very perfect, orthodiagonal and clinodiagonal very imperfect. $H.=5...6$; $G.=2.9...3.4$. Pellucid in all degrees; vitreous, but sometimes pearly or silky. Colourless; often white, but usually some shade of gray, yellow, green, brown, or black. B.B. fuses, generally intumescing and boiling, to a gray, green, or black glass. Those containing most iron are most fusible, and are also partially soluble in hydrochloric acid, which scarcely affects the others. Chem. com. very variable, and hardly reducible to any general formula. Analyses range from 40 to 60 per cent. silica, 0 to 17 alumina, 0 to 30 lime, 0 to 36 iron protoxide (or peroxide), 0 to 4 manganese protoxide, 0 to 8 soda, 0 to 3 potash, and 0 to 1.5 fluorine, with a little water.

Fig. 124.

Mineralogy.

Mineralogy.

The more remarkable varieties are,—

1. *Tremolite*, *Grammatite*, or *Calamite*.— $3 \text{ Mg}^5 \text{ Si}^6 + \text{Ca}^5 \text{ Si}^6 + \text{Ca F}$, with 60.85 silica, 24.53 magnesia, 13.74 lime, and 0.88 fluoric acid. White, gray, green, rarely yellowish or blue; in long prismatic crystals, often bent and striated longitudinally. Pearly or silky; semitransparent or translucent. B.B. fuses readily to a white or nearly colourless glass. Lapland, Sweden, Arendal, Campo Longo, St Gotthardt, and other parts of the Alps; in the Pyrenees, Silesia, Siberia, North America; Glen Tilt, Glenelg, Tiree, and many parts of Scotland.

2. *Actinolite*, *Actinote*, or *Strahlstein*.—Colour green, inclining to black, gray, or brown. Translucent, or only on the edges. Long prismatic crystals, or radiated columnar masses. B.B. melts to a greenish or blackish enamel. Sweden, Tyrol, North America, Glenelg, Isle Oronsay, and Aberdeenshire.

3. *Asbestos*, *Amianthus*, and *Byssolite*.—Fine fibrous. White, gray, or green. The fibres often easily separable, elastic, and flexible. Savoy, Tyrol, and Corsica. *Rock-cork*, felt-like, and swims on water; Saxony, Sweden, Portsoy and Leadhills in Scotland. *Rock-leather*, flat and flexible; Leadhills, Aberdeenshire, and Strontian; and *Rock-wood*, near Sterzing in the Tyrol.

4. *Anthophyllite*.—Clove-brown to leek-green; translucent, radiating, and columnar; pearly on cleavage planes. B.B. very difficultly fusible. In it the lime is chiefly replaced by protoxide of iron. Kongsberg and near Brevig in Norway, Greenland, and the United States.

5. *Hornblende*.—Green or black, seldomer brown or gray. $G = 3.3 \dots 4$. B.B. fuses rather easily to a yellow, greenish, or black enamel. $(\text{Mg}^3 + \text{Ca}^2) \text{ Si}^6 + \text{Fe Al}$, with 47.9 silica, 13.2 alumina, 15.5 magnesia, 14.4 lime, and 9.0 iron protoxide in the black variety. Three varieties are distinguished. (a.) The Noble or *Pargasite*, pale celadine or olive-green, and strong pearly or vitreous lustre; at Pargas in Finland, Tyrie in Scotland. (b.) Common Hornblende, dark leek or blackish green, opaque; a constituent of many rocks, as in Norway, the Alps, and Scottish Highlands (Ben Lair, East Rona). Streak greenish-gray. (c.) Basaltic, velvet-black, foliated, opaque; streak gray or brown, in basalt and volcanic rock. Ural, Arendal, Bohemia.

Arfvedsonite.— $3 \text{ Fe}^5 \text{ Si}^6 + \text{Na}^5 \text{ Si}^6$, with 52.3 silica (2 alumina), 36.9 iron protoxide, 8.6 soda, and 2 lime. Pure black, opaque; streak grayish-green. Cleavage, very perfect along a prism of $128^\circ 55'$. $G = 3.44$; $H = 6$. Fusible in fine splinters in the flame of a candle. B.B. intumesces much, and melts to a black magnetic globule. Not soluble in acids. Greenland, Frederiksvärn in Norway, and Arendal.

The *Raphilite*, from Upper Canada, seems only tremolite.

Uralite.—Dark-green or greenish-black, with the outward form of augite, the internal structure and composition of hornblende. The Ural. Is probably a pseudomorph.

**101. AUGITE, Pyroxene. $\{\text{Ca Si} + (\text{Mg}, \text{Fe}) \text{ Si}, \text{ or } \text{Ca}^3 \text{ Si}^2 + (\text{Mg}, \text{Fe})^3 \text{ Si}^2\}$

Fig. 125.

Fig. 126.

Monoclinohedric; $C = 74^\circ$, $\infty P 87^\circ 6'$, $P 120^\circ 39'$, —P VOL. XV.

$131^\circ 29'$, $2P 96^\circ 36'$. Crystals, $\infty P (M)$. $\infty P \infty (r)$. $(\infty P \infty) (l)$. $P (s)$. (fig. 125) ∞P . $2P$. $0P$. $3P$. $\infty P \infty$, and $\infty P \infty$. $(\infty P \infty)$. $P \infty$. ∞P , almost always prismatic, imbedded, or attached; also granular, columnar, and scaly. Macles (fig. 126) common. Cleavage, prismatic along ∞P (with angles of $87^\circ 6'$ and $92^\circ 54'$), generally rather imperfect; orthodiagonal and clinodiagonal imperfect. $H = 5 \dots 6$; $G = 3.2 \dots 3.5$. Pellucid in all degrees; vitreous; in some pearly on $\infty P \infty$. Colourless, and white, but usually gray, green, or black. B.B. generally fusible; imperfectly soluble in acids. Chem. com. generally

Mineralogy.

	Silica.	Lime.	Magnesia.	Iron.
a. Magnesia-augite.....	56.36	25.46	18.18	...
b. Magnesia-iron-augite....	52.72	23.81	8.50	14.97
c. Iron-augite.....	49.52	22.37	...	28.11

Analysis gives 47 to 56 silica, 20 to 25 lime, 5 to 15 magnesia, 1 to 20 iron protoxide, with 0 to 3 manganese protoxide, and 0 to 8 alumina. The alumina, chiefly found in very dark green or black augites, may replace part of the silica.

The more important varieties are—

1. *Diopside*.—Grayish or greenish-white, to pearl-gray or leek-green; streak white. Crystallized or broad-columnar, or concentric lamellar. Transparent to translucent on the edges. Not affected by acids. B.B. fuses to a whitish semitransparent glass. Mussa Alpe (*Mussite*) and Ala (*Alalite*) in Piedmont, Swarzenstein in the Tyrol; also the Alps, Scandinavia, Finland, Ural, and North America.

2. *Sahlite*, *Malacolite*.—Green, rarely yellow, brown or red; streak white. Translucent, or only on the edges; vitreous, inclining to pearly. Seldom crystallized (*Baikalite*), mostly columnar or lamellar. B.B. melts to a dark-coloured glass. Fassathal (*Fassaites*), Piedmont, Arendal, Philipstadt in Sweden; in the vicinity of Lake Baikal (*Baikalite*); near Lake Lherz in the Pyrenees (*Lherzolite*); Sahla, Sweden; Glentilt, Glenelg, Tiree, in Scotland; Tyrol, and North America. *Coccolite* is a distinct granular sahlite or augite.

3. *Augite*.—Leek-green, greenish-black, or velvet-black, rarely brown; streak greenish-gray. Vitreous to resinous; translucent or opaque. Only slightly affected by acids. B.B. fuses to a black, often magnetic glass. An essential component of many rocks, basalt, dolerite, clinkstone, and augite porphyry, in Germany, Auvergne, Vesuvius, and in many parts of Scotland; associated chiefly with labradorite, also with olivine, leucite, or nepheline; rarely if ever with quartz.

4. *Hedenbergite*.—Black or blackish-green; opaque or translucent on the edges. B.B. melts to a black magnetic glass. Seems a lime-iron augite. Tunaberg. *Jeffersonite*, from Sparta, New Jersey; *Hudsonite*, from the Hudson River; and *Polylite*, are related.

5. *Amianthus*.—Some asbestiform minerals are probably augite, but the greater number are rather hornblende.

6. *Breislackite*.—Fine yellowish or brown woolly crystals. Vesuvius, and Capo di Bove near Rome.

Hornblende and augite agree so closely in crystalline forms and chemical composition, that it has sometimes been proposed to unite them in one species. They, however, differ too widely to justify their union. Thus, hornblende contains more silica, and a half to one per cent. of fluoric acid, which does not appear in augite. Hornblende, too, is more fusible, and ranges lower in specific gravity (hornblende from 2.931 to 3.445; augite, 3.195 to 3.525). Though both possess a cleavage parallel to their vertical prisms, yet these differ in angular dimensions. They also occur in distinct geognostic positions. Hornblende in rocks containing quartz or free silica, and mostly with minerals that are neutral compounds of silica, as orthoclase and albite; augite in rocks that do not contain free silica, and mostly with minerals that are not neutral silicates, as labradorite, olivine, and leucite. Hence there are two distinct series of massive or igneous rocks; the hornblende

Mineralogy.

series, including granite, syenite, diorite, diorite-porphyr, and red porphyry; and the augite series or hypersthene rock, gabbro, dolerite, nepheline rock, augite-porphyr, and leucite-porphyr.

Compact; fracture coarse splintery. Very tenacious. $H.=6\ldots6.5$; $G.=2.9\ldots3$. Translucent, dull, or resinous. Leek-green, to greenish-white or blackish-green. Feels slightly greasy. B.B. become white and melt with difficulty to a gray mass. Chem. com. 57.7 silica, 24.8 magnesia, 17.4 lime; or 58.5 silica, 28.3 magnesia, and 13.2 lime, but with 1 to 3 protoxide of iron and 1 to 2.5 water. China and the East, also in New Zealand. Seen varieties of hornblende or augite. Cut into ring-stones or amulets.

Granular; cleavage, one perfect, two others in traces. Translucent. Bluish-gray changing to yellowish-gray on exposure. B.B. infusible. Chem. com. 46 to 47 silica, 43 to 44 magnesia, 6 iron protoxide, and 3.5 lime. Bolton, Massachusetts.

Isomorphous with augite, $\infty P 87^\circ$. Crystalline and granular, or disseminated. Cleavage, orthodiagonal very perfect, prismatic ∞P distinct, clinodiagonal very imperfect. $H.=6$; $G.=3.3\ldots3.4$. Opaque or translucent on thin edges; vitreous or resinous, but metallic pearly on the cleavage planes, of which one is copper-coloured, two silvery. Pinchbeck-brown, inclining to copper-red, pitch-black, and grayish-black; streak greenish-gray. Not affected by acids. B.B. melts more or less easily to a greenish-black glass, often magnetic. Chem. com. generally 46 to 58 silica, 0 to 4 alumina, 11 to 26 magnesia, 1 to 5 lime, 13 to 34 iron protoxide, 0 to 6 manganese protoxide. Paul's Island (*Paulite*), Labrador, and Greenland. Hypersthene rock in Norway, Elfdal in Sweden, Skye and Ardnamurchan in Scotland. Also Cornwall; the Harz, and other parts of Germany.

Monoclinohedric, like augite; $C.=72^\circ$, $\infty P 86^\circ$; indistinct crystals or granular. Cleavage, orthodiagonal very perfect, ∞P imperfect, clinodiagonal in traces. $H.=4.5\ldots5$; $G.=3.2\ldots3.5$. Translucent, or only on the edges; resinous or vitreous; on the more perfect cleavage planes, which are often slightly curved and fibrous; metallic-pearly or silky. Clove-brown to pinchbeck-brown, sometimes greenish or yellowish; streak white. Not affected by acids. B.B. very difficultly fusible to a dark-brown or blackish-green glass. Chem. com. 58.6 silica, 33.0 magnesia, and 8.4 iron protoxide; but also 1 to 2 alumina, 0 to 2.2 lime, and 0 to 3 manganese protoxide. Kraubat in Styria, Kupferberg in Baireuth, Ullenthal in Tyrol, and near Marburg.

Like augite, and only a variety, with very perfect cleavage in the clinodiagonal, a metallic-pearly lustre, and gray or pinchbeck-brown colour. B.B. melts easily to a grayish or greenish enamel. Chem. com. 50 to 53 silica, 1 to 5 alumina, 15 to 23 magnesia, 11 to 20 lime, and 5 to 12 manganese protoxide. Constituent of the Gabbro. Baste in the Harz, Silesia, the Alps, Apennines, and Ural. *Vanadine-bronzite*, containing soda and vanadic acid, and *Diaclasite*, seem merely diallage.

Monoclinohedric, crystalline, or granular. Cleavage, $\infty P 87^\circ$ 5' imperfect, ($\infty P \infty$) perfect, also $\infty P \infty$. Brittle. $H.=5\ldots5.5$; $G.=3.5\ldots3.6$. Translucent; vitreous or partly pearly. Dark rose-red, bluish-red, or reddish-brown. Not affected by acids. B.B. fusible. Chem. com. 45.33 silica,

and 53.67 manganese protoxide, with 3 to 5 lime, and 0 to 6 iron protoxide. Langbanshytta, Katharinenburg, the Harz, and New Jersey. The *Bustamite*, pale-greenish or reddish-gray, with 14 lime, Mexico; *Fowlerite*, New Jersey, with 7 to 11 iron protoxide, and *Paisbergite*, Sweden, are varieties. *Hydropite*, *Photocite*, *Allagite*, and *Hornmanganese*, mere mixtures.

Monoclinohedric; $C.=84^\circ 40'$, $\infty P 140^\circ$, or $C.=69^\circ 48'$, $\infty P 87^\circ, 28'$. Very rarely crystallized, mostly broad prismatic or laminar. Cleavage, along OP and $\infty P \infty$ perfect, but planes uneven or rough; meet at $95^\circ 23'$. $H.=5$; $G.=2.7\ldots2.9$. Translucent; vitreous, or pearly on cleavage. White, inclining to gray, yellow, red, or brown; streak white. Phosphoresces with heat or friction; gelatinizes in hydrochloric acid. B.B. difficultly fusible to a semitransparent glass. Chem. com. 52.5 silica and 47.5 lime, but with 0 to 2 magnesia, and 0 to 2 iron protoxide. Bannat, Finland, Sweden, North America, Ceylon, Capo di Bove, Monaltrie in Aberdeenshire, and the Castle Rock at Edinburgh.

Monoclinohedric. Crystals long acute-pointed prisms. Cleavage like augite, $\infty P (86^\circ 56')$. $H.=6\ldots6.5$; $G.=3.4\ldots3.6$. Nearly opaque; vitreous. Brownish or greenish-black; streak greenish-gray. Imperfectly soluble in acids. B.B. fuses easily to a black magnetic glass. Chem. com. 55.6 silica, 32 iron peroxide, and 12.4 soda, but with 1 to 3 manganese peroxide, and also 3 to 4 titanous acid. Eger and Porsgrund in Norway.

Triclinohedric; $\infty P \infty (M): \infty P \infty (t) = 112^\circ 30'$; $\infty P' (h): \infty P (g) = 90^\circ 40'$; $OP (P): \infty P \infty = 92^\circ 34'$, $OP: \infty P \infty = 88^\circ 0'$; crystals very low eight-sided prisms (fig. 127), small, attached. Cleavage, basal and brachydiagonal perfect. $H.=5\ldots5.5$; $G.=3.4\ldots3.5$. Thin laminæ translucent, greenish, and brownish. Splendent vitreous; black. Slowly soluble in boiling h. acid. B.B. fuses easily with effervescence to a black magnetic bead. Chem. com. 54.7 silica, 20.3 lime, and 25.0 iron protoxide, but with 0.3 to 6 alumina, 2.2 magnesia, and 2 to 10 manganese protoxide. Arendal, Zetland, and Gouverneur, New York.

Fig. 127.

Massive. Fracture conchoidal; brittle. $H.=4\ldots4.5$. $G.=2.55\ldots2.62$. Opaque; resinous or vitreous. Brownish-black or blackish-green; streak liver-brown. B.B. fuses to a black globule. Chem. com. 50.7 silica (with 2.68 phosphoric acid), 14 alumina, 19.6 iron protoxide, 10.9 magnesia, and 4.8 water. Sordawala in Finland.

Very fine, easily separable, but tough elastic fibres. $H.=4$; $G.=3.2\ldots3.3$. Translucent; silky, or dull. Indigo blue; streak lavender-blue. B.B. fuses easily to a black magnetic glass. Chem. com. 50.3 silica, 35.0 iron protoxide, 2.2 magnesia, 6.7 soda, and 5.8 water. Orange River in South Africa, Stavern in Norway, and Greenland.

Triclinohedric; prismatic; usually columnar or granular. Cleavage, $\infty P'$ to $\infty P = 94^\circ 36'$ distinct. Fracture uneven, splintery; rather brittle. $H.=3.5\ldots4$; $G.=2.55\ldots2.60$. Opaque, or translucent on the edges; resinous, or pearly. Greenish-white, asparagus-green, and yellowish-gray. B.B. becomes black, then white, and fuses with very much difficulty. Chem. com. silicate of magnesia with a little silicate of lime, water, and bituminous matter. Storgard, Finland. Probably decomposed augite.

Mineralogy.

Mineralogy.

Brittle; fracture conchoidal. $H.=5.5...6$; $G.=2.90...2.95$. Opaque; vitreous. Grayish or velvet-black, sometimes with red spots; streak pale greenish-gray. Imperfectly soluble in acids. B.B. fuses to a magnetic globule. Chem. com., by Turner's analysis, 47.09 silica, 13.91 alumina, 15.43 lime, 20.07 iron peroxide, 1.94 copper oxide. St Just near Penzance, Calton Hill, Edinburgh (?).

116. TACHYLITE.— $\text{Al Si}^2 + 3 (\text{Fe}, \text{Ca}, \text{Mg}, \text{Mn}, \text{Na}, \text{K}) \text{Si}$. Conchoidal. $H.=6.5$; $G.=2.52$. Opaque; vitreous or resinous. Velvet, brownish, or greenish black; streak dark-gray. B.B. fuses very easily to an opaque glass; soluble in h. acid. Vogelsberg (*Hyalomelan*) near Dransfeld, Munden, and Iceland. Seems a vitreous basalt.

FAMILY X.—CLAYS.

Amorphous, earthy, variously-coloured masses. $H.=1...5$, but generally low or $1...3$; $G.=1...3$, but often about 2. Many have a shining streak, adhere to the tongue, feel greasy, and fall down in water. Some then form a ductile paste and are used for pottery. These are slightly affected by acids (under 25 per cent. of mass, soluble.) They are chiefly silicates of alumina, with about 10 to 12 per cent. water. Others with 20 to 25 per cent. water, and almost entirely soluble in acids, do not become plastic, and in the fire become misshapen or fuse; but often combine with grease or oil to an earthy soap. Many are thus of great economic importance. They rarely form true species, and are mostly indefinite mixtures or mere products of the decomposition of rocks and minerals.

*117. KAOLIN, Porcelain-earth.— $\text{Al Si}^3 + 2 \text{H}$.

Massive in beds and veins. Fracture uneven; fine-earthly, very soft, sectile, and friable. $H.=1$; $G.=2.2$. Opaque, dull. White or gray, inclining to blue, green, yellow, or red. Feels meagre when dry, and plastic when wet. B.B. infusible. Not affected by h. acid, but decomposed by warm s. acid, leaving silica. Chem. com. very variable, but approximates to 47.2 silica, 39.1 alumina, and 13.7 water. Chiefly a product of the decomposition of orthoclase, or of granite, porphyry, and other rocks containing this mineral. Cornwall and Devonshire in Britain, Limoges in France, Meissen in Saxony, are the chief localities for the kaolin used in manufacturing porcelain.

*118. CLAY.

Clays are merely varieties of kaolin, mixed with quartz-sand, carbonate of lime, magnesia, the oxyhydrates of iron and manganese, or other substances. Generally they are compact and friable, of white, yellow, red, blue, gray, or brown colours. Their spec. gr. varies from 1.8 to 2.7. Varieties are,—*Pipe-clay*, grayish or yellowish-white, with a greasy feel; adheres strongly to the tongue; and when wet is very plastic and tenacious, and in the fire burns white. Abundant in Devonshire, and in the Trough of Poole in Dorsetshire; in France, Belgium, and Germany. Used for manufacturing tobacco-pipes and similar articles. *Potter's clay*, red, yellow, green, or blue, becoming yellow or red when burnt; more easily fused than the former, and often effervesces with acids. That used in the potteries in England comes chiefly from Devonshire. *Loam*, coarser and more impure, with more sand, and consequently less plastic. *Shale* or *Slate-clay*, grayish-black, and much mixed with bituminous or carbonaceous matter. *Bituminous shale*, known by its shining, resinous streak. *Black chalk*, with more carbon, leaves a black mark on paper. *Iron-clay* contains much peroxide of iron, is reddish-brown, and forms the basis of many amygdaloids and porphyries.

119. ROCK-SOAP, Bergseife.

Compact. Fracture earthy or conchoidal; sectile. $H.=1...2$. Streak resinous. Colour pitch-black and bluish-black. Feels very greasy; writes, but does not soil. Adheres strongly to the tongue, and falls to pieces in water.

Mineralogy.

Chem. com. 44 to 46 silica, 17 to 26 alumina, 6 to 10 iron peroxide, 13 to 25 water. Arnstedt, Cassel, Bilin, and Isle of Skye. Used for crayons by painters, and for washing cloth.

120. PLINTHITE.

Compact; earthy. $H.=2...3$; $G.=2.34$. Brick-red or brownish-red. Does not adhere to the tongue. B.B. becomes black, but is infusible. Chem. com. 30.9 silica, 20.8 alumina, 26.1 iron peroxide, 2.6 lime, and 10.6 water. Antrim in Ireland. *Erinite*, from the same place, is similar.

121. GREEN-EARTH.— $\text{Si}, \text{Al}, \text{Fe}, \text{Mg}, \text{K}, \text{H}$.

Massive, forming crusts. Fracture, fine earthy; sectile. $H.=1...2$; $G.=2.8$. Opaque; streak shining. Green. Feels greasy. B.B. fuses to a black magnetic glass; not affected by acids. Common in the trap rocks of Faroe, Iceland, Scotland, and other countries; that used in the arts chiefly from Monte Baldo near Verona, and Cyprus. *Glaucconite*, small round green grains, in the greensand of England, France, Germany, and North America, is essentially a hydrous silicate of iron protoxide and potash, but with 43 to 57 silica, 5 to 17 alumina, 19 to 27 iron protoxide, 5 to 15 potash, 1 to 4 magnesia, 0 to 3 lime, and 7 to 13 water. In New Jersey forms a valuable manure.

122. YELLOW-EARTH.— $(\text{Fe}, \text{Al})^2 \text{Si}^3 + 4 \text{H}$.

Fracture fine earthy or slaty. $H.=1...2$; $G.=2.2$. Ochre-yellow. Greasy; adheres slightly to the tongue, and pulverizes in water. B.B. infusible, but becomes red; partially soluble in h. acid. A mixture of silicate of alumina, peroxide of iron, and water. Harz, France, and Scotland. Used as a coarse pigment.

123. HALLOYSITE.— $\text{Al Si} + 4 \text{H}$.

Reniform. $H.=1.5...2.5$; $G.=1.9...2.1$. Semitranslucent, and more so when moist. White, inclining to blue, green, or yellow. Adheres slightly to the tongue. B.B. infusible; soluble in c. s. acid. Chem. com. nearly 41.5 silica, 34.4 alumina, and 24.1 water. Liege, Tarnowitz, Thiviers in France; Eifel (*Lenzinite*); Scotland (*Tuesite*).

*124. FULLER'S-EARTH, Walkerde.

Fracture uneven, slaty, or earthy. $H.=1...1.5$; $G.=1.8...2.0$. Opaque; dull, but streak resinous. Green, gray, or white. Very greasy; scarcely adheres to the tongue. Falls down in water, but does not become plastic. That from Reigate in Surrey contained 53 silica, 10 alumina, 9.75 iron peroxide, 1.25 magnesia, 0.5 lime, and 24 water. It is used in preparing cloth,—the best for this purpose being found in England, as at Reigate, Maidstone in Kent, Woburn in Bedfordshire, &c.; also near Maxton in Scotland, in Saxony, Bohemia, and Styria.

125. ALLOPHANE.— $\text{Al Si} + 5 \text{H}$.

Botryoidal and reniform. Fracture conchoidal, brittle. $H.=3$; $G.=1.8...2$. Pellucid; vitreous. Pale-blue, white, green, or brown. B.B. intumesces and becomes white, but does not fuse; gelatinizes in acids. Chem. com. often near 24.3 silica, 40.4 alumina, and 35.3 water; occasionally with 2 to 3 oxides of iron or copper and 2 to 4 carbonate of lime or magnesia. Charlton near Woolwich, Baden, Bonn, and Saal-field.

126. SCHRÖTTERITE.— $\text{Al}^5 \text{Si}^2 + 20 \text{H}$.

Amorphous. Conchoidal. $H.=3...3.5$; $G.=2$. Greenish, yellowish, or with brown spots. B.B. infusible, but burns white; gelatinizes in h. acid. Freienstein in Styria.

127. BOLE.

Earthy, in nests and veins. Conchoidal. $H.=1...2$; $G.=2.2...2.5$. Opaque, or translucent on the edges; dull resinous; streak shining. Brown, yellow, or red. Feels greasy; some adhere strongly to the tongue, others not at all. In water crackle and fall to pieces. B.B. harden, and generally fuse to an enamel; in acids are more or less soluble. Chem. com. hydrous silicates of alumina and iron peroxide in various proportions. Dransfeld, Stolpen, Cler

Mineralogy.

mont, Auvergne, the trap rocks of the Hebrides and other parts of Scotland, and Ireland. *Sinopite*, red, from Asia Minor, is supposed to be the Sinopian earth of antiquity. *Fetthol*, from Freiberg, and *Ochran*, of a yellow colour, are infusible B.B.

128. TERATOLITE.

Fracture uneven, or earthy. $H.=2.5...3$; $G.=2.5$. Opaque; dull. Lavender-blue to plum-blue, often with reddish-white veins and spots. Feels rough and meagre. B.B. infusible. Schuler's analysis gave 41.66 silica, 22.85 alumina, 12.98 iron peroxide, 3.04 lime, 2.55 magnesia, 0.93 potash, 1.68 manganese peroxide, 14.20 water (=99.89). Planitz near Zwickau; the *Terra miraculosa Saxonie* of old authors.

129. KOLLYRITE.— $\text{Al}_2^3 \text{Si} + 10 \text{H}$.

Fine-earth. Fracture even or conchoidal. $H.=1...2$; $G.=2.0...2.15$. Semitranslucent or opaque; dull or glimmering. Snow-white, rarely reddish, greenish, or yellowish. Feels greasy, and adheres strongly to the tongue. B.B. infusible; gelatinizes imperfectly with acids. Chem. com. 14 silica, 46 alumina, and 40 water. Schemnitz, Pyrenees, and Saxony. *Scarbroite*, from Scarborough, is similar, but with more (48) water.

130. LITHOMARGE, Steinmark.

Kaolin substances; in general compact, earthy, or pseudomorphous. $H.=2.5...3.0$; $G.=2.4...2.6$. Opaque, or dimly translucent; dull. White, yellow, or red. Feel greasy, and adhere more or less to the tongue. Landshut, Clausthal, and the Harz. Similar are *Carnat*, fine red; and *Myelin*, pale yellow or red, and reniform; both from Rochlitz in Saxony; also *Melopsite*, yellowish or greenish-white, from Neudeck in Bohemia.

131. MILOSCHIN, Serbian.— $(\text{Al}, \text{Cr}) \text{Si} + 3 \text{H}$.

Fracture conchoidal, or earthy. $H.=2$; $G.=2.13$. Indigo-blue to celadine-green. Adheres to the tongue, and crackles in water. B.B. infusible; partially soluble in h. acid. Contains 3.6 chrome oxide. Rudnaik in Servia.

132. KEROLITE.— $4 \text{Mg Si} + \text{Al Si} + 15 \text{H}$.

Reniform. Uneven, conchoidal, or splintery; rather brittle. $H.=2...3$; $G.=2.3...2.4$. Translucent; dull resinous. White, inclining to gray, yellow, green, or red. Feels greasy, but does not adhere to the tongue. B.B. infusible. Frankenstein in Silesia.

133. AGALMATOLITE, Figure- } $4 \text{Al Si}^2 + \text{K Si}^3 + 3 \text{H}$.

stone, Pagodite. Massive or slaty. Fracture splintery; rather sectile. $H.=2...3$; $G.=2.8...2.9$. Translucent, or only on the edges; dull or glimmering. Green, gray, red, and yellow. Feels somewhat greasy, but does not adhere to the tongue. B.B. burns white and fuses slightly on very thin edges; soluble in warm s. acid. Chem. com. 55 silica, 33.1 alumina, 7.6 potash, and 4.4 water, with 0.5 to 3 iron peroxide, and 0 to 3 lime. China, where it is cut into various works of art; also Nagyag in Hungary, and Saxony. *Cimolite*, pure white clay from Argentiera and Milo, used for cleaning cloth, is similar.

134. SOAPSTONE, Saponite.— $6 \text{Mg Si} + \text{Al Si} + 5 \text{H}$.

Massive; sectile and very soft. $H.=1.5$; $G.=2.26$. White, or light-gray, yellow, and reddish-brown; streak shining. Feels greasy, and writes feebly; does not adhere to the tongue. B.B. fuses to a colourless porous glass; soluble in s. acid. Chem. com. 50 silica, 11.8 alumina, 27.8 magnesia, and 10.4 water. Lizard Point and St Clear in Cornwall, and Dalarne in Sweden (*Piotine*).

135. ONKOSIN.— $2 \text{Al Si}^2 + (\text{K}, \text{Mg}) \text{Si}^2 + 2 \text{H}$.

Fracture uneven or splintery; sectile. $H.=2$; $G.=2.8$. Translucent; slightly resinous. Apple-green or brown. B.B. intumesces and fuses; soluble in s. not in h. acid. Salzburg.

136. PIPESTONE.— $(\text{Al}, \text{Fe}) \text{Si}^3 + (\text{Na}, \text{Ca}, \text{Mg}) \text{Si} + \text{H}$.

Compact; fracture earthy; sectile. $H.=1.5$; $G.=2.6$. Opaque, dull. Grayish-blue, black, or red (*Catlinite*). B.B. infusible. Used by the North American Indians for pipes.

137. MEERSCHAUM.— $2 \text{Mg}^2 \text{Si}^3 + 3 \text{H}$.

Fracture fine earthy; sectile. $H.=2...2.5$; $G.=0.8...1.0$ (when moist nearly 2). Opaque, dull. Streak slightly shining. Yellowish and grayish-white. Feels rather greasy, and adheres strongly to the tongue. B.B. contracts, becomes hard, and fuses on the edges; soluble in h. acid, leaving silica. Chem. com. 62.6 silica, 28.3 magnesia, and 9.1 water; but others give also 0.7 to 2.7 carbonic acid, and 14 hygroscopic water. Asia Minor, Greece, near Madrid and Toledo; Moravia and Wermeland (*Aphrodite*, $G.=2.21$). Chiefly used in forming heads for tobacco pipes.

138. PIMELITE.— $(\text{Ni}, \text{Mg})^3 \text{Si}^3 + \text{H}$.

Fracture conchoidal. $H.=2.5$; $G.=1.4$ (*Alizite*)...2.3. Translucent; dull resinous. Colour apple-green; streak yellowish-white. Feels greasy. B.B. fuses to a slag only on thin edges. With borax shows reaction for nickel (32.66 nickel oxide). Silesia. *Razoumoffskin* is by some united to pimplite, but the variety from Kosemutz in Silesia contained no nickel.

139. DERMATIN.— $(\text{Mg}, \text{Fe}) \text{Si} + 2 \text{H}$.

Reniform. $H.=2.5$; $G.=2.136$. Resinous. Colour blackish-green; streak yellowish-white. Does not adhere to the tongue. B.B. cracks and becomes black. Waldheim in Saxony.

*FAMILY XI.—GARNET.

Chiefly tesseral. $H.=6...7.5$; $G.=3.1...3.8$. All fusible and soluble in acids, but not readily, or only after ignition. Mostly highly coloured, and often with fine gem-like lustre; but rarely transparent, mostly translucent or opaque. Are mostly anhydrous silicates of alumina and the earths, coloured by oxides of iron, manganese, and chrome.

Occur imbedded, or in veins and druses, in the older crystalline rocks, but rarely as essential constituents.

**140. GARNET.— $\text{R}^3 \text{Si}^2 + \text{K Si}$, or $\text{R}^3 \text{Si} + \text{K Si}$.

Tesseral; most common forms αO (fig. 3), and 202 (fig. 6). These are often combined (figs. 18 and 19). Also granular or compact. Cleavage dodecahedral, but very imperfect; fracture conchoidal, or uneven and splintery. $H.=6.5...7.5$; $G.=3.5...4.3$. Pellucid in all degrees; vitreous or resinous. Rarely colourless or white; generally red, brown, black, green, or yellow. B.B. in general fuse easily to a glass, black or gray, in those containing much iron, green or brown in the others, and often magnetic; imperfectly soluble in h. acid, some wholly, after long digestion, leaving the silica in powder. Chem. com. exceedingly variable, but generally form two series, according as K is chiefly alumina or chiefly iron peroxide; and these are again divided according as R is more especially lime, iron protoxide, magnesia, or similar bases.

The more important varieties are:—

(1.) *Almandine*, or *Noble Garnet*.—Columbine-red inclining to violet, blood-red, or reddish-brown; streak white; transparent or translucent; sometimes magnetic. Is an iron-alumina garnet, $\text{Fe}^3 \text{Si}^2 + \text{Al Si}$, with 37 silica, 20.1 alumina, and 42.9 iron protoxide. Common in the primary rocks, in crystals, or rarely forming beds and veins. The finest are from Pegu, Ceylon, and the East. Large crystals at Fahlun, Arendal, Kongsberg, the Tyrol, the Ural, and in North America. It is common in the mica-slates of Perth, Inverness, and Zetland; in granite at Rubislaw, Aberdeen. Used as an ornamental stone.

(2.) *Manganese-alumina Garnet*; $\text{R}=\text{Mn}$; reddish-brown; Spessart, Sweden.

Mineralogy.

Minera-
logy.

(3.) *Lime-alumina Garnets*.— $\text{Ca}^3 \text{Si}^2 + \text{Al} \text{Si}$, with 40·7 silica, 22·5 alumina, and 36·8 lime. To these belong—

(a.) *Grossular*.—White to olive-green, and translucent. Wilui River, Siberia, the Ural, and Tellemark in Norway.

(b.) *Cinnamon-stone, Hessonite, or Kaneelstein*.—Hyacinth-red to honey or orange-yellow; and transparent or translucent. Ceylon and Wermeland. *Romanzowite*, Kimito in Finland, is similar. When polished, this variety is often named Hyacinth.

(c.) *Common Lime-garnet*.—Red, brown, yellow, or green, and with part at least of the alumina replaced by iron peroxide. Abundant in Piedmont, Vesuvius, the Ural, and North America.

(4.) *Magnesia-garnet*.— R , chiefly magnesia; opaque, resinous; coal-black. $G.=3.157$. Arendal.

(5.) *Iron-garnets*.— $\text{Ca}^3 \text{Si}^2 + \text{Fe} \text{Si}$, with 36·2 silica, 31·1 iron peroxide, and 33·6 lime. $G.=3.7...4$. More difficultly fusible and more easily soluble in h. acid than the others.

(a.) *Common Iron-garnet, Rothoffite, Allochroite*.—Sub-translucent or opaque. Green, brown, yellow, or black, with white, gray, or yellow streak. Sweden and Arendal.

(b.) *Melanite*.—Black; opaque; in thin splinters translucent. Streak gray; slightly magnetic. Albano near Frascati, Vesuvius, France, Lappmark. *Pyreneite*, near Barèges in the Pyrenees.

(c.) *Colophonite*.—Yellowish-brown to pitch-black, also yellow or red; resinous; streak white. $G.=3.43$. Arendal.

(6.) *Uvarovite, or Chrome-garnet*.—Emerald-green; vitreous; streak greenish-white. Translucent or only on the edges. $G.=3.4$; $H.=7.5$. B.B. infusible. Bissersk and Kyschtinsk in the Ural.

141. *PYROPE*.— $(\text{Mg}, \text{Fe}, \text{Ca}, \text{Mn})^3 \text{Si}^2 + \text{Al} \text{Si}$.

Tesseral, but crystals (cubes) rare and indistinct; generally in roundish grains. Cleavage not perceptible; fracture conchoidal. $H.=7.5$; $G.=3.7...3.8$. Transparent or translucent; vitreous. Dark-hyacinth to blood-red. B.B. becomes black and opaque, but regains its colour and transparency on cooling; fuses with difficulty to a black glass; not soluble in acids, partially after fusion. Chem. com. 41·35 silica, 22·35 alumina, 15 magnesia, 9·94 iron protoxide, 5·29 lime, 4·17 chrome-protooxide, and 2·58 manganese-protooxide (*Moberg*). The chrome has also been considered as the oxide or acid. Zöblitz in Saxony, Meronitz and Mittelgebirge in Bohemia, and Elie in Fife (Elie rubies). Valued as a gem.

142. *HELVINE*. $\left\{ \begin{array}{l} \text{Mn S} + 3 \text{R}^2 \text{Si}, \text{ or} \\ \text{Mn S}, \text{Mn O} + (\text{Mn}, \text{Fe})^3 \text{Si}^2 + \text{G} \text{Si} \end{array} \right.$

Tesseral, and tetrahedral; $\frac{O}{2}$ or $\frac{O}{2} - \frac{O}{2}$ (fig. 128). Im-

bedded or attached. Cleavage, octahedral imperfect. $H.=6...6.5$; $G.=3.1...3.3$. Translucent on the edges; vitreous to resinous. Wax-yellow, siskin-green, or yellowish-brown. B.B. in the red flame fuses with intumescence to a yellow obscure pearl; soluble in h. acid, evolving sulphuretted hydrogen, and gelatinizes. Chem. com. 34 silica, 10 glucina, 8 iron protoxide, 43 manganese protoxide, and 5 sulphur. Schwarzenberg in Saxony, and near Modum in Norway.

Fig. 128.

143. *IDOCRASE*, $\left\{ \begin{array}{l} 3 (\text{Ca}, \text{Mg}, \text{Fe})^3 \text{Si} + 2 \text{Al} \text{Si}^2, \text{ or} \\ \text{Vesuvian. } 3 (\text{Ca}, \text{Mg}, \text{Fe})^3 \text{Si} + 2 (\text{Al}, \text{Fe}) \text{Si} \end{array} \right.$

Tetragonal; $P 74^\circ 27'$. Crystals of ∞P , $\infty P\infty$, $0P$, P , $P\infty (56^\circ 29')$, $\infty P3$. Columnar; more rarely tabular or

pyramidal (figs. 129, 130). Cleavage, prismatic along $\infty P\infty$ and ∞P , but imperfect; fracture uneven, splintery. $H.=6.5$; $G.=3.35...3.45$ (or 4). Pellucid; vitreous or resinous. Yellow, green, brown, almost black, rarely azure-blue; streak white. B.B. fuses easily with intumescence to a yellowish-green or brown glass; partially soluble in h. acid, after fusion wholly, and gelatinizes. Chem. com. 39 silica, 22 alumina, 32 lime, 5 iron protoxide, and 2 magnesia. Vesuvius, Wilui River in Siberia, Mussa-alp in Piedmont, Egg in Norway, Wicklow in Ireland, Monaltrie in Aberdeenshire, and near Broadford in Skye, in Scotland.

Also columnar or granular.

Fig. 129.

Fig. 130.

Gahnite, Loboite, Gökumite, from Gökum; *Frugardite*, from Finland; *Egeran*, from near Eger; *Cyprine*, from Tellemark, Norway (azure-blue or green, contains copper, and B.B. melts easily in the inner flame to a red pearl); *Xanthite*, from Amity in New York—seem only idocrase.

Used as an ornamental stone, the brown being named hyacinth, the green chrysolite, but it is not highly valued.

*144. *EPIDOTE*. $\left\{ \begin{array}{l} (\text{Ca}, \text{Mg}, \text{Fe})^3 \text{Si}^2 + 2 (\text{Al}, \text{Fe}, \text{Mn}) \text{Si} \\ \text{or } \text{R}^3 \text{Si} + 2 \text{R} \text{Si} \end{array} \right.$ (*Rams.*)

Monoclinohedric; $C=89^\circ 27'$, $\infty P2 63^\circ 8'$, $P\infty 64^\circ 36'$, $-P\infty 63^\circ 43'$, $P 70^\circ 9'$. $-P 70^\circ 33'$. Crystals horizontal-prismatic, as in fig. 131, where $\infty P\infty (M)$. $P\infty (T)$ $-P\infty (r) - P (n)$. Generally in druses; the surface often horizontally striated. Macles united by a face of $P\infty$; also columnar, granular, or compact. Cleavage, orthodiagonal very perfect, along $P\infty$ rather perfect. Fracture conchoidal, uneven, or splintery. $H.=6...7$; $G.=3.2...3.5$. Pellucid in all degrees; vitreous, on cleavage adamantine. Especially green, yellow, and gray; rarely red and black. B.B. fusible; strongly ignited, or after fusion all are soluble in h. acid, and gelatinize. Varieties are,—

Fig. 131.

(1.) *Zoisite*.—White, yellowish, or brownish-gray; chiefly large imbedded crystals, or foliated and columnar. B.B. intumesces and forms a white or yellow porous mass, and on the edges fuses to a clear glass. Is a lime-alumina epidote, = 42·4 silica, 31·4 alumina, 26·2 lime, with very little iron oxide or magnesia. Sau Alpe in Carinthia, the Ural, and Connecticut. *Thulite*, rose or peach-blossom red, from Souland in Norway, is similar.

(2.) *Pistazite, Thallite*.—Pistacio-green to blackish-green and black, also yellow or brown. Crystallized, granular, or earthy, also in crusts. B.B. fuses on the edges, and swells into a dark-brown slag. Is an iron-epidote, with 10 to 16 peroxide and 2 to 6 protoxide of iron. Arendal, the Ural, the Alps (Mont Blanc), Pyrenees, the Harz, Finland, Greenland, and North America. In Scotland, in syenite in Zetland, in gneiss in Sutherland, in trap in Mull and Skye, in quartz in Rona, in clay-slate in Arran, and in porphyry in Arran and Glencoe. *Puschkinite*, from the Ural, *Withamite*, from Glencoe, in minute bright-red crystals; and *Bucklandite*, in small black crystals, from Lake Laach and Siberia, are this variety.

(3.) *Manganese-epidote*.—With much manganese-peroxide (14 to 20). Dark violet-blue or reddish-black; streak cherry-red. $H.=6.5$; $G.=3.4$. B.B. melts easily to a black glass. St Marcel in Piedmont.

Minera-
logy.

Triclinohedric. Crystals usually very unsymmetrical (figs. 132 and 133), with u to $P = 135^\circ 24'$, u to $r = 115^\circ 39'$,

Fig. 132.

Fig. 133.

P to $r = 134^\circ 48'$; attached singly, or in druses. Also laminar or broadly radiated. Cleavage, imperfect along a plane truncating the sharp edge between P and u . $H. = 6.5 \dots 7$; $G. = 3 \dots 3.3$. Pellucid; vitreous. Clove-brown, inclining to smoke-gray or plum-blue, but often cinnamon-brown in one direction, dark violet-blue in a second, and pale olive-green in a third. B.B. intumesces and fuses easily to a dark-green glass, becoming black in the ox. flame; not soluble in h. acid till after ignition, when it gelatinizes. Chem. com. about 44 silica, 5 boracic acid, 16 alumina, 11 iron peroxide, 1.5 manganese-peroxide, 2.5 magnesia, and 20 lime. Bourg d'Oisans in Dauphiné, and the Botallack mine in Cornwall, Kongsberg in Norway, Arendal, Nordmark in Sweden, Pyrenees, Savoy, Tyrol, Thum in Saxony (*Thummerstein*), the Ural, and North America.

Rhombic or monoclinohedric, only indistinct; thin four or six-sided prismatic crystals, or granular. Cleavage, prismatic distinct; fracture conchoidal. $H. = 5.5$; $G. = 3.1$. Translucent or opaque; vitreous or pearly. Gray, indigo-blue, or bluish-black. B.B. becomes yellowish-brown, and fuses readily to an olive-green glass; partly soluble in acids. Island of Syra. Similar are,—

Wichtyne.—Massive; black. B.B. fuses to a black enamel; not affected by acids. Wichtis in Finland. *Violan*.—Massive; opaque, resinous. Dark violet-blue. B.B. fuses easily to a clear glass. St Marcel in Piedmont.

FAMILY XII.—CYANITE.

Triclinohedric or rhombic, often in long prismatic forms. $H. = 5 \dots 7.5$; $G. = 2.9 \dots 3.8$. B.B. infusible; insoluble in acids. Some show fine colours and high vitreous lustre. They are chiefly anhydrous silicates of alumina. Occur especially in the crystalline strata.

Triclinohedric. Generally broad prismatic lengthened crystals formed by two faces meeting at $106^\circ 16'$. Macles are common, united by $\infty P \infty$. Also even, curved, or radiated. Cleavage, along the prisms very (or less) perfect; brittle. $H. = 5$ on cleavage planes, on other faces $= 7$; $G. = 3.5$ to 3.7 . Pellucid, vitreous; on cleavage pearly. Fig. 134. Colourless, or blue, gray, green, yellow, or red. Not affected by acids. B.B. infusible. Chem. com. 37.6 silica, and 62.4 alumina. St Gotthardt, Tyrol (*Rhaetizite*), Pontivy in France, Bohemia, Nigg near Aberdeen, Botriphny in Banffshire, and Hillswick in Zetland.

Fig. 134.

Triclinohedric, with $\infty P' : \infty P = 98^\circ$, $P' : \infty P' = 105^\circ$. Crystals long and slender; also fibrous or parallel. Cleavage, macrodiagonal highly perfect. $H. = 7 \dots 7.5$; $G. = 3.2 \dots 3.26$. Translucent; vitreous, inclining to pearly. Grayish-brown, clove, or hair-brown. B.B. infusible; not af-

ected by acids. Chem. com. like cyanite, from which it is scarcely distinct. Chester and Norwich in Connecticut, Tvedestrand in Norway. The *Xenolite*, Finland; *Bucholzite*, *Fibrolite*, and *Bamlite*, from Bamle in Norway, seem also cyanite; *Wörthite*, an altered variety.

Rhombic; $\infty P 90^\circ 44'$, $\bar{P} \infty 109^\circ 6'$. Crystals $\infty P \cdot 0P$, or this with $\bar{P} \infty$ (fig. 135); prismatic, attached or imbedded; also columnar, or granular. Cleavage, ∞P rather indistinct; traces along $\infty \bar{P} \infty$, $\infty \bar{P} \infty$ and $\bar{P} \infty$. Fracture uneven, splintery. $H. = 7 \dots 7.5$; $G. = 3.1 \dots 3.3$. Pellucid; vitreous. Gray, green, red, or blue. B.B. infusible; not affected by acids. Chem. com. 40.4 silica and 59.6 alumina, with 1 to 2 iron peroxide. Andalusia, Lissens in Tyrol, Penig in Saxony, Westford in Massachusetts, Litchfield in Connecticut; and Botriphny in Banffshire, Tyrie in Aberdeenshire, and Killiney Bay in Wicklow.

Fig. 135.

Chiastolite.— $H. = 5 \dots 5.5$; $G. = 3$. Dirty or pale gray, yellow, or red. Occurs imbedded in clay-slate, and often appears like four crystals separated by a black cross (fig. 136). Fichtelgebirge, Brittany, the Pyrenees, Sierra Morena, Wolfscrag near Keswick, and on Skiddaw in Cumberland; near Balahulish in Argyleshire, Boharm in Banffshire, and in Wicklow.

Fig. 136.

Rhombic; $\infty P' 128^\circ 42'$, $\bar{P} \infty 70^\circ 46'$. Crystals $\infty P (M)$. $\infty \bar{P} \infty (o)$. $0P (p)$. Macles very common, like figs. 137 or 138. Cleavage, brachydiagonal perfect, traces along ∞P ;

Fig. 137.

Fig. 138.

fracture conchoidal, or uneven and splintery. $H. = 7$; $G. = 3.5 \dots 3.8$. Translucent or opaque; vitreous, inclining to resinous. Reddish to blackish-brown; streak white. B.B. infusible; not affected by h. partially by s. acid. Chem. com. ranges from 28 to 40 silica, 45 to 55 alumina, 15 to 18 iron peroxide, with 0.2 to 2.5 magnesia. St Gotthardt and Greiner in Tyrol, Finisterre, Pyrenees, Spain, the Ural, and in North America; in Scotland, Bixeter Voe in Zetland, in Aberdeenshire, and the Hebrides.

Rhombic; $\infty P = 120^\circ$, broad indistinct prisms, chiefly of $\infty \bar{P} \infty$, bounded by the curved faces of P (fig. 139). Usually thin foliated or broad radiated. Cleavage, brachydiagonal highly perfect; very brittle. $H. = 6$; $G. = 3.3 \dots 3.4$. Pellucid; vitreous; pearly on $\infty \bar{P} \infty$. Colourless, but generally yellowish or greenish-white; also violet-blue. Insoluble in acids. B.B. infusible, but some decrepitate into small white scales. Chem. com. 85 alumina and 15 water. Rare. Ural and Schemnitz, Broddbo and St Gotthardt.

Fig. 139.

Hexagonal; $0P$. ∞P . $\infty P2$, or granular scaly. Cleavage, basal very perfect. $H. = 2.5 \dots 3$; $G. = 2.3 \dots 2.4$. Translucent; vitreous; pearly on $0P$. Colourless or reddish-white.

Mineralogy.

Slowly soluble in warm acids. B.B. exfoliates, and gives out a strong light, but is infusible. Chem. com. 65.5 alumina and 34.5 water. Near Slatoust in the Ural. Stalactitic, greenish or grayish-white (*Gibbsite*); Richmond, Massachusetts, Villa Rica in Brazil.

153. PERICLASE.—Mg.

Tesseral, only in octahedrons. Cleavage, hexahedral perfect. $H.=6$; $G.=3.75$. Transparent; vitreous. Dark-green. B.B. infusible; powder soluble in acids. Chem. com. magnesia, with 5 to 8 protoxide of iron. Monte Somma.

FAMILY XIII.—GEMS.

All very hard, $H.=7..9$, or scratch quartz, except a few $=6$, which are scarcely true gems; $G.=2.6..4.7$, but mostly high in the finest. Insoluble in acids, and infusible B.B. in the true gems. These have a high lustre, brilliant colours, and take a fine polish, and are therefore much valued. They are, however, rare, and generally small. Chem. com. variable, but mostly simple. Chiefly occur in the older igneous or metamorphic rocks.

*154. ZIRCON.— $Zr^3 Si$, or $Zr^3 Si$, or $Zr^3 Si$.

Tetragonal; $P 84^\circ 20'$. Crystals, $\infty P \cdot P$, often with $3 P 3$; also $\infty P \infty \cdot P$, or $\infty P \infty (s) \cdot \infty P (l) \cdot P (P) \cdot 3 P 3 (x) \cdot P \infty (t) \cdot 4 P 4 (y) \cdot 5 P 5 (z)$ (fig. 140), chiefly prismatic or pyramidal, and in rounded grains. Cleavage, along P and ∞P , both rather imperfect; fracture conchoidal or uneven. $H.=7.5$; $G.=2..4.7$. Transparent to opaque; vitreous, often adamantine. Rarely white, generally gray, yellow, green, or frequently red and brown. B.B. loses its colour, but is infusible; not affected by any acid except con. s. acid, after long digestion. Chem. com. 66.23 zirconia (and noria, *Svanberg*), and 33.77 silica, with 0 to 2 iron peroxide as colouring matter. Southern Norway, Ilmen Mountains, Arendal, Sweden, Carinthia, Tyrol, Ceylon, and North America; in Scotland, at Scalpay in Harris, and Criffel.

Fig. 140.

The colourless varieties are often sold for diamonds. The more brilliantly coloured are named hyacinth.

155. MALAKON.— $3 Zr^3 Si + H$.

Tetragonal; $P 82^\circ$. Crystals, like zircon. $H.=6$; $G.=3.9$. Opaque; resinous or vitreous. Internally bluish-white, but on the surface mostly brownish, reddish, yellowish, or blackish. Chem. com. zircon, with 3 per cent. water. Hitterö in Norway, Malakon. *Erstedtite* from Arendal, *Tachyaphyllite* from Krageroe, and *Calyptolite*, are probably altered zircon.

*156. SPINEL.— $Mg \ddot{Al}$, or $(Mg, Fe) (\ddot{Al}, \ddot{Fe})$.

Tesseral; O alone or predominating, ∞O and $3 O 3$. Macles united by a face of O (fig. 141); also in grains or fragments. Cleavage, octahedral imperfect; fracture conchoidal. $H.=8$; $G.=3.4..3.8$. Transparent to opaque; vitreous. Red, blue, green, and black; streak white. B.B. infusible and unchanged. Chem. com. 71 alumina and 29 magnesia; but some 1 to 5 silica, 3 to 20 iron protoxide, 0 to 6 iron peroxide, and the red varieties 1 to 5 chrome. The varieties are:—

Fig. 141.

Spinel or *Spinel-ruby*, rose-red (*Balas ruby*), yellow or orange-red (*Rubicelle*), violet (*Almandine ruby*) or brown; $G.=3.52$; from Ceylon, Ava, and the East. Much prized as ornamental stones. *Sapphirine*.—Pale sapphire-blue to greenish or reddish blue; $G.=3.4..3.7$;

Mineralogy.

with 4 per cent. iron protoxide; Aker in Sweden, Greenland, and North America. *Pleonaste*, opaque or translucent, black; $G.=3.65..3.8$; with 8 to 20 iron protoxide; Candy in Ceylon (*Candite*, or *Zeilanite*), Monte Somma, Monzoni, Arendal, Bohemia (*Hercinite*), the Ural, and New York. *Chlorospinel*, grass-green, with a yellowish-white streak; $G.=3.59$; Slatoust in the Ural.

157. AUTOMOLITE, Gahnite.— $Zn \ddot{Al}$.

Tesseral; O , alone or macled. Cleavage, O perfect; brittle, with conchoidal or splintery fracture. $H.=8$; $G.=4.3..4.6$. Opaque or translucent on the edges; vitreous, inclining to resinous. Dark leek-green to blackish-green and blue; streak gray. B.B. unchanged; not affected by acids or alkalis. Chem. com. 56 alumina and 44 zinc oxide, but with 4 to 6 protoxide of iron, and 2 to 5 magnesia. Fahlun, Broddbo, Haddam in Connecticut, and Franklin in New Jersey. *Dysluite*, yellowish-brown, with manganese, from Sterling, Massachusetts; and *Kreitonite*, brown, from Bodenmais, are similar.

*158. CORUNDUM.— \ddot{Al} .

Rhombohedral; isomorphous with peroxide of iron and chrome; $R 86^\circ 4'$. Crystals chiefly of $\infty P 2 (s)$, $OR (o)$, $R (P)$, are pyramidal (fig. 142), prismatic (fig. 143), or

Fig. 142.

Fig. 143.

rhombohedral. Macles common, united by a face of R . Cleavage, rhombohedral along R , or basal. Extremely tough, and difficultly frangible. $H.=9$; $G.=3.9..4.2$. Transparent or translucent; vitreous, or pearly on OR . Colourless and white, but generally blue, red, yellow, brown, or gray. B.B. unchanged. Chem. com. alumina, with a minute proportion of peroxide of iron or other colouring matter.

Varieties are:—(1.) *Sapphire*, highly transparent, very imperfect cleavage and conchoidal fracture; colourless, blue (*Salamstein*), seldomer green, yellow, red (*Oriental rubies*), or brown; Ceylon, Ava, Pegu, Minsk, Slatoust, Bilin in Bohemia, and Expailly in Auvergne. (2.) *Corundum*, rough crystals or foliated, less transparent and duller colours; Malabar, Ceylon, Ava, Canton in China, Siberia, St Gotthardt, and Piedmont. Some (*Asteria* or *star sapphire*) show a bright opalescent star of six rays. (3.) *Adamantine spar*, with distinct cleavage, hair-brown, and adamantine; Gellivara, Ural, Malabar, and North America. (4.) *Emery*, compact, dimly translucent, and gray or indigo-blue; Asia Minor near Smyrna, Naxos, Spain, Saxony, and Greenland. Sapphire and rubies are highly valued as ornamental stones; emery as a polishing material.

159. CHRYSOBERYL, Cymophane.— $G \ddot{Al}^3$.

Rhombic; P with polar edges $86^\circ 16'$ and $139^\circ 53'$. Crystals of $\infty \bar{P} \infty (M)$, $\infty \bar{P} \infty (T)$, $\bar{P} \infty (z)$, or this with $\infty P 3 (s)$, and also with $P (o)$ (fig. 144), are short and broadly columnar, or thick tabular with vertical striæ. Macles very common, united by a face of $\bar{P} \infty$. Cleavage,

Fig. 144.

Mineralogy.

lite, large prisms or foliated, green or brownish; near Brevig in Norway, Unity in Maine, and Haddam in Connecticut. (c.) *Fahlunite*, *Triclasite*, compact, greenish-brown or black foliated; H.=2.5...3; G.=2.5...2.8; Fahlun. (d.) *Weissite*, kidney-shaped and ash-gray or brown; Fahlun and Lower Canada. (e.) *Pyrargillite*, indistinct imbedded crystals, black passing into brown or red, dull resinous lustre; H.=3.5; G.=2.5; Helsingfors. (f.) *Pinite*, crystallized, or massive and laminar, with imperfect cleavage; H.=2...3; G.=2.7...2.9; semitranslucent or opaque, dull or resinous, and dirty-gray, green, or brown; B.B. fuses to a glass, sometimes clear, at other times dark-coloured; Auvergne, Schneeberg, Penig in Saxony, in the Harz, Cornwall, Aberdeenshire, the United States, and Greenland (*Gieseckite*). *Oosite* from Geroldsau in Baden, snow-white, opaque, fragile, is similar. (g.) *Gigantolite*; H.=3.5; G.=2.8...2.9; opaque, dull resinous, and greenish-gray or brown; B.B. intumesces slightly, and fuses easily to a greenish slag; Tammela in Finland. (h.) *Praseolite*, lamellar and green; Brevig in Norway.

** 167. TOURMALINE, Schorl.

Rhombohedral; R 133° 10'. Crystals of OR (*k*), -1R (155°) (*n*), R (*P*), -2R (103° 3') (*o*), ∞P2 (*s*), and ∞R (*l*), usually long prismatic, striated, and remarkable for hemimorphism, ∞R appearing as a triangular prism (figs. 150,

Fig. 150.

Fig. 151.

151); also radiating, columnar, or fibrous. Cleavage, R and ∞P 2 both imperfect; fracture conchoidal or uneven. H.=6.5...7.5; G.=3...3.3. The black opaque, the others pellucid; vitreous. Colourless, but gray, yellow, green, blue, red, brown, and most frequently black. Often several colours in layers perpendicular, or parallel to the axis. By friction acquires positive, by heat polar electricity; powder white, often magnetic. B.B. some fuse, others only intumesce, and some both fuse and intumesce. Powder not soluble in h., only imperfectly in s. acid. Chem. com. very complex, with 36 to 41 silica, 5 to 10 boracic acid, 1.3 to 2.7 fluorine, 0 to 0.3 phosphoric acid, 30 to 45 alumina, 0 to 13 iron peroxide, 0 to 5 manganese peroxide, 0 to 10 iron protoxide, 0.5 to 1.5 magnesia, 0 to 2 lime, 1 to 2.6 soda, 0.1 to 2 potash, and 0 to 1.5 lithia. Rammelsberg makes five groups in two divisions:—

A. Tourmalines with no lithia, and little or no manganese:—

- (1.) Magnesia Tourm. — $\text{R}^3 \text{Si}^2 + 3 \text{R} \text{Si}$; yellow and brown, with much magnesia and little iron.
- (2.) Magnesia-iron T. — $\text{R}^3 \text{Si}^2 + 4 \text{R} \text{Si}$; apparently black; with an average amount of magnesia and iron.
- (3.) Iron T. — $\text{R}^3 \text{Si}^2 + 6 \text{R} \text{Si}$; deep black with most iron and least magnesia.

B. Tourmalines with lithia and little magnesia:—

- (4.) Iron-manganese T. — $\text{R} \text{Si} + 3 \text{R} \text{Si}$; blue (or violet) and green T., with iron.
- (5.) Manganese T. — $\text{R} \text{Si} + 4 \text{R} \text{Si}$; red or colourless, with no iron.

Groups 2 and 3 are the most common, and known as *Schorl*, the red varieties as *Rubellite*, the colourless as *Achroite*.

The finest transparent varieties or noble tourmalines come from Ceylon, Siberia, and Brazil. The dark-blue or *Indicolite* occurs chiefly in Utoe. Large crystals of the dark opaque varieties occur in Greenland, Arendal, the Tyrol, and various parts of North America. In England, Bovey in Devonshire and St Just in Cornwall, are well-known localities; and in Scotland large prisms, often curved or broken, abound in the granite of Aberdeenshire.

Tourmaline is not much valued as a gem, the colours being rarely pure. *Zeuxite* seems only Tourmaline.

* 168. CHRYSOLITE, Olivine, Peridot.—(Mg , Fe)² Si.

Rhombic; ∞P (*n*) 130° 2', $\bar{P} \infty$ (*d*) 76° 54', 2 $\bar{P} \infty$ (*k*) 80° 53'; also ∞ $\bar{P} \infty$ (*M*), ∞ $\bar{P} \infty$ with P (*p*), OP (fig. 152). The crystals are frequently prismatic and imbedded; also massive and granular. Cleavage, ∞ $\bar{P} \infty$ rather distinct; fracture conchoidal. H.=6.5...7; G.=3.3...3.5. Transparent or translucent; vitreous. Olive-green, also yellow and brown, rarely colourless. B.B. infusible; soluble and gelatinizing in acids. Chem. com. 38 to 43 silica, 43 to 51 magnesia, 8 to 18 iron protoxide, with a little manganese. *Chrysolite* is the fine green transparent and crystallized varieties from the East, Esne in Egypt, and Brazil. *Olivine*, the darker and less pellucid, from Vesuvius, Unkel on the Rhine, the basalts of Germany, and the trap of Arthur Seat and other parts of Scotland; also in meteoric iron, as in the mass found by Pallas in Siberia, and in that of Otumpa in South America. Used as an ornamental stone, but not much valued.

Fig. 152.

The following seem mere varieties:—

Hyalosiderite.—Brown or yellow, very ferruginous and metallic-looking; H.=5; G.=2.875; in other respects like olivine; Kaiserstuhl in the Breisgau. *Chusite*, *Limbelite*, and *Tautolite*; Lake Laach. *Batrachite*, greenish-gray or white, translucent; Rizoni Mountain, Tyrol. *Monticellite*, transparent, colourless or yellowish; Vesuvius.

Fayalite.—Crystalline, columnar and foliated, but often as if fused. Greenish or pitch-black, brownish or brass-yellow, with a resinous metallic lustre. H.=6.5; G.=4.15. Partly soluble in h. acid. Chem. com. $\text{Fe}^2 \text{Si}$ with 29.7 silica, 70.5 iron protoxide, and 2 to 8 manganese protoxide.

Knebelite.—Massive, opaque, gray, green, brown, or red. Chem. com. 32.5 silica, 32 iron protoxide, and 35 manganese protoxide.

Tephroite.—Granular, with two cleavages at right angles. H.=5.5; G.=4...4.12. Lustre adamantine. Ash-gray, with reddish-brown tarnish. Chem. com. 70 manganese protoxide and 30 silica. Franklin and Sparta, New Jersey.

169. CHONDRODITE, Maclurite, { $n \text{Mg}^2 \text{Si}^2 + [8 \text{Mg F} + 3 \text{Si F}^2]$ }
Brucite, Humite.

Rhombic; ∞P 94° 26', $\bar{P} \infty$ 112° 2'; but crystals on three types, and often monoclinic in character or indistinct; chiefly in round grains or granular. Cleavage indistinct; fracture imperfect conchoidal. H.=6.5; G.=3.15...3.25. Transparent or translucent; lustre vitreous or resinous. Yellow, red, brown, green, and almost black; streak white or yellowish. B.B. infusible, or only on very thin edges; decomposed by acids. Chem. com. 33 to 37 silica, 55 to 60 magnesia, 2.6 to 9.7 fluorine, with 1.7 to 6.7 iron protoxide. Chondrodite occurs at Pargas in Finland, Åker, and Gullsjö in Sweden, Sparta in New Jersey, and Orange

Mineralogy.

Mineralogy.

county in New York; also in Saxony and on Loch Ness in Scotland. *Humite* on Monte Somma.

FAMILY XIV.—METALLIC STONES.

Crystallization predominantly rhombic; some tesseral or monoclinohedric; but many massive, or products of decomposition, and thus rather metallic clays or rocks. The crystalline species are rather hard; $H. = 5.5 \dots 6.5$; and with $G. = 3.6 \dots 5.6$. Those with high specific gravity are mostly infusible B.B., the others fusible. Most are soluble in acids, often gelatinizing. They are mostly silicates with a metallic base, and thus an intermediate group between the true stones and the metallic ores. Often opaque, and black or brown and yellow. They occur especially in the igneous and metamorphic rocks, or metallic veins of Scandinavia and the Ural.

*170. *LIVÉRITE*, Yenite, } $\ddot{\text{Fe}}^2 \ddot{\text{Si}} + 3 \ddot{\text{Fe}}^2 \ddot{\text{Si}} + \text{Ca}^3 \ddot{\text{Si}}^2$
Ilvaite.

Rhombic; P, polar edges $138^\circ 26'$ and $117^\circ 34'$, ∞P $111^\circ 12'$, $\bar{P} \infty 112^\circ 40'$. Crystals $\infty P2(s).P(o)$. $\bar{P} \infty (d)$ (fig. 153), are long prismatic and vertically striated; also radiated columnar or fibrous. Cleavages all imperfect; brittle. $H. = 5.5 \dots 6$; $G. = 3.9 \dots 4.2$. Opaque, resinous or imperfect metallic. Brownish or greenish-black; streak black. B.B. fuses easily to a black magnetic globule; soluble in h. acid forming a yellow jelly. Chem. com. 28.8 silica, 24.8 iron peroxide, 33.4 iron protoxide, and 13.0 lime. Rio in Elba, Fossum, Kupferberg, Rhode Island, and Greenland. *Wehrlite*, iron-black, with greenish-gray streak, and B.B. difficultly fusible, is a variety; Hungary.

Fig. 153.

171. *HISINGERITE*, Thraulite. — $\ddot{\text{Fe}}^2 \ddot{\text{Si}}^3 + 2 \ddot{\text{Fe}} \ddot{\text{Si}} + 10 \ddot{\text{H}}$. Reniform, or in crusts. $H. = 3.5 \dots 4$; $G. = 2.6 \dots 3$. Opaque; resinous. Brownish or bluish-black; streak liver or yellowish brown. B.B. fuses with difficulty; soluble in acids, leaving slimy silica. Chem. com. 32.5 silica, 33.5 iron peroxide, 15.1 iron protoxide, and 19 water, of the Thraulite from Bodenmais. Also Gillinge, Rydarrhyttan in Sweden, and Breitenbrun in Saxony (*Polyhydrite*).

172. *ANTHOSIDERITE*. — $\ddot{\text{Fe}}^3 \ddot{\text{Si}}^3 + 2 \ddot{\text{H}}$.

Fine fibrous or flower-like; very tough. $H. = 6.5$; $G. = 3$. Opaque or translucent; silky. Ochre-yellow to yellowish-brown. B.B. becomes reddish-brown, then black, and fuses with difficulty. Soluble in h. acid. Chem. com. 61 silica, 35 iron peroxide, and 4 water. Minas Geraes in Brazil.

173. *NONTRONITE*. — $\ddot{\text{Fe}} \ddot{\text{Si}}^3 + 5 \ddot{\text{H}}$.

Massive. Fracture uneven. $G. = 2 \dots 2.3$; $H. = 2 \dots 3$. Opaque; dull or glimmering; streak resinous. Straw-yellow, yellowish-white, or siskin-green. B.B. decrepitates, becomes black and magnetic, but without fusing; soluble, and gelatinizes in warm acids. Chem. com. nearly 43 silica, 36 iron peroxide, and 21 water, with 3.5 alumina and 2 magnesia. Nontron in France, Harz, and Bavaria.

Chloropal is similar, but B.B. brown and infusible. Unghwar in Hungary, and near Passau. *Pinguite*, sectile; $H. = 1$; feels greasy; and B.B. fuses on the edges; is also a silicate of iron oxides with water; Wolkenstein in Saxony, near Zwickau, and Suhl.

174. *CHLOROPHLETTE*. — $(\ddot{\text{Fe}}, \ddot{\text{Mg}})^3 \ddot{\text{Si}}^4 + 18 \ddot{\text{H}}$.

Massive. Cleavage in two directions; fracture conchoidal, earthy; very soft and sectile. $G. = 2.02$. When first exposed translucent and pistacio or olive-green, but soon changes to brown or black, and opaque. B.B. melts to a black glass. Chem. com. of a specimen from Faroe, 32.85 silica, 22.08 iron protoxide, 3.44 magnesia, and 41.63

water. Squir More in Rum, Faroe, and Iceland; also in Fife and near Newcastle.

175. *THORITE*. — $\ddot{\text{Th}}^2 \ddot{\text{Si}} + 2 \ddot{\text{H}}$.

Massive. Fracture conchoidal; hard and brittle. $G. = 4.63 \dots 4.8$. Opaque; splendent; vitreous. Reddish-brown, or black clouded with red; streak dark-brown. B.B. infusible; gelatinizes with h. acid. Chem. com. essentially 73.4 thorina, 16.8 silica, and 9.8 water, but combined with very many other substances: lime, iron, manganese, magnesia, uranium, lead, tin, potash, soda, and alumina. Near Brevig in Norway.

176. *EULYTINE*. — $\ddot{\text{Bi}} \ddot{\text{Si}}^2$.

Tesseral and tetrahedral; $\frac{202}{2}$ and $-\frac{202}{2}$. The crystals (like fig. 9) very small, and often with curved faces. Cleavage very imperfect; fracture conchoidal. $H. = 4.5 \dots 5$; $G. = 5.9 \dots 6$. Transparent and translucent; adamantine. Clove-brown, yellowish-gray or white; streak white or gray. B.B. fuses readily with intumescence to a brown bead, leaving a yellow ring on the charcoal; decomposed by h. acid, forming gelatinous silica. Chem. com. 21 silica and 79 bismuth peroxide, with 3.3 phosphoric acid, 2.4 iron peroxide, and 1.3 fluorine. Schneeberg, and Bräunsdorf near Freiberg.

Hypochlorite or *Green Iron-earth*, also from Schneeberg, in reniform crusts, or very fine earthy; semitranslucent or opaque. Dull, and siskin or olive-green. $H. = 6$; $G. = 2.9 \dots 3$. B.B. infusible, but becomes blackish-brown; and forms a yellow ring on the charcoal; insoluble in acids. It seems a mixture of silicate of iron and bismuth with phosphate of alumina.

177. *GADOLINITE*. { $(\ddot{\text{Y}}, \ddot{\text{Ce}}, \ddot{\text{Fe}})^2 \ddot{\text{Si}}$, and
 $(\ddot{\text{Y}}, \ddot{\text{Ce}}, \ddot{\text{Fe}}, \ddot{\text{La}})^3 \ddot{\text{Si}}$.

Monoclinohedric, probably; with $P \infty 49^\circ$, $\infty P 115^\circ$, $(2 P \infty) 70\frac{1}{2}^\circ$ nearly (Scheerer); but crystals rare and indistinct. Cleavage very indistinct, or none; fracture conchoidal or splintery. $H. = 6.5$; $G. = 4.0 \dots 4.4$. Opaque or translucent on the edges; vitreous, often resinous. Black; streak greenish-gray. B.B. the conchoidal (vitreous) varieties incandesce vividly, intumescence, but do not fuse; the splintery varieties form cauliflower-like ramifications, but do not incandesce; gelatinizes in h. acid. Chem. com. uncertain, but 25 to 29 silica, 36 to 51 yttria, 10 to 15 protoxide of iron, 5 to 17 protoxide of cerium with lanthanum, and 0 to 12 glucina. Krageroe in Norway, Ytterby, and Finbo.

178. *ALLANITE*, Cerin, Orthite. — $3 \ddot{\text{R}}^3 \ddot{\text{Si}}^2 + 2 \ddot{\text{Al}} \ddot{\text{Si}}$. Monoclinohedric, like epidote, but distinct crystals rare (fig. 154), mostly long, columnar, or granular. Cleavage imperfect; fracture conchoidal or uneven. $H. = 6$; $G. = 3.2 \dots 3.7$. Opaque, or translucent in thin splinters; imperfect metallic, inclining to vitreous or resinous. Black inclining to green or brown; streak greenish or brownish-gray. B.B. frothes, and melts easily to a black or brown scoria or glass, often magnetic; gelatinizes with h. acid. Chem. com. very variable, but with 30 to 35 silica, 12 to 18 alumina and iron peroxide, whilst $\ddot{\text{R}}$ includes protoxides of cerium (11 to 24), lanthanum (2 to 8), iron (4 to 21), and manganese (0 to 3.5), with lime (2 to 12), yttria (0.3 to 4), and magnesia (0.4 to 5). Allanite occurs in Greenland, also at Hitteroe, the Jotun Fjeld, and Snarum; Cerin at Rydarrhyttan; Orthite at Finbo, Fahlun, Arendal, and Krageroe.

Fig. 154.

Pyrorthite, with carbonaceous and other matter; *Ural-orthite*, from the Ilmen Mountains, containing more alumina; *Bodenite*, from Boden, Saxony; and *Bagrathonite*, from Achmatowsk, are only varieties.

179. *TSCHEFFKINITE*.

Massive. Fracture flat conchoidal. $H. = 5 \dots 5.5$; $G. =$

Mineralogy.

Mineralogy.

4·5. Opaque; vitreous, splendid. Velvet-black; streak dark-brown. B.B. intumesces greatly, becomes porous, and often incandesces; in the strongest white heat fuses to black glass; gelatinizes with warm h. acid. Chem. com. 21 silica, 20 titanic acid, 11 iron protoxide, and 47 peroxides of cerium, lanthanum, and didymium. Ilmen Mountains near Miask.

180. CERITE.— $(\text{Ce}, \text{R})^2 (\text{Ce}, \text{R})^2 \text{Si} + \text{H}$.

Hexagonal; $\text{OP} \propto \text{P}$, in low six-sided prisms, but very rare. Generally fine granular, almost compact. Cleavage, traces; fracture uneven, splintery; brittle. $\text{H} = 5\cdot5$; $\text{G} = 4\cdot9\ldots5$. Translucent on the edges, or opaque; dull, adamantine, or resinous. Clove-brown, cherry-red, or pearl-gray; streak white. B.B. infusible, but becomes dirty yellow; soluble in h. acid, leaving gelatinous silica. Chem. com. 22 silica, 72 protoxide of cerium (with didymium and lanthanum), and 6 water, with iron protoxide and lime. Bastnaes near Ridderhyttan.

181. TRITOMITE.— $\text{Si}, \text{Ce}, \text{La}, \text{Ca}, \text{H}$.

Tesseral in tetrahedrons. Fracture conchoidal; brittle. $\text{H} = 5\cdot5$; $\text{G} = 4\cdot16\ldots4\cdot7$. Vitreous; translucent on the edges. Dark-brown. B.B. swells and cracks; soluble in acids. Lamoe near Brevig.

182. PYROCHLORE.— $2 (\text{Ca}, \text{Th}, \text{Ce}, \text{Fe}) \text{Ni} + \text{Na F}$.

Tesseral; O. Cleavage octahedral; brittle; fracture conchoidal. $\text{H} = 5$; $\text{G} = 3\cdot8\ldots4\cdot3$. Opaque or translucent; resinous. Dark reddish-brown, or almost black, some crystals ruby-red and transparent; streak pale-brown. B.B. becomes yellow and fuses with much difficulty into a blackish-brown scoria; the fine powder soluble in con. s. acid. Chem. com. very complex, but the Miask variety, 62 to 67 niobic (mixed with titanic and tungstic) acid, 10 to 13 lime, 6 to 13 oxide of cerium and thoria, and 7 fluoride of sodium; but yttria, iron, zirconia, lithia, and in that from Norway, also uranium, occur. Miask in Ural, Brevig and Fredriksvårn in Norway; also Chesterfield in Massachusetts (*Microlite*).

Pyrrhite, small orange-yellow octahedrons; $\text{H} = 6$; is a niobate of zirconia, with iron and uranium. Mursinsk and Azores.

183. OERSTEDTITE.

Tetragonal; $\text{P } 84^\circ 26'$, like zircon. $\text{H} = 5\cdot5$; $\text{G} = 3\cdot629$. Opaque or translucent on the edges; adamantine vitreous. Reddish-brown. B.B. infusible. Forchhammer found 19·71 silica, 2·61 lime, 2·05 magnesia, 1·14 iron protoxide, 68·96 titanate of zirconia, 5·53 water. Arendal.

184. KEILHAUTE, } $(3 \text{Ca Si} + (\text{Al}, \text{Fe}) \text{Si}) + \text{Y Ti}^3$
Yttrotitanite.

Monoclinohedric; $\text{C} = 58^\circ$, $\text{OP} = 114^\circ$. Cleavages, along -2 P intersecting at 138° . $\text{H} = 6\ldots7$; $\text{G} = 3\cdot5\ldots3\cdot7$. Translucent; vitreous or resinous. Blackish-brown; by transmitted light reddish; streak grayish-brown. B.B. fuses easily with effervescence to a black shining slag; with borax forms a blood-red glass in the red. flame; in powder soluble in h. acid. Chem. com. 28·8 silica, 27·8 titanic acid, 19·5 lime, 9·3 yttria, 6·9 alumina, and 7·7 iron peroxide. Near Arendal.

185. WÖHLERITE.

Rhombic; $\text{OP } 127^\circ 6'$, $\text{P} \propto 140^\circ 54'$. Cleavage perfect; fracture conchoidal. $\text{H} = 5\ldots6$; $\text{G} = 3\cdot41$. Translucent; vitreous or resinous. Yellow, inclining to red or brown. B.B. fuses to a yellowish glass; easily soluble in warm con. h. acid, depositing silica and niobic acid. Analysis—30·62 silica, 14·47 niobic acid, 15·17 zirconia, 3·67 iron and manganese protoxide, 26·19 lime, and 7·78 soda. Fredriksvårn (*Eukolite*), and Brevig in Norway.

ORDER II.—SALINE STONES.

Comprises minerals which, in external aspect and com-

position, resemble (or are) the salts of the chemist. With a few exceptions, as rock-salt and fluor-spar, they are combinations of the second order of two oxygen compounds. The acid component is one of the common acids,—the carbonic, sulphuric, boracic, or phosphoric acid,—not silica or alumina, as in the former order. They are almost all crystallized, and predominantly in rhombic or monoclinohedric forms, but some rhombohedric or tesseral. Their hardness is low; one 7, a few about 5, most lower. $\text{G} = 1\cdot5\ldots4\cdot7$. All are soluble in acids, except the sulphates (three); more than half in water. B.B. all fusible or decompose. Many of them are products of decomposition. Occur rather in veins than as components of rocks.

**FAMILY I.—CALC-SPAR.

Generally rhombohedric in crystals and cleavage. $\text{H} = 3\ldots4\cdot5$; $\text{G} = 2\cdot6\ldots3\cdot4$, becoming higher as the metallic element increases. They are soluble and often effervesce in acids; and become caustic or alkaline when burned. They form a series of closely-related compounds of carbonic acid with lime, magnesia, and isomorphous bases, as the protoxide of iron. Are generally white, translucent, with a vitreous, or pearly lustre.

**186. CALC-SPAR, Calcareous Spar, } Ca C .
Carbonate of Lime.

Rhombohedral; $\text{R } 105^\circ 5'$; the forms and combinations exceeding those of any other mineral. Among them are more than thirty rhombohedrons, especially $-\frac{1}{2}\text{R } 135^\circ$, R , $-2\text{R } 79^\circ$, and $4\text{R } 66^\circ$, with OR and $\propto\text{R}$ as limiting forms; more than fifty distinct scalenohedrons, as R^3 , R^2 , and $\frac{1}{2}\text{R}^3$; and the second hexagonal prism $\propto\text{P}2$, whilst hexagonal pyramids are among the rarer forms. Some of the most usual combinations are $\propto\text{R}$. $-\frac{1}{2}\text{R}$ (fig. 157); or $-\frac{1}{2}\text{R}$. $\propto\text{R}$, very frequent; also $\propto\text{R}$. OR ; likewise -2R . R ; R^3 . $\propto\text{R}$. -2R ; R^5 (y). R^3 (r). R (P). 4R (m). $\propto\text{R}$ (C) (fig. 155); and many others, upwards of an hundred distinct combinations being known.

Macles are not uncommon, especially with the systems of axes parallel (figs. 156, 157), and others conjoined by a

Fig. 155.

Fig. 156.

Fig. 157.

face of R with the chief axes almost at right angles, $89^\circ 8'$ (fig. 82); or by a face of $-\frac{1}{2}\text{R}$, in which the chief axes form an angle of $127\frac{1}{2}^\circ$; and usually many times repeated, so that the centre crystals appear in lamellæ not thicker than paper (fig. 81). Cleavage, rhombohedric along R very perfect and easily obtained, so that the conchoidal fracture is rarely observable; brittle. $\text{H} = 3$; $\text{G} = 2\cdot6\ldots2\cdot8$; pure transparent crystals = 2·72. Pellucid in all degrees. Very distinct double refraction. Lustre vitreous, but several faces resinous, and OR pearly. Most frequently colourless or white, but often gray, blue, green, yellow, red, brown, or black; streak grayish-white. B.B. infusible, but becomes caustic and emits a bright light; effervesces, and is entirely soluble in h. or n. acid. The fine powder ignited on platina-foil over the spirit-lamp, according to *v. Zehmen*,

Mineralogy.

forms a somewhat connected mass, and even adheres to the platina. Chem. com. of the purest varieties, carbonate of lime, with 43·87 carbonic acid and 56·13 lime, or 40 calcium, 12·2 carbon, and 47·8 oxygen; but usually contain magnesia and protoxide of iron or manganese. Remarkable specimens of the crystallized variety, or proper calc-spar, are found in Andreasberg and other parts of the Harz (six-sided prisms), Freiberg, Tharand, Maxen, Alston Moor in Cumberland (flat rhombic crystals), and in Derbyshire (pale yellow transparent pyramids).

Certain varieties are distinguished, as,—Iceland spar, remarkable for its transparency and double refraction, occurs massive in a trap rock in that island. *Slate spar*, thin lamellar, often with a shining white pearly lustre, and greasy feel; Wicklow in Ireland, Glentilt in Scotland, and Norway. *Aphrite*, fine scaly, from Hessia and Thuringia.

Marble is the massive crystalline variety of this mineral, produced by igneous action on compact limestone. Paros, Naxos, and Tenedos furnished the chief supply to the Grecian artists; Carrara, near the Gulf of Genoa, to those of modern times. Some of the coloured marbles of the ancients were impure limestones, as the *Cipollino*, zoned with green talc or chlorite; and *Verde antique*, mixed with green serpentine. *Ruin marble* shows irregular markings like ruins; Val d'Arno (Florentine marble), and Bristol (Cotham marble). *Lucullite*, from Egypt, and *Anthracomite*, from Kilkenny in Ireland, are black from carbon. *Lumachello*, from Bleiberg in Carinthia, exhibits beautiful iridescent colours from fossil shells, sometimes deep-red or orange (*Fire marble*).

Limestone occurs in all formations under various names, as *Oolite*, egg or roe-stone, round concretions, with a concentric structure like the roe of fish; *Pisolite*, or peastone, similar structure; *Chalk*, soft earthy; *Lithographic stone*, yellowish and compact, from Solenhofen; and *Marl*, calcareous matter more or less mixed with clay. *Tufa*, or calcareous tufa, generally a recent deposit from calcareous springs, has often a loose friable texture, but at other times is hard and compact; and in the neighbourhood of Rome forms the common building stone or *Travertino*. The sandstone of Fontainebleau is carbonate of lime ($\frac{1}{3}$) mixed with quartz sand ($\frac{2}{3}$), and occasionally crystallizing in rhombohedrons.

This mineral is employed in many ways,—the coarser varieties, as lime, for mortar, manure, tanning, a flux in melting iron and other ores, or in preparing glass, and similar purposes; the finer, as marbles, for sculpture, architecture, and ornamental stone-work; the chalk for writing, white-washing, or producing carbonic acid.

Plumbocalcite.—Cleavage, R 104° 53'. White and pearly; softer than calc-spar; but G.=2·824. Contains 2·3 to 7·8 carbonate of lead. Wanlockhead and Leadhills, Scotland.

**187. *DOLOMITE*, Bitter Spar.—Ca \ddot{C} + Mg \ddot{C} .

Rhombohedral; R 106° 15'—20'; most frequent form R; also R and $\frac{1}{2}$ R, or OR, ∞ R, and 4R. The rhombohedrons often curved and saddle-shaped; also granular or compact, often cellular and porous. Cleavage, rhombohedral along R. H.=3·5...4·5; G.=2·85...2·95. Translucent; vitreous, but often pearly or resinous. Colourless or white, but frequently pale-red, yellow, or green. B.B. infusible, but becomes caustic, and often shows traces of iron and manganese; fragments effervesce very slightly or not at all in hydrochloric acid; the powder is partially soluble, or wholly when heated; the very fine powder ignited on platina-foil for a few minutes over a spirit-lamp continues pulverulent, but intumesces slightly during ignition. Chem. com. generally carbonate of lime, with more than 20 per cent. carbonate of magnesia and less than 20 per cent. carbonate of iron.

Varieties are,—*Dolomite*, massive, granular, easily divisible, white; *Rhomb* or *Bitter-spar*, larger grained, or distinctly crystallized and cleavable, often inclining to green;

and *Brown-spar* and *Pearl-spar*, in simple crystals or in imitative forms, of colours inclining to red or brown, more distinct pearly lustre, and under 10 per cent. carbonate of iron. Traversella in Piedmont, St Gotthardt, Gap in France, Alston in Cumberland, in Derbyshire, and at Leadhills and Charlestown in Scotland. Greenish, maced; Miemo, in Tuscany (*Miemite*), and Tharand in Saxony (*Tharandite*). *Gurhofian*, from Gurhof in Austria, is white and compact.

The massive and compact varieties are very common, and valued as building-stones (cathedral of Milan, York Minster, and the New Houses of Parliament). The Parian marble, and also the Iona marble in the Hebrides, have been supposed to belong to this species.

Predazzite.—Granular; white and vitreous on the cleavage planes. H.=3·5; G.=2·623. Contains 6·98 per cent. water. Predazzo in Tyrol.

188. *BREUNNERITE*, Giobertite.—Mg \ddot{C} .

Rhombohedral; R 107° 10'—30'; as yet only R; and granular or columnar. Cleavage, R very perfect, with straight faces. H.=4...4·5; G.=2·9...3·1. Transparent or translucent on the edges; highly vitreous. Colourless, but often yellowish, brown, or blackish-gray. B.B. infusible, but generally becoming gray, or black and magnetic; soluble in acids, often only when pulverized and warmed. Chem. com. essentially carbonate of magnesia, with 51·7 carbonic acid and 48·3 magnesia, but often mixed with 8 to 17 carbonate of iron or manganese. Tyrol, St Gotthardt, Harz, Fassathal; also Unst in Zetland.

Mesitine-spar, splendid, yellow, lenticular crystals; G.=3·35...3·4; Traversella in Piedmont: and *Pistomasite*; G.=4·4; Salzburg; are similar.

189. *MAGNESITE*.—Mg \ddot{C} .

Reniform or massive. H.=3...5; G.=2·85...2·95. Sub-translucent or opaque; streak shining. Snow-white, grayish, or yellowish-white, and pale-yellow. Adheres slightly to the tongue. B.B. and with acids acts like breunnerite. Chem. com. pure carbonate of magnesia, with no metallic oxides. Tyrol, Norway, North America.

190. *HYDROMAGNESITE*.—Mg⁴ \ddot{C} s + 4 H.

Monoclinohedric; C=82 $\frac{1}{2}$ °, ∞ P 88° nearly. Crystals small, acicular; also massive. H.=1·5...3·5; G.=2·14...2·18. Vitreous or silky. White. B.B. infusible; soluble with effervescence in acids. Chem. com. 36·2 carbonic acid, 44 magnesia, and 19·3 water. Moravia, Kumi, Hoboken in New Jersey, and Texas in Pennsylvania. The *Hydromagnocalcite* is a similar yellow sinter from Vesuvius with part of the magnesia replaced by lime.

**191. *ARRAGONITE*, Needle Spar, Flos-ferri.—Ca \ddot{C} .

Rhombic; ∞ P 116° 16', P ∞ 108° 27'. The most common combinations are ∞ P ∞ (h), ∞ P (M). P ∞ (h, P), generally long prismatic (like fig. 158, and separate crystals in fig. 159); ∞ P ∞ . ∞ P. O \ddot{P} , generally short prismatic; 6P $\frac{1}{2}$. ∞ P. P ∞ , acute pyramidal. But simple crystals are rare,

Fig. 158.

Fig. 159.

Fig. 160.

from the great tendency to form macles, conjoined by a face of ∞ P, and repeated (figs. 159, 160). Also columnar, fibrous, and in crusts, stalactites, and other forms. Cleav-

Mineralogy.

Mineralogy.

age, brachydiagonal distinct, also ∞P and $\tilde{\infty}$ imperfect; fracture conchoidal or uneven. $H.=3.5\ldots 4$; $G.=2.8\ldots 3$ (massive 2.7). Transparent or translucent; vitreous. Colourless, but yellowish-white to wine-yellow, reddish-white to brick-red; also light-green, violet-blue, or gray. In the closed tube, before reaching a red heat, it swells and falls down into a white coarse powder, evolving a little water. A portion of this powder heated in the forceps, B.B., colours the flame carmine-red when strontia is present; on charcoal it becomes caustic, and with fluxes acts like calc-spar. Chem. com. carbonate of lime, occasionally mixed with (0.1...4) carbonate of strontia. Valencia, Molina, and in Arragon; Leogang in Salzburg, and Antiparos. *Flos-ferri*, coralloid, in the iron mines of Styria. *Satin-spar*, fine fibrous silky, at Dufton; stalactitic in Buckinghamshire, Devonshire, coast of Galloway, and Leadhills; also deposited as tufa by the Carlsbad and other hot springs.

Arragonite is most readily distinguished from calc-spar by falling to pieces at a low temperature, and by its less distinct and prismatic cleavage.

Tarnowitzite contains 2 to 4 carbonate of lead. Tarnowitz in Silesia.

**FAMILY II.—FLUOR SPAR.

Crystallization tesseral, hexagonal, or rhombic. $H.=4\ldots 5$, in one 7; $G.=2.9\ldots 4.7$, but mostly about 3. All soluble in acids, and mostly fusible or altered by heat. Those containing fluorine, when warmed with concentrated sulphuric acid, evolve vapours that corrode glass; those with phosphoric acid, when moistened with sulphuric acid, colour B.B. the flame green.

**192. FLUOR SPAR.—Ca F.

Tesseral; the most common form is the cube $\infty O\infty$, then the octahedron O , and the rhombic dodecahedron ∞O ; but many other forms occur in combinations. Macles are common; also coarse granular, columnar, or compact and earthy. Cleavage, octahedral perfect; conchoidal fracture; brittle. $H.=4$; $G.=3.1\ldots 3.2$. Pellucid in all degrees; vitreous. Colourless, but generally very various, and beautiful shades of yellow, green, blue, and red; often two or more in one specimen. Many varieties phosphoresce when heated (*Chlorophane*, with a bright green light). B.B. decrepitates, often violently, phosphoresces and fuses in thin splinters to an opaque mass; slowly soluble in h. or nitric acids, readily in s. acid, with evolution of hydrofluoric acid. Chem. com. neutral fluoride of calcium, containing 48.14 fluorine, and 51.86 calcium (=72.45 lime), Fluor-spar is a very common mineral, chiefly in veins, as with tin ores in Saxony, Bohemia, Cornwall; with silver at Freiberg, Marienberg, Kongsberg; with lead in Derbyshire (near Castletown), Cumberland (Alston Moor), Northumberland and Ireland. It is rare in Scotland, but in greenstone near Gourrock, in granite near Ballater in Aberdeenshire, on the Avon in Banffshire, and in Sutherland. In Derbyshire it occurs in large crystalline masses either with concentric colours or of a rich translucent blue (*Blue John*), and is wrought into various ornamental articles. Fluor spar is also used for etching on glass, and as a flux in reducing metallic ores, especially iron and copper.

193. YTROCERITE.

Very similar to fluor spar. Granular, crystalline, or in crusts. Cleavage imperfect. $H.=4\ldots 5$; $G.=3.4\ldots 3.5$. Translucent or opaque; weak vitreous lustre. Violet-blue to gray or white. B.B. infusible on charcoal alone, and evolves fluorine when heated with s. acid. Chem. com. fluorides of calcium, cerium, and yttrium, in variable proportions. Finbo and Broddbo near Fahlun, Massachusetts, and Amity in New York.

194. FLUOCERITE.—Ce F + Ce² F³.

Hexagonal; ∞P . $\tilde{O}P$. $H.=4\ldots 5$; $G.=4.7$. Opaque or

translucent on the edges; lustre weak. Pale brick-red or yellowish; streak yellowish-white. In the closed tube gives out fluorine. B.B. infusible. Chem. com. 82.64 peroxide of cerium, 1.12 yttria, and 16.24 hydrofluoric acid, *Berzelius*. Finbo and Broddbo.

195. FLUOCERINE.—Ce² F³ + $\tilde{C}e\tilde{H}$.

Massive, with traces of cleavage; fracture conchoidal. $H.=4.5$. Opaque; vitreous or resinous. Yellow, inclining to red or brown; streak brownish-yellow. B.B. infusible. Analysis, 84.21 peroxide of cerium, 10.85 hydrofluoric acid, and 4.95 water. Finbo. A similar mineral from Bastnaes gave fluoride of cerium (and lanthanum) 50.15, peroxide of cerium 36.43, and water 13.4.

196. CRYOLITE.—3 Na F + Al² F³.

Rhombic (or tetragonal?), but only indistinct crystalline or granular. Cleavage, basal perfect, two others less so, the three nearly at right angles; brittle. $H.=2.5\ldots 3$; $G.=2.9\ldots 3$. Translucent, and after immersion in water almost transparent; vitreous, but on $\tilde{O}P$ rather pearly. Colourless and snow-white, but often grayish, yellowish, or reddish. B.B. fuses very easily (even in the flame of a candle) to a white enamel; in open tube shows traces of fluorine; partially soluble in h. acid; wholly so in s., with evolution of fluorine. Chem. com. 53.7 fluorine, 13.1 aluminium, and 33.2 sodium. Arksutfiord in West Greenland, Miask in Ural. Used as an ore of aluminium.

197. CHIOLITE.— $\begin{cases} 3 Na F + 2 Al^2 F^3 = A \\ 2 Na F + Al^2 F^3 = B. \end{cases}$

Tetragonal, with middle edge $113^\circ 25'$ (or rhombic with ∞P $124^\circ 22'$); mostly granular. Cleavage, P rather perfect. $H.=4$. Resinous. White. Very easily fusible (more so than cryolite), colouring the flame deep yellow; evolves fluorine acid. Chem. com. twofold; one variety (A) with $G.=2.8\ldots 2.9$, containing 18.7 aluminium, 23.8 sodium, and 57.5 fluorine; the second (B), with $G.=3.0\ldots 3.1$, containing 16.4 aluminium, 27.8 sodium, and 55.8 fluorine. Miask in Siberia.

Fluellite.—Small, white, transparent, rhombic pyramids; polar edges $109^\circ 6'$ and $82^\circ 12'$, middle 144° . Consists essentially of fluorine and aluminium. Stenna-gwyn in Cornwall.

Prosopite.—Crystals like datholite. $H.=4.5$. Vitreous. Colourless and transparent. Contains fluorine, aluminium, calcium, and water. Altenberg; Schlackenwalde (?).

198. HOPEITE.

Rhombic; $\infty \tilde{P}2$, $82^\circ 20'$; P with polar edges $106^\circ 36'$ and 140° . Cleavage, macrodiagonal perfect. $H.=2.5\ldots 3$; $G.=2.76\ldots 2.85$. Vitreous or pearly. Grayish-white. B.B. melts to a clear globule, tinging the flame green; soluble in acids without effervescence. Chem. com. oxide of zinc and cadmium, with phosphoric (or boracic?) acid, and much water. Altenberg near Aix la Chapelle.

**199. APATITE.—3 Ca² $\tilde{\tilde{P}}$ + Ca (Cl, F).

Hexagonal, and pyramidal-hemihedric; P $80^\circ 26'$; the

Fig. 161.

Fig. 162.

most common forms are ∞P (M), $\infty P2$ (e), $\tilde{O}P$ (P), P (x). The crystals (figs. 161, 162) are short prismatic or thick tabular, and often striated vertically. Also granular, fibrous, or compact. Cleavage, prismatic and basal both imper-

Mineralogy.

Mineralogy.

fect; fracture conchoidal or uneven and splintery; brittle. $H.=5$; $G.=3.16...3.25$. Transparent to opaque; vitreous, but resinous on the cleavage planes and fracture. Colourless, and white, but generally light-green, gray, blue, violet, or red. B.B. fusible in thin splinters with much difficulty to a colourless, translucent glass; moistened with sulphuric acid it colours the flame green; soluble in nitric or h. acid. Chem. com. phosphate of lime (91 to 92.3), with chloride (0 to 4.2) and fluoride (4.6 to 7.7) of calcium. In tin mines in Saxony, Bohemia, St Michael's Mount, St Agnes, and Botallack in Cornwall; in granite at Bovey Tracey in Devonshire, and at Calbeck Fell in Cumberland; also at St Gotthardt, the Tyrol, and at Hammond and Edenville in New York. *Moroxite*, opaque greenish-blue from Arendal. *Asparagus-stone*, translucent, wine-yellow crystals from the Zillerthal in Tyrol. *Phosphorite*, massive, from Logrosan in Estremadura.

Magnesia-apatite, from Kusiusk in the Ural, contains 7.74 magnesia.

200. *HERDERITE*, *Allogonite*.— $\text{Al}, \text{Ca}, \text{P}$, F.

Rhombic; P middle edge $77^\circ 20'$, ∞P $115^\circ 53'$. Cleavage, 0P and ∞P imperfect; fracture conchoidal. $H.=5$; $G.=2.9...3$. Translucent; vitreous, inclining to resinous. Yellowish or greenish-white. B.B. difficultly fusible to a white enamel; moistened with s. acid colours the flame green; soluble in warm h. acid. Ehrenfriedersdorf in Saxony, but extremely rare.

201. *CHILDRENITE*.— $2(\text{Fe}, \text{Mn})^4, \text{P} + \text{Al}^3 \text{P} + 15 \text{H}$.

Rhombic; P $102^\circ 41'$, $130^\circ 4'$, $97^\circ 52'$; usual form P. $2\bar{P}\infty$. $\infty\bar{P}\infty$ (fig. 163). Cleavage, P imperfect. $H.=4.5...5$. $G.=3.18...3.3$. Translucent; vitreous. Yellowish-white to wine or ochre-yellow, brown, or almost black. B.B. infusible, but colours the flame bluish-green; slowly soluble in warm h. acid. Chem. com. 30.7 iron protoxide, 9 manganese protox., 14.5 alumina, 29 phosphoric acid, and 17 water. Tavistock in Devonshire, Crinnis in Cornwall, and Callington in Cumberland.

Fig. 163.

202. *XENOTIME*.— $\text{Y}^3 \text{P}$.

Tetragonal; P $82^\circ 30'$. Crystals P. ∞P . Cleavage, ∞P . $H.=4.5$; $G.=4.39...4.55$. Translucent in thin splinters; resinous. Yellowish or reddish-brown, and flesh-red; streak paler. B.B. infusible. Chem. com. 62.82 yttria, and 37.18 phosphoric acid, with traces of fluoric acid, and 3.39 phosphate of iron. Lindesnaes and Hitteroe in Norway, Ytterby and Georgia, U.S.

203. *BORACITE*.— Mg^2, B^4 .

Tesseral, and hemihedric; $\infty O\infty$, ∞O , and $\frac{O}{2}$. Cleavage, octahedral very imperfect; fracture conchoidal; brittle. $H.=7$; $G.=2.9...3$. Transparent; or translucent on the edges. Vitreous or adamantine. Colourless or white, often grayish, yellowish, or greenish. Becomes polar electric by heat. B.B. fuses with difficulty to a clear yellowish bead, which on cooling forms a white opaque mass of needle-like crystals; at same time colours the flame green; soluble in h. acid. Chem. com. 69.8 boracic acid, and 30.2 magnesia. Lüneberg and Segeberg in Holstein.

Stassfurtite.—Compact, or in very minute prismatic crystals. White. Chem. com. same as boracite, and thus dimorphous. Stassfurt in Germany.

Rhodizite agrees with boracite; only $H.=8$ and $G.=3.3...3.42$. B.B. fuses difficultly on the edges, colouring the flame first green, then green above and red below, and at last in some varieties all red. Chem. com. borate of lime. Murinsk in Siberia.

204. *HYDROBORACALONITE*.— $\text{Ca} \text{B}^3 + 6 \text{H}$

Delicate snow-white crystals, with 19 lime, 46 boracic acid, and 35 water. Iquique in Peru.

205. *HYDROBORACITE*.— $\text{Ca}^2 \text{B}^3 + \text{Mg}^2 \text{B}^3 + 12 \text{H}$.

Radiating and foliated like gypsum. $H.=2$; $G.=1.9...2$. Translucent. White, but partly red. B.B. melts easily, tinging the flame green; easily soluble in warm acids. Chem. com. 13.52 lime, 10.57 magnesia, 49.58 boracic acid, and 26.33 water. Caucasus. A similar mineral with soda in place of magnesia is found in Peru.

*206. *DATHOLITE*, Borate of Lime.— $\text{Ca} \text{B} + \text{Ca} \text{Si} + \text{H}$.

Monoclinohedric; C $=88^\circ 19'$, ∞P (f) $77^\circ 30'$, $\infty P2$ (g) $116^\circ 9'$, $-P$ (P) 122° , $-2P\infty$ (a) $43^\circ 56'$, ($\infty P\infty$) (s), $2P\infty$ (o) (fig. 164); or rhombic with $b:f 90^\circ$, $b:a 135^\circ$; $b:c 141^\circ 9'$, and $f:g 160^\circ 39'$; also coarse granular. Cleavage, orthodiagonal and ∞P very imperfect; fracture uneven or conchoidal. $H.=5...5.5$; $G.=2.9...3$. Transparent

Fig. 164.

or translucent; vitreous; on the fracture resinous. Colourless or white, inclining to gray, green, yellow, and red. In closed tube yields water. B.B. intumesces, and melts easily to a clear glass, colouring the flame green; the powder gelatinizes in h. acid. Chem. com. 38.3 silica, 21.5 boracic acid, 34.6 lime, and 5.6 water. Arendal, Utøe, Andreasberg, Seisser Alpe, Sonthofen (*Humboldtite*); Toggianna in Modena; also Salisbury Crags, Corstorphine Hill, and Glen Farg, in Perthshire; Connecticut and New Jersey.

Botryolite.—Fine fibrous, botryoidal or reniform, snow-white or hair-brown; otherwise, and in chem. com., like datholite, but with two atoms water. Arendal.

FAMILY III.—HEAVY SPAR.

Crystallization rhombic specially. $H.=3...4.5$; $G.=3.2...4.7$, but mostly $3.6...4.5$. Soluble in acids, except barytes. B.B. fusible or decompose. Those containing baryta colour the flame yellowish-green; those with strontia carmine red, best seen when moistened with h. acid. The sulphates fused with soda and then moistened leave a black stain on silver.

**207. *BARYTES*, Heavy Spar.— $\text{Ba} \text{S}$.

Rhombic; ∞P (g) $101^\circ 40'$, $\bar{P}\infty$ (f) $74^\circ 35'$, $\frac{1}{2}\bar{P}\infty$ (d) $102^\circ 17'$; and 0P (c), (figs. 165, 166, 167). The crystals tabular or columnar, often in druses or groups; also foliated, fibrous, granular, or compact. Cleavage, basal perfect, prismatic along ∞P less perfect; brachydiagonal traces. $H.=3...3.5$; $G.=4.3...4.7$ (4.48). Transparent to translucent; vitreous or resinous. Colourless and white, but generally reddish-white, or flesh-red, yellow, gray, bluish, greenish, or brown. B.B. decrepitates violently, and fuses very difficultly, or only on the edges, colouring the flame yellowish-green; not soluble in acids. Chem. com. 34.3 sulphuric acid, and 65.7 baryta, but occasionally with 1 to 15 sulphate of strontia. Very

Fig. 165.

Fig. 166.

Fig. 167.

common, chiefly in veins, either alone or accompanying ores. Crystals at Dufton, Bohemia, Felsobanya and Kremnitz in Hungary, Auvergne, and United States. Columnar at Freiberg. The radiated from near Bologna, or the *Bolognese stone*, phosphoresces in the dark. Massive or *Cawk* from Derbyshire and Staffordshire; in Scotland, at Leadhills,

Mineralogy.

Mineralogy.

Braid Hills near Edinburgh, the Pentlands and Cheviots, and Arran, where mined as a white pigment.

Lime Barytes from Freiberg, Strontian, and Derbyshire, seems a mixture with sulphate of lime; crystals, tabular, in rosettes and other groups. $G=4.0...4.3$.

Hepatite.—Dark-gray, from carbonaceous matter; Kongsberg. *Allomorphite*, scaly, white and pearly, at Unterworbach near Rudolstadt, agrees essentially (98.05 sulphate of baryta, 1.90 sulphate of lime) with barytes.

208. DREELITE.— $\text{Ca } \ddot{\text{S}} + 3 \text{Ba } \ddot{\text{S}}$.

Rhombohedral; $R 93^\circ$. Cleavage, R imperfect. $H.=3...4$; $G.=3.2...3.4$. Lustre dull; on cleavage pearly. White. B.B. fuses to a white vesicular glass; effervesces with h . acid, but only partially dissolves. Chem. com. 61.73 sulphate of baryta, 14.27 sulphate of lime, 8.05 carbonate of lime, 9.71 silica, 2.40 alumina, 1.52 lime, 2.31 water. Nuissière near Beaujeu.

*209. WITHERITE.— $\text{Ba } \ddot{\text{C}}$.

Rhombic; $\infty P 118^\circ 30'$, $2 \ddot{P} \infty 68^\circ$. Crystals $\infty P . P \infty . 2 \ddot{P} \infty$ (fig. 168); more common spherical, botryoidal, or reniform, with radiated columnar texture. Cleavage, ∞P distinct, $2 P \infty$ and $\infty \ddot{P}$ imperfect; fracture uneven. $H.=3...3.5$; $G.=4.2...4.3$. Semitransparent or translucent; vitreous, or resinous on the fracture. Colourless, but generally yellowish or grayish. B.B. fuses easily to a transparent globule, opaque when cold; on charcoal boils, becomes caustic and sinks into the support; soluble with effervescence in nitric or h . acid. Chem. com. 22.3 carbonic acid and 77.7 baryta. Alston Moor in Northumberland, and Lancashire, where it is used for poisoning rats; also in Styria, Salzburg, Hungary, Sicily, Siberia, and Chili.

Fig. 168.

210. ALSTONITE.— $\text{Ba } \ddot{\text{C}} + \text{Ca } \ddot{\text{C}}$.

Rhombic; $\infty P 118^\circ 50'$, $2 \ddot{P} \infty 111^\circ 50'$; usual combination $P . 2 \ddot{P} \infty . \infty P$, resembling a hexagonal pyramid. Cleavage, ∞P and $\infty \ddot{P} \infty$ rather distinct. $H.=4...4.5$; $G.=3.65...3.76$. Translucent; weak resinous. Colourless or grayish-white. Chem. com. 66 carbonate of baryta and 34 carbonate of lime, thus identical with the baryto-calcite. Fallowfield near Hexham, and Alston Moor.

211. BARYTO-CALCITE.— $\text{Ba } \ddot{\text{C}} + \text{Ca } \ddot{\text{C}}$.

Monoclinohedric; $C.=69^\circ 30'$; $\infty P 95^\circ 15'$, $P 106^\circ 54'$, $P \infty 119^\circ$ (fig. 169); also columnar and granular. Cleavage, P perfect, $P \infty$ less perfect. $H.=4$; $G.=3.6...3.7$. Transparent or translucent; vitreous, inclining to resinous. Yellowish-white. B.B. infusible, but becomes opaque and caustic. Chem. com. like Alstonite, Alston Moor.

Fig. 169.

*212. CELESTINE.— $\text{Sr } \ddot{\text{S}}$.

Rhombic; forms like those of barytes and sulphate of lead; $\infty P 104^\circ 8'$, $P \infty 75^\circ 58'$. Usual combinations $\ddot{P} \infty . \infty P . OP$, this with $\frac{1}{2} P \infty$, also $OP . \infty P$ (fig. 170); also columnar, and foliated; or fibrous, fine granular or compact. Cleavage, basal perfect; prismatic along ∞P less perfect. $H.=3...3.5$; $G.=3.9...4$. Transparent or translucent; vitreous or resinous. Colourless, but usually bluish-white to indigo-blue, and rarely reddish or yellowish. B.B. decrepitates and fuses easily to a milk-white globule; colours the flame carmine-red. Distinguished from barytes by a splinter after ignition in the inner flame, being moistened with h . acid, and held in the blue border of the flame of a candle, colouring this of a lively purple-red. Scarcely affected by acids. Chem. com. 43.6 sulphuric acid, and 56.4 strontia. Sulphur mines of Girgenti and other parts, of Sicily, Herrengrund in Hungary, Bex, Salzburg, Monte

Fig. 170.

Viale near Verona, and Meudon and Montmartre near Paris; in England near Bristol, and Knaresborough; in Scotland at Inverness, Tantallan Castle, Calton Hill. Used for strontium preparations, and red-light in fire-works.

Baryto-celestine.—Radiating columnar or foliated. Bluish-white; very brittle and friable. $H.=2.5$; $G.=3.92$. B.B. difficultly fusible. Chem. com. $2 \ddot{\text{Sr}} \ddot{\text{S}} + \text{Ba } \ddot{\text{S}}$, with 36 strontia, and 23 baryta. Diamond Island in Lake Erie, Kingstown in Upper Canada, and Binnenthal.

*213. STRONTIANITE.— $\text{Sr } \ddot{\text{C}}$.

Rhombic; $\infty P 117^\circ 19'$, $\ddot{P} \infty 108^\circ 12'$. Crystals (fig. 171) and macles like arragonite; also broad columnar and fibrous. Cleavage, prismatic along ∞P (M), and $2 \ddot{P} \infty (P)$ ($69^\circ 16'$) imperfect. $H.=3.5$; $G.=3.6...3.8$. Translucent or transparent; vitreous or resinous on fracture. Colourless, but often light asparagus or apple-green, more rarely grayish or yellowish. B.B. fuses in a strong heat only on very thin edges; intumesces in cauliflower-like forms, shines brightly, and colours the flame red; easily soluble with effervescence in acids; the solution in hydrochloric acid, evaporated and then dissolved in alcohol, makes this burn with a carmine-red flame. Chem. com. 30 carbonic acid and 70 strontia, but often contains carbonate of lime (6 to 8). Leogang in Salzburg, Bräunsdorf in Saxony, Hamm in Westphalia, the Harz, at Schoharie and other parts of the United States (*Emmonite*); Strontian in Argyllshire, Leadhills, Yorkshire, and Giant's Causeway. It is used to produce red fire in pyrotechnic exhibitions.

Fig. 171.

Stromnite or *Barystrontianite*.—Yellowish-white, semitranslucent, faint pearly lustre. $H.=3.5$; $G.=3.7$. Contains 68.6 carbonate of strontia, 27.5 sulphate of baryta, and 2.6 carbonate of lime. Stromness in Orkney.

FAMILY IV.—GYPSUM.

Crystallization rhombic or monoclinohedric. $H.=2...3$, or less, many yield to the nail. $G.=2.2...2.9$, or also low. All, except the sulphates, soluble in acids, some in water; also fusible in general. Mostly translucent and colourless, but often coloured by mixtures.

**214. GYPSUM.— $\text{Ca } \ddot{\text{S}} + 2 \text{H}$.

Monoclinohedric; $C.=81^\circ 26'$; the most common forms are $\infty P 111^\circ 14'$, $P 138^\circ 44'$, $P 143^\circ 28'$, and ($\infty P \infty$). Two common combinations are $\infty P (f) . (\infty P \infty) (P)$ — $P (l)$ (fig. 172), and this with P . Lenticular crystals often occur; macles frequent (fig. 83 above); also granular, compact, fibrous, scaly, or pulverulent. Cleavage, clinodagonal very perfect, hemipyramidal along P much less perfect; sectile, thin plates flexible. $H.=1.5...2$ (lowest on P); $G.=2.2...2.4$. Transparent or translucent; vitreous, on cleavage pearly or silky. Colourless and snow-white, but often red, gray, yellow, brown, and more rarely greenish or bluish. In the closed tube yields water. B.B. becomes opaque and white; exfoliates and fuses to a white enamel, which is alkaline; soluble in 400 to 500 parts of water, scarcely more so in acids. Chem. com. sulphate of lime with two atoms water, or 46.47 sulphuric acid, 32.65 lime, and 20.88 water.

Fig. 172.

Gypsum is a very common mineral, often in nests or reniform masses in clay or marl. Transparent crystals, or *Selenite*, occur in the salt mines of Bex in Switzerland, of the Tyrol, Salzburg, and Bohemia, in the sulphur mines

Mineralogy.

Mineralogy.

of Sicily, at Lockport in New York, in the clay of Shot-over Hill near Oxford, at Chatley near Bath, and many other localities. Fibrous gypsum at Ilfeld in the Harz, and Matlock in Derbyshire. Compact gypsum at Volterra in Tuscany (*Alabaster*), and in whole beds in many parts of Germany, France, Italy, and England, often with rock-salt.

The finer varieties, or *Alabaster*, are cut into various ornamental articles. Plaster of Paris, used for casts and other works of art, is formed by calcining gypsum at a temperature below 300° Fahr., and grinding it down to a fine powder, which forms a paste that soon hardens by absorbing the water driven off by the heat.

*215. ANHYDRITE, Muriazit, Karstenite.— $\text{Ca} \ddot{\text{S}}$.

Rhombic; $\infty P 91^\circ 10'$, $\bar{P} \infty 96^\circ 36'$. Crystals $OP \cdot \infty \bar{P} \infty \cdot \infty \bar{P} \infty \cdot \infty P$, but rare; chiefly granular, or almost compact or columnar. Macles rare. Cleavage, macrodiagonal and brachydiagonal both very perfect, basal perfect. $H.=3 \dots 3.5$; $G.=2.8 \dots 3$. Transparent or translucent; vitreous; on $\infty \bar{P} \infty$ pearly. Colourless or white, but often blue, red, or gray; streak grayish-white. In closed tube gives no water. B.B. fuses difficultly to a white enamel; with fluor spar fuses readily to a clear globule, which becomes opaque when cold, and, on continuation of the heat, intumesces and becomes infusible; very slightly soluble in water or acids. Chem. com. 58.75 sulphuric acid and 41.25 lime.

The crystalline, or *Muriacite*, occurs in the salt mines of Bex, Hall in Tyrol, and Aussee in Styria; also Sulz on the Neckar, and Bleiberg. Compact at Ischel in Austria, Berchtesgaden, Eisleben, and the Harz. Granular, or *Vulpinite*, near Bergamo. The contorted, or *Gekrösstein*, chiefly at Wieliczka and Bochnia.

216. POLYHALITE.— $2 \text{Ca} \ddot{\text{S}} + \text{Mg} \ddot{\text{S}} + \text{K} \ddot{\text{S}} + 2 \text{H}$.

Rhombic; $\infty P 115^\circ$; mostly columnar or fibrous. Cleavage, ∞P imperfect. $H.=3.5$; $G.=2.7 \dots 2.8$. Translucent; pearly or resinous. Colourless, but generally pale red, seldom gray. Weak bitter, and slightly saline taste. Soluble in water, leaving gypsum. B.B. fuses on charcoal to an opaque reddish bead, becoming white when cold. Chem. com. sulphates of lime 45, of magnesia 20.5, of potassa 28, and water 5.5. Ischel, Aussee, and Berchtesgaden.

217. GLAUBERITE, Brongniartine.— $\text{Na} \ddot{\text{S}} + \text{Ca} \ddot{\text{S}}$.

Monoclinohedric; $C=68^\circ 16'$; $\infty P 83^\circ 20'$, $\bar{P} 116^\circ 20'$. Crystals $OP \cdot \bar{P}$, with ∞P (fig. 173). Cleavage, basal perfect, along ∞P traces. $H.=2.5 \dots 3$; $G.=2.75 \dots 2.85$. Translucent; vitreous to resinous. Colourless, but yellowish or grayish-white. Taste slightly saline and bitter. B.B. decrepitates violently, and melts to a clear glass; decomposed by water, which removes the sulphate of soda. Chem. com. 51 sulphate of soda, and 49 sulphate of lime. Villarubia in Spain, Vic, Berchtesgaden; near Brugg in Aargau, Aussee and Ischel in Austria, and Tarapaca in Peru.

Fig. 173.

218. ALUNITE, Alumstone.— $3 \text{Al} \ddot{\text{S}} + \text{K} \ddot{\text{S}} + 6 \text{H}$.

Rhombohedral; $R. 89^\circ 10'$. Crystals, R , or $R. OR$ (fig. 174); also fine granular, earthy, or compact. Cleavage, basal rather perfect. $H.=3.5 \dots 4$; $G.=2.6 \dots 2.8$. Translucent; vitreous, on OP pearly. Colourless and white, but grayish, yellowish, or reddish. B.B. infusible alone. Becomes blue with cobalt solution; soluble in warm con. s. acid, not in h. acid. Chem. com. 37.95 alumina, 10.66 potash, 39.42 sulphuric acid, and 11.97 water. Beregszasz in Hungary, Tofia in the Papal States; also in Tuscany, near Naples, Lipari Islands, Auvergne, Milo, and Argentiera.

Fig. 174.

219. ALUMINITE, Websterite.— $\text{Al} \ddot{\text{S}} + 9 \text{H}$.

Reniform, and very fine scaly or fibrous. Fracture earthy; sectile or friable. $H.=1$; $G.=1.7$. Opaque; dull or glimmering. Snow-white or yellowish-white. In closed tube yields much water. B.B. emits sulphurous fumes, the remainder being infusible; easily soluble in h. acid. Chem. com. 29.8 alumina, 23.2 sulphuric acid, and 47 water. Newhaven in Sussex; Eperney, Auteuil, and Lunel Vieil in France; Halle and Morl in Prussia.

220. PHARMACOLITE.— $\text{Ca} \ddot{\text{S}} + 6 \text{H}$.

Monoclinohedric; $C=65^\circ 4'$; $\infty P 117^\circ 24'$, $\bar{P} 139^\circ 17'$. Crystals prismatic; often acicular or capillary, or radiated fibrous crusts. Cleavage, clinodiagonal very perfect; sectile and flexible. $H.=2 \dots 2.5$; $G.=2.6 \dots 2.8$. Translucent; vitreous; pearly or silky. Colourless and white, but sometimes rose-red or green. Yields water in the closed tube. B.B. fuses to a white enamel; in the inner flame on charcoal gives arsenic fumes, and fuses to a semi-translucent grain, colouring the flame blue; easily soluble in acids. Chem. com. 51 arsenic acid, 25 lime, and 24 water. Andreasberg, Riechelsdorf, Biber, Joachimsthal in Bohemia, Markirchen, and Wittichen in the Schwarzwald.

Picropharmacolite contains magnesia. *Roselite*, vitreous; rose-red. B.B. with borax forms a deep blue glass. Chem. com. arsenic acid, oxide of cobalt, lime, magnesia, and water. Schneeberg in Saxony.

221. HAIDINGERITE.— $\text{Ca} \ddot{\text{S}} + 3 \text{H}$.

Rhombic; $\infty P 100^\circ$. Cleavage very perfect; sectile, flexible. $H.=2 \dots 2.5$; $G.=2.8 \dots 2.9$. Transparent or translucent. Colourless and white. Chem. com. 85.68 arseniate of lime and 14.32 water. Joachimsthal in Bohemia.

222. BERZELIITE.— $\text{Ca} \ddot{\text{S}} + \text{Mg} \ddot{\text{S}}$.

Massive, with traces of cleavage. Brittle. $H.=5.5$; $G.=2.52$. Translucent on the edges; resinous. Honey-yellow or yellowish-white. B.B. infusible, but becomes gray; soluble in nitric acid. Contains also 2 to 4 manganese protoxide. Longbanshytta in Sweden.

223. STRUVITE, Guanite.— $(\text{NH}^4 \text{O}, \text{Mg}^2) \ddot{\text{P}} + 12 \text{H}$.

Rhombic and hemihedric; $\bar{P} \infty 63^\circ 7'$, $\bar{P} \infty 95^\circ$. Cleavage, brachydiagonal perfect. $H.=1.5 \dots 2$; $G.=1.66 \dots 1.75$. Transparent or opaque; vitreous. Colourless, but yellow or brown. In the closed tube yields water and ammonia. B.B. fuses to a white enamel; soluble in h. acid, and very slightly in water. Chem. com. 29.9 phosphoric acid, 16.3 magnesia, 10.6 ammonia, and 44 water. Under St Nicolai church at Hamburg, and in guano from Africa.

FAMILY V.—ROCK-SALT.

Crystallization monoclinohedric and rhombic, some tesseral and hexagonal. $H.=1.3$, but most about 2; $G.=1.5 \dots 3$, but generally 2. All soluble in water, and B.B. fusible or decompose. When pure, mostly white, translucent, and vitreous. They are chiefly products of decomposition, and occur especially in the rainless regions, or in lakes not communicating with the sea.

**224. ROCK-SALT.— Na Cl .

Tesseral; almost always cubes. Generally granular and fibrous. Cleavage, hexahedral very perfect; fracture conchoidal; rather brittle; yields slightly when scratched with the nail. $H.=2$; $G.=2.1 \dots 2.2$. Transparent or translucent; vitreous. Colourless or white, but often red, yellow, gray, and rarely blue. Taste saline. In the closed tube decrepitates, and yields a little water. B.B. on charcoal fuses and partly evaporates, partly sinks into the support. With soda fuses to a clear mass, colouring the flame yellow. Very soluble in water. Chem. com. 60

Mineralogy.

Mineralogy.

chlorine and 40 sodium, but often with various impurities.

This important mineral is very widely disseminated, either in thick masses, with clay, anhydrite, and gypsum, or as an efflorescence, covering extensive tracts of country. The most celebrated European deposits occur at Wieliczka and other parts of Galicia, in Hungary, Siebenburg, Moldavia, Styria, Salzburg (Hallein), in Tyrol (Hall); also in Bavaria, Wurtemberg, Switzerland (Bex), and Spain, especially at Cardona. In England the chief deposits are in Cheshire, as at Northwich. As an efflorescence it is most abundant on the sandy plains in Brazil, at the foot of the Atlas Mountains in Africa, in Abyssinia, in Arabia, and in the Steppes round the Caspian Sea and Lake Ural. Also as a sublimation among the lavas of Vesuvius.

Sylvin, or chloride of potassium, found as a sublimation on Vesuvius, and in the rock-salt of Hallein and Berchtesgaden, agrees in most characters with rock salt ($G.=1.9 \dots 2$).

*225. ALUM.— $\ddot{R}\ddot{S} + (\ddot{Al}, \ddot{Fe})\ddot{S}^3 + 24\ddot{H}$.

Tesseral; O, sometimes with ∞O and ∞O . Generally fibrous crusts, or as an efflorescence. Cleavage, octahedral imperfect; fracture conchoidal. $H.=2 \dots 2.5$; $G.=1.75 \dots 1.9$. Translucent. Colourless and white. Taste sweetish astringent. Easily soluble in water. B.B. generally evolves sulphurous fumes.

(a.) *Potash-alum*, with $\ddot{R}=\ddot{K}$, and 32.52 sulphuric acid, 10.86 alumina, 9.96 potash, and 45.66 water. In the closed tube it fuses, intumesces, and yields much water. In the Silurian alum-slates of Sweden, Norway, and Scotland; the coal formation, Hurler and Campsie, in Scotland; the lias near Whitby; in the brown-coals of Hessa and the Rhine; and in the volcanic formations of the Lipari Islands, Sicily, and the Azores.

(b.) *Ammonia-alum*, with $\ddot{R}=\text{NH}^4\text{O}$, and about 4 per cent. ammonia and 48 water. In the closed tube it forms a sublimate of sulphate of ammonia. Tschermig in Bohemia.

(c.) *Soda-alum*, with $\ddot{R}=\ddot{Na}$, and 7 soda and 48 water. Like potash-alum, but more easily soluble. Near Mendoza in South America, the Solfatara at Naples, and Milo.

(d.) *Magnesia-alum*.— $\ddot{R}=\ddot{Mg}$ with Mn. Translucent and silky, but soon changes in the air. South Africa, Iquique in Peru (*Pickeringite*).

(e.) *Iron-alum* (*Feather-alum*), with $\ddot{R}=\ddot{Fe}$. Hurler near Paisley, Mörsfeld in Rhenish Bavaria, Krisuvig in Iceland (*Hversalt*).

226. VOLTAITE.— $3(\text{Fe}, \text{K}, \text{Na})\text{S} + (\ddot{Fe}, \ddot{Al})\ddot{S}^3 + 12\ddot{H}$.

Tesseral. Black, brown, or green; greenish-gray streak. Otherwise like alum, but more difficultly soluble in water. Solfatara of Pozzuoli.

227. ALUNOGENE, Halotrichite, Hair Salt.— $\ddot{Al}\ddot{S}^3 + 18\ddot{H}$.

Capillary or acicular, in crusts or reniform masses. $H.=1.5 \dots 2$; $G.=1.6 \dots 1.7$. Silky. White, inclining to green or yellow. Tastes like alum. B.B. in closed tube intumesces, yields much water, and is infusible. Chem. com. 36.05 sulphuric acid, 15.40 alumina, 48.55 water. Volcanoes of South America, coal and brown coal strata of Germany, and on old walls.

228. MIRABILITE, Glauber-salt.— $\ddot{Na}\ddot{S} + 10\ddot{H}$.

Monoclinohedric; $C=72^\circ 15'$; $\infty P 86^\circ 31'$, $P 93^\circ 12'$. Crystals predominantly OP and ∞P (fig. 175); but generally efflorescent crusts. Cleavage, orthodiagonal very perfect; fracture conchoidal. $H.=1.5 \dots 2$; $G.=1.4 \dots 1.5$. Pellucid and colourless; taste cool, saline, and bitter; decomposes readily in the atmosphere, and falls into powder. Gives no precipitate with carbonate of soda. Chem. com. 19.3 soda, 24.7 sulphuric acid, and 56 water.

As an efflorescence in quarries and on old walls in many

VOL. XV.

countries, on Vesuvius in lava. Used in medicine, and in preparing glass and soap.

N.B.—No. 228-237 form a sub-family of *Metallic salts*, or *Vitriols*.

*229. MELANTERITE, Green or Iron Vitriol, Copperas. } $\ddot{Fe}\ddot{S} + 7\ddot{H}$.

Monoclinohedric; $C=75^\circ 40'$; $\infty P (f) 82^\circ 21'$, $-P (P) 101^\circ 35'$, $(P\infty) (o) 69^\circ 17'$, $(\infty P\infty) (u)$, (fig. 176); chiefly stalactitic, reniform, or in crusts. Cleavage, basal very perfect, ∞P less so. $H.=2$; $G.=1.8 \dots 1.9$. Translucent, rarely transparent; vitreous. Leek or mountain-green, often with a yellow coating; streak white. Taste sweetish astringent. Very soluble. B.B. becomes brown, then black and magnetic. Chem. com. 26.0 protoxide of iron, 28.8 sulphuric acid, and 45.2 water. Bodenmais, Rammelsberg in the Harz, Fahlun, Schemnitz, Bilin, and Hurler near Paisley. Used in dyeing, in manufacturing ink, Prussian blue, and sulphuric acid.

Fig. 176.

230. BOTRYOGENE, } $\ddot{Fe}\ddot{S}^2 + 3\ddot{Fe}\ddot{S}^2 + 36\ddot{H} 2 (?)$.
Red vitriol.

Monoclinohedric; $C=62^\circ 26'$; $\infty P 119^\circ 56'$. Crystals small and short prismatic. More common botryoidal and reniform. Cleavage, ∞P rather distinct. $H.=2 \dots 2.5$; $G.=2 \dots 2.1$. Translucent; vitreous. Hyacinth-red, orange-yellow, and yellowish-brown; streak ochre-yellow. Taste slightly astringent. Partially soluble in water, leaving a yellow ochre. Chem. com. sulphates of the protoxide and peroxide of iron (48), with 31 water, and about 21 sulphates of magnesia and lime; the two latter considered mixtures by Berzelius. Fahlun in Sweden.

231. COPIAPITE.— $\ddot{Fe}^2\ddot{S}^2 + 18\ddot{H}$.

Six-sided tables, but crystal-system uncertain; also granular. Cleavage perfect. Translucent; pearly. Yellow. Chem. com. 30.7 iron peroxide, 38.3 sulphuric acid, and 31 water. Copiapo in Coquimbo in Chili. Also radiated fibrous masses; dirty greenish-yellow, incrusting the former. Contain 32 sulphuric acid, and 37 water; but both are probably mixtures. To these may be added—

Fibroferrite, also from Chili. *Yellow Iron-ore*, from the brown coal at Kolosoruk in Bohemia and Modum in Norway. Both are reniform, or compact and earthy. $H.=2.5 \dots 3$; $G.=2.7 \dots 2.9$. Colour ochre-yellow. Not soluble in water, with difficulty in hydrochloric acid.

Apatelite, reniform earthy, yellow, from Auteuil near Paris, is similar; also *Vitriol ochre* from Fahlun. *Misy*, from Rammelsberg in the Harz, contains sulphates of iron, copper, zinc, and other metals.

232. COQUIMBITE.— $\ddot{Fe}\ddot{S}^3 + 9\ddot{H}$.

Hexagonal; $P 58^\circ$. Crystals OP , with ∞P and P ; usually granular. Cleavage, ∞P imperfect. $H.=2 \dots 2.5$; $G.=2 \dots 2.1$. White, also brown, yellow, red, and blue. Taste astringent. Chem. com. 28.5 iron peroxide, 43.6 sulphuric acid, and 28.9 water. Copiapo in Chili, and Calama in Bolivia.

233. TECTIZITE.— $\ddot{Fe}, \ddot{S}, \ddot{H}$.

Rhombic; dimensions unknown. $H.=1.5 \dots 2$; $G.=2$ nearly. Vitreous or resinous. Clove-brown. Saxony near Schwarzenberg, and at Bräunsdorf.

*234. CYANOSE, Blue Vitriol.— $\ddot{Cu}\ddot{S} + 5\ddot{H}$.

Triclinohedric. Crystals very unsymmetric; ∞P (n) to ∞P (r), forms an angle of $79^\circ 19'$; $P' (P)$ to $\infty P' (T)$ $127^\circ 40'$, to ∞P (n) $120^\circ 50'$, to ∞P (r) $103^\circ 27'$, and

Mineralogy.

Mineralogy.

$\infty P'$ (T) to ∞P (M) $123^\circ 10'$ (fig. 177). More often stalactitic, reniform, or as an incrustation. Cleavage, along $\infty P'$ and ∞P very imperfect; fracture conchoidal. $H.=2.5$; $G.=2.2...2.3$. Translucent; vitreous. Blue. Taste very nauseous. Readily soluble in water, from which metallic copper is precipitated by iron. B.B. on charcoal, especially with soda, is easily reduced to metallic copper. Chem. com. 32 protoxide of copper, 32 sulphuric acid, and 36 water.

Fig. 177.

Abundant in the water of some mines, as in the Harz, Hungary, Tyrol, Fahlun, in Anglesea, Cornwall, and Wicklow. Also on the lava of Vesuvius. Used in dyeing, and in forming blue and green pigments.

*235. GOSLARITE, White Vitriol.— $Zn \ddot{S} + 7 H$.

Rhombic; $\infty P 90^\circ 42'$, isomorphous with epsomite; $\infty P \infty P$ (fig. 178). Mostly granular, or stalactitic, reniform, and encrusting. Cleavage, brachydiagonal perfect. $H.=2...2.5$; $G.=2...2.1$. Pellucid; vitreous. White, inclining to gray, yellow, green, or red. Taste nauseous astringent. Chem. com. 28.2 zinc oxide, 27.9 sulphuric acid, and 43.9 water. Rammelsberg in the Harz, Fahlun, Schemnitz, Holywell in Flintshire, in Cornwall, at Villefranche, and Guipuzcoa in Spain. Used in dyeing and medicine.

Fig. 178.

236. BIEBERITE, Cobalt Vitriol.— $(Co, Mg) \ddot{S} + 7 H$.

Monoclinohedric; similar to melanterite; usually stalactitic, or an efflorescence. Pale rose-red. Taste astringent. Chem. com. 20 cobalt oxide, 4 magnesia, 29 sulphuric acid, and 47 water. Bieber near Hanau, and Leogang in Salzburg.

237. JOHANNITE, Uran Vitriol.

Monoclinohedric; $C=85^\circ 40'$; $\infty P 69^\circ$. Crystals similar to trona (fig. 181), but very small. Cleavage, ∞P . $H.=2...2.5$; $G.=3.19$. Semitransparent; vitreous. Bright grass-green, with paler streak. Chem. com. a hydrous sulphate of the protoxide of uranium. Joachimsthal and Johann-Georgenstadt.

*238. NATRON.— $Na \ddot{C} + 10 H$.

Monoclinohedric; $C=57^\circ 40'$. Crystals ($\infty P \infty$). ∞P . $P \infty P$ (fig. 179); with ∞P (M) $79^\circ 41'$, P (P) $76^\circ 28'$. Cleavage, ∞P distinct; ($\infty P \infty$) less so. $H.=1...1.5$; $G.=1.4...1.5$. Pellucid; vitreous. Colourless or grayish-white. B.B. melts easily, colouring the flame yellow. Chem. com. 2.18 soda, 15.4 carbonic acid, and 6.28 water; but mixed with chloride of sodium, and other salts. On lava, as on Vesuvius and Etna; as an efflorescence on the ground in Hungary, Egypt, Tartary, and in mineral springs and lakes. Used in the manufacture of soap, in dyeing, bleaching, and medicine.

Fig. 179.

239. THERMONATRITE.— $Na \ddot{C} + H$.

Rhombic; $\infty P 2$ (d) $107^\circ 50'$, $P \infty$ (o) $83^\circ 50'$; with $\infty P \infty$ (P), in rectangular tables (fig. 180). Cleavage, (p) perfect. $H.=1.5$; $G.=1.5...1.6$. Colourless. B.B. like natron, but does not melt. Chem. com. 50.1 soda, 35.4 carbonic acid, and 14.5 water. Natron lakes of Lagunilla in Colombia, of Lower Egypt, and of the steppes between the Ural and Altai.

Fig. 180.

240. TRONA, Urao.— $Na^2 \ddot{C}^3 + 4 H$.

Monoclinohedric. Crystals OP and $\infty P \infty$ ($103^\circ 15'$), (fig. 181). Cleavage, $\infty P \infty$ perfect. $H.=2.5...3$; $G.=2.1...2.2$. Transparent to translucent; colourless. Does not decompose in the air. Taste alkaline. Chem. com. 37.93 soda, 40.24 carbonic acid, and 21.83 water. Fezzan and Barbary (*Trona*), Lagunilla in Colombia (*Urao*).

Fig. 181.

241. GAYLUSSITE.— $Na \ddot{C} + Ca \ddot{C} + 5 H$.

Monoclinohedric; $C=78^\circ 27'$; $\infty P 68^\circ 51'$, $P 110^\circ 30'$. Cleavage, ∞P imperfect; fracture conchoidal. $H.=2.5$; $G.=1.9...1.95$. Transparent; vitreous; colourless. Slowly and partially soluble in water. B.B. fuses readily to an opaque bead. Chem. com. 34.5 carbonate of soda, 33.6 carbonate of lime, 30.4 water, with 1.5 clay. Lagunilla near Merida.

*242. BORAX, Tinkal.— $Na \ddot{B}^2 + 10 H$.

Monoclinohedric; $C=73^\circ 25'$; $\infty P 87^\circ$, $P 122^\circ 34'$; almost isomorphous with augite. Twin crystals frequent. Cleavage, ($\infty P \infty$) perfect; ∞P less distinct; fracture conchoidal, rather brittle. $H.=2...2.5$; $G.=1.7...1.8$. Pellucid; resinous. Colourless, but yellowish, greenish, and grayish-white. Taste feebly alkaline and sweetish. B.B. intumesces greatly, becomes black, and melts to a transparent bead, colouring the flame yellow, or, with sulphuric acid, green; soluble in 12 parts of cold water. Chem. com. of the pure salt, 16.37 soda, 36.53 boracic acid, and 47.10 water; but often contains many impurities. Shore of salt lakes in Thibet and Nepal, and in South America near Potosi. Borax is prepared from this mineral, and is used for blowpipe experiments, in preparing fine glass, in medicine, and for dyeing.

*243. SASSOLINE.— $B + 3 H$.

Triclinohedric; OP : $\infty P \infty 75^\circ 30'$; usually fine scaly six-sided tables, or fibrous, and stalactitic. Macles frequent. Cleavage, basal very perfect; sectile and flexible. $H.=1$; $G.=1.4...1.5$. Translucent; pearly. Grayish or yellowish-white. Taste acidulous and slightly bitter. Feels greasy. Easily soluble in boiling, less so in cold water. Frothes up and melts in the candle flame to a hard transparent glass, colouring the flame green. Chem. com. 56.3 boracic acid, and 43.7 water. Vulcano in the Lipari Islands, hot springs of Sasso near Sienna, and lagoni of Tuscany.

*244. NITRE, Salpetre.— $K \ddot{N}$.

Rhombic; ∞P (M) 119° , $2P \infty$ (P) 71° , $P \infty 110^\circ$, $\infty P \infty$ (h), (fig. 182); isomorphous with aragonite. Only occurs acicular, capillary, or pulverulent. Cleavage indistinct; fracture conchoidal. $H.=2$; $G.=1.9...2$. Semitransparent; vitreous, or silky. Colourless, white or gray. Taste saline and cooling. Deflagrates when placed on hot charcoal; and B.B. on platina wire melts very easily, colouring the flame violet. Chem. com. 46.6 potash, and 53.4 nitric acid, but always more or less mixed. In the limestone caves of many countries, Hungary, Spain, India. Used for producing nitric acid, in glass-making, medicine, and the manufacture of gunpowder.

Fig. 182.

245. NITRATINE.— $Na \ddot{N}$.

Rhombohedral; $R=106^\circ 30'$, isomorphous with dolomite. Cleavage rather perfect. $H.=1.5...2$; $G.=2.1...2.2$. Translucent or transparent, with very distinct double refraction; vitreous. Colourless, or grayish and yellowish-white. Taste saline and cooling. Deflagrates on hot charcoal. B.B. fuses on platina wire, colouring the

Mineralogy.

Mineralogy.

flame yellow. Chem. com. 36.6 soda, and 63.4 nitric acid, but mixed with common salt and other substances. Tarapaca in Chili. Used in the arts as a substitute for nitre; but deliquesces in the air.

246. NITROCALCITE.— $\text{Ca} \ddot{\text{N}} + \dot{\text{H}}$.

Fibrous or pulverulent. White or gray. Translucent. Taste sharp and bitter. Readily soluble in water, and deliquesces in the air; melts slowly on burning charcoal, with slight detonation. Chem. com. 32.00 lime, 57.54 nitric acid, and 10.56 water. Limestone caves of Kentucky; on old walls and limestone rocks.

247. NITROMAGNESITE.— $\text{Mg} \ddot{\text{N}} + \dot{\text{H}}$.

In the same places and similar to nitrocalcite. Taste bitter. Chem. com. 24 magnesia, 65 nitric acid, and 11 water.

*248. SAL-AMMONIAC.— $\text{N H}^4 \text{Cl}$.

Tesseral; O, also $\infty \text{O} \infty$, ∞O , and 303. In crusts, stalactites, and earthy or pulverulent. Cleavage, O imperfect; fracture conchoidal. $\text{H.} = 1.5 \dots 2$; $\text{G.} = 1.5 \dots 1.6$. Pellucid; vitreous. Colourless, but gray or yellow, rarely green, brown, or black. Taste saline and pungent. B.B. volatilizes without fusing; on copper wire colours the flame bluish-green. Chem. com. (32 per cent. ammonia, or) 33.9 ammonium, and 66.1 chlorine. Chiefly occurs as a sublimate on active volcanoes, Vesuvius, Etna, the Solfatara, Vulcano, and Iceland; also near ignited coal seams, Newcastle, and Scotland. Used in medicine, dyeing, and various metallurgic operations.

249. MASCAGNINE.— $\text{N H}^3 \ddot{\text{S}} + \dot{\text{H}}$.

Rhombic; $\infty \text{P } 107^\circ 40'$, $\bar{\text{P}} \infty 121^\circ 16'$; $\infty \text{P} \cdot \infty \bar{\text{P}} \infty \cdot \text{P}$ (fig. 183); but chiefly in crusts and stalactites. Cleavage rather perfect; sectile. $\text{H.} = 2 \dots 2.5$; $\text{G.} = 1.7 \dots 1.8$. Pellucid, vitreous. Colourless, white or yellowish. Taste pungent and bitter; easily soluble, and deliquesces. B.B. decrepitates, melts, and volatilizes. Chem. com. 25.9 ammonia, 60.5 sulphuric acid, and 13.6 water. Near volcanoes, as Etna, Vesuvius, the Solfatara, the Lipari Islands, in the lagoon near Sienna, and in ignited coal beds, as at Bradley in Staffordshire.

Fig. 183.

250. ARCANITE, Glaserite.— $\ddot{\text{K}} \ddot{\text{S}}$.

Rhombic; acute pyramids, with $\infty \text{P } 120^\circ 24'$, $2\bar{\text{P}} \infty 67^\circ 38'$, OP , and other forms. Mostly in crusts, or pulverulent. Cleavage, basal imperfect. $\text{H.} = 2.5 \dots 3$; $\text{G.} = 2.73$. Pellucid; vitreous or resinous. Colourless or white. Taste saline, bitter. B.B. decrepitates, fuses, and becomes hepatic. Chem. com. 54.04 potash and 45.96 sulphuric acid. Lavas of Vesuvius and other volcanoes.

251. THENARDITE.— $\ddot{\text{Na}} \ddot{\text{S}}$.

Rhombic; acute pyramids P, with OP and ∞P , in crusts and druses. Cleavage, basal rather perfect; fracture uneven. $\text{H.} = 2.5$; $\text{G.} = 2.6 \dots 2.7$. Pellucid, vitreous. White. Taste feebly saline. B.B. colours the flame deep yellow, and fuses. Chem. com. 43.82 soda, and 56.18 sulphuric acid. Salinas d'Espartinas near Aranjuez, and Tarapaca. Used for preparing soda.

252. LOWEITE.— $2 (\ddot{\text{Na}} \ddot{\text{S}} + \ddot{\text{Mg}} \ddot{\text{S}}) + 5 \text{H}$.

Compact with traces of one cleavage. $\text{H.} = 2.5 \dots 3$; $\text{G.} = 2.376$. Vitreous. Yellowish-white to flesh-red. Taste slightly saline. Chem. com. 20.3 soda, 13.2 magnesia, 52 sulphuric acid, and 14.5 water. Ischel.

*253. EPSOMITE, Epsom-salt.— $\ddot{\text{Mg}} \ddot{\text{S}} + 7 \text{H}$.

Rhombic; P mostly hemihedric, $\infty \text{P } 90^\circ 38'$; $\infty \text{P} (M) \cdot \infty \bar{\text{P}} \infty (o) \cdot \text{P} (l)$ (fig. 184). Granular, fibrous, or earthy. Cleavage, brachydiagonal perfect. $\text{H.} = 2 \dots 2.5$; $\text{G.} = 1.75$. Pellucid; vitreous; and white. Taste saline, bitter. B.B. on charcoal fuses, incandescs, and shows alkaline reaction; with solution of cobalt becomes pale rose-red. Chem. com. 16.32 magnesia, 32.53 sulphuric acid, and 51.15

Mineralogy.

water. Efflorescence on various rocks, as at Hurlet near Paisley, Idria, Montmartre, and Freiberg; on the ground in Spain, and the Russian steppes; in mineral waters, as at Epsom in Surrey (Epsom salts), Saidschütz and Seidlitz in Bohemia. Used in medicine and in preparing magnesia.

Astrakanite.—White, transparent, prismatic crystals among the salts in the salt lakes near the Wolga. Chem. com. 41.00 sulphate of soda, 35.18 sulphate of magnesia, 21.56 water. Reussin, white, six-sided, and pointed crystals, from Seidlitz and Saidschütz in Bohemia, is similar, but seems a mixture.

Fig. 184.

ORDER III.—SALINE ORES.

Resemble the saline stones both in external characters and chemical composition, forming almost a parallel series, with metallic oxides in place of the earthy bases. Lime or magnesia occasionally occur in more or less extent, and the acid element is one of the common acids of the chemist. Crystallization in the carbonates is often rhombohedral, in the others monoclinohedric or rhombic. Other systems only occur in rare cases.

Hardness is not high, mostly 3...4, in a few as high as 5, and as low as 2. Their specific gravity is high, from the metallic element in their composition; mostly from 3...4 in the salts of iron or copper, and from 5...7 or 8 in the salts of lead and some others. They are almost all soluble in acids, and the carbonates effervesce. B.B. mostly fusible, decomposed, or reduced, and with fluxes form coloured glasses characteristic of the different metals. They are mostly translucent, rarely transparent. Their lustre is often pearly or vitreous. Some are white, others are coloured, and these colours are now characteristic of the metal as the essential element.

*FAMILY I.—THE SPARRY IRON ORES.

Crystallization and cleavage rhombohedral. $\text{H.} = 3.5 \dots 5$; $\text{G.} = 3.3 \dots 4.5$. They are all soluble in acids, and often effervesce. B.B. they are all infusible, but decomposed, and leave a magnetic residue, and show reactions of metals. The colours are white, but often with a brown, yellow, or red tinge, especially when weathered. They chiefly occur in veins.

*254. SIDERITE, Sparry Iron, Sphärosiderite, } $\text{Fe} \ddot{\text{C}}$.
Chalybite. }

Rhombohedral; $\text{R } 107^\circ$. Chiefly R, often curved, saddle-shaped, or lenticular, occasionally OR, $-\frac{1}{2}\text{R}$, ∞R , -2R , $\infty \text{P}2$. Frequently fine or coarse granular, more rarely botryoidal or reniform (*Sphärosiderite*). Cleavage, rhombohedral along R perfect. $\text{H.} = 3.5 \dots 4.5$; $\text{G.} = 3.7 \dots 3.9$. Translucent in various degrees, becoming opaque when weathered; vitreous or pearly. Rarely white, generally yellowish-gray or yellowish-brown, changing to red or blackish-brown on exposure. B.B. infusible, but becomes black and magnetic; with borax and salt of phosphorus shows reaction for iron; with soda usually for manganese. In acids soluble with effervescence. Chem. com. carbonate of iron, with 62.6 protoxide of iron and 37.9 carbonic acid, but usually 0.5 to 10, or even 25, protoxide of manganese, 0.2 to 15 magnesia, and 0.1 to 2 lime. In beds or masses, in Styria, Carinthia, and Westphalia; in veins in Anhalt and the Harz; also in the Pyrenees, and the Basque provinces of Spain, as near Bilbao. The crystals at Joachimsthal, Freiberg, Klausthal, Beeralstone in Devonshire, Alston Moor in Cumberland, and in many of the tin mines of Cornwall.

Mineralogy.

Clay ironstone, gray, blue, brown, or black, $G.=2.8\dots 3.5$; $H.=3.5\dots 4.5$, is an impure variety. It occurs chiefly in slate-clay or marls, in layers or nodular masses, especially in the coal formation of Britain, Belgium, and Silesia. These contain 50 to 85 per cent. carbonate of iron, and yield 25 to 42 metal. The Lanarkshire black band contains 70 carbonate of iron, 23 carbonaceous matter, 7 of silica, alumina, and lime, and yields 33.7 iron. In 1855 Great Britain produced 3,217,000 tons iron, worth about twelve millions sterling. South Wales alone produced about 839,000 tons, and Scotland 828,000 tons, worth nearly three millions sterling.

Junkerite, from Brittany, is a mere variety of siderite. *Oligon spar*, varieties with more than 20 per cent. manganese protoxide.

Ankerite.— $R\ 106^\circ 12'$, but mostly massive and granular. $G.=2.9\dots 3.1$; otherwise like siderite. Contains 51 carbonate of lime, 12 to 33 carbonate of magnesia, 12 to 36 carbonate of iron, and 0 to 3 carbonate of manganese protoxide. Styria. Used as an ore or flux.

255. *DIALLOGITE*, Red Manganese.— $Mn\ \ddot{C}$.

Rhombohedral; $R\ 106^\circ 51'$; R and $-\frac{1}{2}R$, sometimes OR and $\infty P\ 2$. Crystals often curved, lenticular, or saddle-shaped; also spherical, reniform, and columnar or granular. Cleavage, R perfect. $H.=3.5\dots 4.5$; $G.=3.3\dots 3.6$. Translucent; vitreous or pearly. Rose-red to flesh-red; streak white. B.B. usually decrepitates and becomes greenish-gray or black, but is infusible; the powder soluble with effervescence in warm h. acid. Chem. com. 62 manganese protoxide and 38 carbonic acid, but usually mixed with carbonates of lime 0 to 13, magnesia 0 to 7, or iron 0 to 15. Freiberg, Schemnitz, Kapnik, Nagyag, Elbingerode, and near Sargans. At the latter, also hydrated, and fibrous, silky (*Wiserite*); compact in Hessia and Glendree, Ireland.

256. *MANGANOCALCITE*.— $(Mn, Ca, Fe)\ \ddot{C}$.

Rhombic; in prisms like arragonite, and bears the same relation to diallogite that arragonite does to calc-spar. $H.=4\dots 5$; $G.=3.03$. Red or reddish-white; vitreous. Schemnitz.

257. *LANTHANITE*.— $La\ \ddot{C} + 3H$.

Rhombic; $\infty P\ 94^\circ$ nearly; small tabular crystals; usually granular or earthy. Cleavage basal. $H.=2.5\dots 3$; $G.=2.7$. Dull or pearly. White or yellowish. B.B. becomes brownish-yellow; soluble in acids with effervescence. Chem. com. 21.1 carbonic acid, 52.9 lanthanum oxide, and 26 water. Bastnäs in Sweden, Lehigh in Pennsylvania.

258. *PARISITE*.— $Ce\ \ddot{C}$, $Ca\ F$, H .

Hexagonal; $P\ 164^\circ 58'$. Cleavage, basal very perfect. $H.=4.5$; $G.=4.35$. Vitreous; on the cleavage planes pearly. Brownish-yellow inclining to red. B.B. infusible and phosphoresces. Chem. com. 23.6 carbonic acid, 60 protoxide of cerium, with lanthanum and didymium, 3.17 lime, 11.51 fluoride of calcium, and 2.4 water. Emerald mines of the Musso Valley in New Granada.

*259. *CALAMINE*, Smithsonian.— $Zn\ \ddot{C}$.

Rhombohedral; $R\ 107^\circ 40'$; R , $4R$, and R^3 . The crystals generally small, obtuse-edged, and rounded. Usually reniform, stalactitic, and laminar or granular. Cleavage, R perfect but curved; fracture uneven conchoidal; brittle. $H.=5.0$; $G.=4.1\dots 4.5$. Translucent or opaque; pearly or vitreous. Colourless, but often pale grayish-yellow, brown, or green. B.B. becomes white, and acts like zinc oxide; soluble in acids with effervescence; also in solution of potash: Chem. com. 64.6 zinc oxide, and 35.4 carbonic acid, but with protoxide of iron 2 to 3, and manganese 3 to 7, lime 1 to 2, or magnesia 0 to 3.

This mineral occurs in beds or veins in the crystalline and transition rocks, and also in the carboniferous and oolite formations. It is most common in limestone, and is often associated with calc-spar, quartz, blende, and ores of

iron and lead. Chessy near Lyons, Altenberg near Aix-la-Chapelle, Brillon in Westphalia, Tarnowitz in Silesia, Hungary, Siberia; also Mendip in Somersetshire, Matlock in Derbyshire, Wanlockhead and Lead Hills in Scotland; compact at Alston Moor. Zinc is obtained chiefly from this mineral by distillation. In Silesia also cadmium.

Kapnite, varieties with 15 to 37 per cent. of iron protoxide. *Zinc-bloom*, reniform, earthy, pale-yellow, and shining streak; seems a mere produce of decomposition. Bleiberg and Raibel in Carinthia.

Herrerite.—Rhombohedric, with curved cleavage planes. $H.=4\dots 5$; $G.=4.3$. Translucent; pearly or vitreous; green. B.B. becomes gray, fumes, and stains the charcoal white. Consists, according to Del Rio, of carbonates of zinc oxide and nickel oxide. Mexico.

*260. *GALMEI*, Electric Calamine.— $Zn^2\ \ddot{Si} + H$.

Rhombic, and hemimorphic; $\infty P\ 2\ (P)$ with polar edges $101^\circ 44'$, and $132^\circ 16'$; $\infty P\ (d)\ 104^\circ 6'$, $P\ (o)\ 117^\circ 8'$, $P\ (l)\ 129^\circ 2'$; common form $\infty P\ \infty\ (s)$. $\infty P\ .\ P\ \infty$ (fig. 185).

Also columnar, fibrous, granular, and earthy. Cleavage, prismatic along ∞P very perfect, along $P\ \infty$ perfect. $H.=5$; $G.=3.3\dots 3.5$. Transparent to translucent; vitreous and pearly. Colourless or white, but often light gray, also yellow, green, brown, and blue; becomes electric by heat. B.B. decrepitates slightly, but is infusible; readily soluble in acids, and gelatinizes. Chem. com. 25.7 silica, 66.8 zinc oxide, and 7.5 water. With calamine, as at Raibel and Bleiberg in Carinthia, Aix-la-Chapelle, Iserlohn, Tarnowitz, and Nertschinsk; also Mendip Hills, Matlock in Derbyshire, and Wanlockhead. Used as an ore of zinc, and in the manufacture of brass.

Fig. 185.

261. *WILLEMITE*, Troostite.— $Zn^2\ \ddot{Si}$.

Rhombohedral; $R\ 115^\circ$; $\infty P\ 2\ .\ R$; also granular and reniform. Cleavage, basal rather perfect, ∞R imperfect; brittle. $H.=4.5$; $G.=4.1\dots 4.2$. Translucent or transparent; dull resinous. White, yellowish, or brown. B.B. in closed tube yields no water, otherwise like galmei. Chem. com. 72.47 zinc oxide and 27.53 silica, with 0 to 9 protoxide of manganese, 0 to 5 iron protoxide, and 0 to 3 magnesia. Aix-la-Chapelle, Liege, Raibel, and Sterling and Franklin in New Jersey.

FAMILY II.—IRON SALTS.

Crystallization predominantly rhombic or monoclinohedric. $H.=2\dots 5.5$; $G.=2.2\dots 4$. They are all soluble in acids, and many easily. B.B. all fusible, and also often easily so. Their colours are often brown, or dark blue and dark green; the streak yellow or red. They are chiefly phosphates or arseniates of iron. The phosphates B.B. moistened with sulphuric acid, colour the flame bluish-green. The arseniates B.B. in the reducing flame, or with carbonate of soda, evolve odour of arsenic.

*262. *VIVIANITE*, } $6\ (Fe^3\ \ddot{P} + 8H) + (\ddot{Fe}^3\ \ddot{P}^2 + 8H)$.

Blue Iron. } Monoclinohedric; $C=71^\circ 25'$, $\infty P\ 111^\circ 12'$, $P\ 119^\circ 10'$, $P\ \infty\ 54^\circ 13'$. Crystals ($\infty P\ \infty$). $\infty P\ \infty\ .\ P\ \infty$ (fig. 186); also spherical or reniform, and fibrous or earthy. Cleavage, clinodiagonal very perfect; thin laminae flexible. $H.=2$; $G.=2.6\dots 2.7$. Translucent or transparent; vitreous or bright pearly on cleavage. Indigo-blue to blackish-green; streak bluish-white, but soon becomes blue on exposure. The white earthy variety also changes to blue in the air; the dry crushed powder is liver-brown. In the closed tube yields much water, intumesces, and becomes spotted with gray and red. B.B. on charcoal becomes red, and then fuses to

Fig. 186.

Mineralogy.

Mineralogy.

a gray, shining, magnetic granule; easily soluble in h. or nitric acid; becomes black in warm solution of potash. Chem. com., the colourless vivianite is a hydrous phosphate of iron protoxide, with 42 iron protoxide, 29 phosphoric acid, and 29 water; but on exposure, when it acquires a blue colour, with 29.1 phosphoric acid, 33.0 iron protoxide, 12.2 iron peroxide, and 25.7 water. Transparent indigo-coloured crystals at St Agnes in Cornwall, and Allentown and Imleytown in New Jersey. Earthy in Cornwall, Styria, North America, Greenland, and New Zealand, and in peat mosses in Northern Germany, Sweden, Norway, and the Zetland Isles. As a recent formation under some old slaughter-houses at the foot of the Castle Rock in Edinburgh. It is sometimes used as a pigment. *Mullicite* and *Anglarite* are varieties.

263. DUFRENÖITE, Green Iron Earth.— $2\text{Fe}^3\text{P} + 5\text{H}$. Rhombic; ∞P about 123° ; spherical or reniform. Cleavage brachydiagonal; very brittle. $\text{H.}=3\ldots3.5$; $\text{G.}=3.3\ldots3.4$. Translucent on the edges, or opaque; shining or dull. Dirty, leek, or blackish green; streak siskin-green. B.B. fuses readily to a porous, black, non-magnetic globule; soluble in h. acid. Chem. com. 63 iron peroxide, 28 phosphoric acid, and 9 water. Westerwald, Hirschberg, and Limoges in France.

264. TRIPLITE.— $\text{Mn}^4\text{P} + \text{Fe}^4\text{P}$. Rhombic (?); only granular. Cleavage, in three directions at right angles; fracture conchoidal. $\text{H.}=5\ldots5.5$; $\text{G.}=3.6\ldots3.8$. Translucent or opaque; resinous. Chesnut or blackish-brown; streak yellowish gray. B.B. on charcoal fuses easily, with strong intumescence, to a black magnetic globule; soluble in h. acid. Chem. com. 34 iron protoxide, 33 manganese protoxide, and 33 phosphoric acid. Limoges in France.

265. ZWIESELITE, Eisenapatit.— $(\text{Fe}, \text{Mn})^3\text{P} + \text{Fe F}$. Rhombic (?), but only massive. Cleavage, in three directions imperfect; fracture conchoidal. $\text{H.}=4.5\ldots5$; $\text{G.}=3.95\ldots4$. Translucent on the edges; resinous. Colour brown; streak yellow. B.B. decrepitates and fuses easily to a bluish-black magnetic globule; easily soluble in warm s. acid, showing traces of fluorine. Chem. com. 30.3 phosphoric acid, 41.4 iron protoxide, 23.3 manganese protoxide, and 6 fluorine. Zwiesel in Bavaria.

266. TRIPHYLITE.— $6(\text{Fe}^3, \text{Mn}^3)\text{P} + \text{Li}^3\text{P}$. Rhombic; ∞P 94° ; chiefly granular. Cleavage, basal perfect, prismatic and diagonal imperfect. $\text{H.}=5$; $\text{G.}=3.6$. Translucent on the edges; resinous. Greenish-gray with blue spots. B.B. fuses very easily to a dark steel-gray magnetic bead; easily soluble in h. acid. Chem. com. 42.64 phosphoric acid, 49.16 iron protoxide, 4.75 manganese protoxide, and 3.45 lithia. Bodenmais in Bavaria. *Tetraphylite* or *Perowskine*, from Tammela in Finland, is similar.

267. MONAZITE, Mengite.— $(\text{Ce}, \text{L}, \text{Th})^3\text{P}$. Monoclinohedric; $\text{C}=77^\circ$, ∞P $94^\circ 35'$; crystals of OP. $\infty\text{P} . (\infty\text{P} \infty) . \text{P} \infty . -\text{P} \infty$, with $\text{OP} : \text{P} \infty = 129^\circ 6'$ $\text{OP} : -\text{P} \infty = 139^\circ 25'$ (fig. 187); thick, tabular, or very short prismatic. Cleavage, basal imperfect. $\text{H.}=5\ldots5.5$; $\text{G.}=4.9\ldots5.25$. Translucent on the edges; dull resinous. Flesh-red, hyacinth-red, and reddish-brown. B.B. infusible; moistened with sulphuric acid, colours the flame green; soluble in h. acid. Chem. com. 28 phosphoric acid, 25 to 37 cerium protoxide, 23 to 27 lanthanum oxide (18 thorina), with 2 tin oxide, 1.5 lime, and some magnesia and manganese. Miask in Ural, and Norwich in Connecticut (*Edwardsite*).

Monazitoid; $\text{G.}=5.281$; brown; partially soluble in acids, and with 18 phosphoric acid; probably a variety.

Fig. 187.

Mineralogy.

268. CRYPTOLITE.— Ce^3P . Acicular crystals, imbedded in apatite. $\text{G.}=4.6$. Transparent. Pale wine-yellow. Soluble as powder in con. s. acid. Wöhler's analysis gave 73.70 cerium oxide (protoxide), 27.37 phosphoric acid, and 1.51 iron protoxide. Arendal.

269. HUREAULITE.— $(\text{Mn}, \text{Fe})^3\text{P} + 8\text{H}$. Monoclinohedric; $\text{C.}=68^\circ$, ∞P $62^\circ 30'$, P 88° ; fracture conchoidal. $\text{H.}=3.5$; $\text{G.}=2.27$. Translucent; resinous. Reddish-yellow or brown. B.B. fuses easily to a black metallic globule; soluble in acids. Chem. com. 38 phosphoric acid, 11.1 iron protoxide, 32.9 manganese protoxide, and 18 water. Hureaux near Limoges.

Beraunite.—Foliated and radiated. $\text{H.}=2$; $\text{G.}=2.87$. Vitreous or pearly. Hyacinth-red or reddish-brown; streak reddish ochre-yellow. B.B. in forceps melts and colours the flame bluish-green; soluble in h. acid. Seems a hydrous phosphate of iron. Beraun in Bohemia. *Kakoxene*, from Žbirow in Bohemia, is similar.

Heterozite.— $\text{H.}=5$; $\text{G.}=3.5$. Opaque, or translucent on the edges; vitreous or resinous. Colour dark-violet or lavender-blue to greenish-gray; streak violet-blue or crimson-red. Chem. com. 41.77 phosphoric acid, 34.89 iron protoxide, 17.57 manganese protoxide, and 4.40 water. Hureaux near Limoges.

270. ALLUAUDITE.— $(\text{Mn}, \text{Na})^3\text{P} + \text{Fe}^3\text{P} + \text{H}$. Rhombic, with cleavage in three directions at right angles. H. above 4; $\text{G.}=3.468$. Translucent on the edges; lustre dull. Clove-brown; streak yellowish-brown. B.B. on platinum wire fuses to a black magnetic globule; in h. acid forms a black solution. Chem. com. 41.25 phosphoric acid, 25.62 peroxide of iron, 23.08 manganese protoxide, 1.06 manganese peroxide, 5.47 soda, 2.65 water, and 0.60 silica. Chanteloube near Limoges.

271. DIADOCHITE.— $\text{Fe}^3\text{P} + 4\text{Fe}^3\text{S} + 32\text{H}$. Reniform and stalactitic. Fracture conchoidal. $\text{H.}=3$; $\text{G.}=2.035$. Resinous; vitreous. Yellow or yellowish-brown; streak white. B.B. intumesces, and fuses on the edges to a black magnetic enamel. Chem. com. 36.7 iron peroxide, 14.8 phosphoric acid, 15.2 sulphuric acid, and 30.3 water. Grafenthal and Saalfeld in Thuringia.

272. DELVAUXINE.— $\text{Fe}^3\text{P} + 24\text{H}$. Massive and earthy. $\text{H.}=2.5$; $\text{G.}=1.85$. Reddish or blackish brown or yellow. B.B. decrepitates, and fuses to a gray magnetic bead. In h. acid forms a brown solution. Chem. com. 35.8 iron peroxide, 48.3 water, and 15.9 phosphoric acid. Visé in Belgium.

Karphosiderite, reniform, opaque, resinous, and straw-yellow, with a greasy feel, is related. $\text{H.}=4.5$; $\text{G.}=2.5$. B.B. becomes red and fuses to a black magnetic bead; consists of hydrous phosphate of iron with a little oxide of zinc. Labrador.

273. PISSOPHANE.— $(\text{Al}, \text{Fe})^3\text{S} + 15\text{H}$. Stalactitic; fracture conchoidal; very easily frangible. $\text{H.}=2$; $\text{G.}=1.9\ldots2$. Transparent or translucent; vitreous. Olive-green to liver-brown; streak greenish-white to pale yellow. B.B. becomes black; easily soluble in h. acid. Chem. com. 7 to 35 alumina, 10 to 40 iron peroxide, 12 sulphuric acid, and 41 water. Saalfeld, and Reichenbach in Saxony.

274. PITTCITE, Iron Sinter.— $\text{Fe}^2\text{S} + 2\text{Fe}^3\text{As} + 24\text{H}$. Reniform and stalactitic; brittle; fracture conchoidal. $\text{H.}=2\ldots3$; $\text{G.}=2.3\ldots2.5$. Translucent, or on the edges; resinous, inclining to vitreous. Yellowish, reddish, or blackish-brown, sometimes in spots or stripes; streak light-yellow, or white. B.B. on charcoal fuses easily, with effervescence and strong arsenical fumes, to a black magnetic

Mineralogy.

globule; easily soluble in h. acid to a yellow fluid. Chem. com. 35 iron peroxide, 26 arsenic acid, 14 sulphuric acid, and 24 water. In many old mines, as Freiberg and Schneeberg.

275. SYMPLESITE.

Monoclinohedric, like gypsum; in very fine prismatic crystals or groups. Cleavage perfect. $H.=2.5$; $G.=2.957$. Transparent or translucent; vitreous; pearly on the cleavage. Pale indigo to celadine-green, with bluish-white streak. B.B. emits arsenic odours, becomes black and magnetic, but does not fuse. Chem. com. arseniate of iron protoxide with water, also a little sulphuric acid and protoxide of manganese. Lobenstein in Reuss.

276. SCORODITE, Neoctese.— $\ddot{\text{Fe}} \ddot{\text{As}} + 4 \text{H}$.

Rhombic; P, with polar edges $103^\circ 5'$ and $114^\circ 34'$. Crystals $\infty P \infty$ and $\infty P \infty (r)$; also $0P (h)$, $\infty P 2 (d)$ $120^\circ 10'$, and $2 P \infty (m)$ 48° (fig. 188); also columnar and fibrous. Cleavage imperfect; rather brittle. $H.=3.5 \dots 4$; $G.=3.1 \dots 3.2$. Translucent; vitreous. Leek-green to greenish-black, also indigo-blue, red and brown. In closed tube yields water and becomes yellow. B.B. on charcoal fuses easily, emitting arsenic vapours, to a gray magnetic slag; easily soluble in h. (not in nitric) acid, forming a brown solution. Chem. com. 49.8 arsenic acid, 34.6 iron peroxide, and 15.6 water. St Austle in Cornwall, Vaulry in France, Schlackenwald and Schönfeld in Bohemia, Antonio Pereira in Brazil, and near Marmato.

Fig. 188.

277. ARSENIOSIDERITE.— $\text{Ca} \ddot{\text{As}} + 3 \ddot{\text{Fe}} \ddot{\text{As}} + 11 \text{H}$.

Spherical and fibrous; friable, and leaves a mark on paper. $H.=1 \dots 2$; $G.=3.52 \dots 3.88$. Opaque; metallic pearly. Ochre brown, becoming darker in the air; streak brownish-yellow. B.B. fuses easily, with reaction for iron and arsenic. Chem. com. 39 arsenic acid, 40.7 iron peroxide, 11.9 lime, and 8.4 water. Romanèche near Mâcon in France.

278. PHARMAKOSIDERITE, } $\ddot{\text{Fe}} \ddot{\text{As}} + \ddot{\text{Fe}} \ddot{\text{As}} + 18 \text{H}$.

Cube Ore.

Tesseral and tetrahedral; usually $\infty O \infty$, with $\frac{O}{2}$, or ∞O . Cleavage, tesseral very imperfect; rather brittle. $H.=2.5$; $G.=2.9 \dots 3$. Semitransparent to translucent; adamantine or resinous. Olive to emerald-green, honey-yellow, and brown; streak straw-yellow. Pyro-electric. In closed tube yields water, and becomes red. B.B. on charcoal fuses easily to a steel-gray magnetic slag; easily soluble in acids. Chem. com. 40.4 arsenic acid, 28.1 iron peroxide, 12.6 iron protoxide, and 18.9 water. Huel Gorland, Huel Unity, and Carharrak in Cornwall; Burdle Gill in Cumberland; also St Leonard in the Haute-Vienne, Lobenstein in Reuss, Schwarzenberg in Saxony, and North America.

Beudantite, said to be rhombohedral; $R 92^\circ 30'$. H . above 4. Resinous; black greenish-gray streak; but probably a mixture of pharmakosiderite with sulphate of lead. Horhausen in Nassau.

FAMILY III.—COPPER SALTS.

Crystallization generally rhombic and monoclinohedric. Hardness generally from 2...3.5, but a few as low as 1...2, others 4...5. Gravity 2...4, but mostly 3...4. The colours are predominantly green, and rarely blue. They are all soluble in acids, and mostly easily so. Mostly fusible B.B. and on charcoal, when moistened with hydrochloric acid, the copper is known by colouring the flame blue.

With soda they are reduced to metallic copper. They are, with a few exceptions, compounds of copper with one of the common acids, and some used as ores of this metal. They occur especially in veins.

279. DIOPTASE, Emerald Copper.— $\text{Cu} \ddot{\text{Si}} + \text{H}$.

Rhombohedral; $R 126^\circ 24'$; $\infty P 2 (s)$.— $2 R (r) 95^\circ 54'$ (fig. 189). Cleavage, R perfect; brittle. $H.=5$; $G.=3.2 \dots 3.3$. Transparent or translucent; vitreous. Emerald-green, rarely verdigris or blackish green; streak green. B.B. in the outer flame becomes black, in the inner red, but is infusible; soluble, and gelatinizes in h. or s. acid, and also in ammonia. Chem. com. 38.7 silica, 50 copper protoxide, and 11.3 water. Altyn-tube in the Kirgis Steppe.

Fig. 189.

280. CHRYSOCOLLA, Copper-green.— $\text{Cu} \ddot{\text{Si}} + 2 \text{H}$.

Botryoidal, reniform, or investing; brittle; fracture conchoidal, and fine splintery. $H.=2 \dots 3$; $G.=2.0 \dots 2.3$. Translucent or semitransparent; weak resinous. Verdigris to emerald green or azure-blue; streak greenish-white. B.B. and with acids like diopase. Chem. com. 34.83 silica, 44.94 copper protoxide, and 20.23 water. Saxony, Bavaria, Ural, Cornwall, Hungary, the Tyrol, Spain, the Harz (*Siliceous malachite*), Mexico, and Chili.

*281. AZURITE, Blue Copper.— $\text{Cu}^3 \ddot{\text{C}} + \text{H}$.

Monoclinohedric; $C=87^\circ 39'$, $\infty P (M) 99^\circ 32'$, $-P (h) 106^\circ 14'$. Crystals $0P \cdot \infty P \cdot \infty P \infty \cdot -P$, or h, M, s, k , in fig. 190; also radiated and earthy. Cleavage, $(P \infty) (P) 59^\circ 14'$, rather perfect; fracture conchoidal, or splintery. $H.=3.5 \dots 4.2$; $G.=3.7 \dots 3.8$. Translucent or opaque; vitreous. Azure-blue, the earthy varieties (and streak) smalt-blue. B.B. on charcoal fuses and yields a grain of copper; soluble with effervescence in acids, and also in ammonia. Chem. com. 69.1 protoxide of copper, 25.7 carbonic acid, and 5.2 water. Crystals at Chessy near Lyons, Kolywan and Nischne-Tagilsk in Siberia, Moldawa in the Bannat; also Redruth in Cornwall, Alston Moor, and Wanlockhead; massive in Cornwall, Thuringia, the Harz, Hessa, and the Ural. Valued as an ore of copper.

Fig. 190.

*282. MALACHITE.— $\text{Cu}^2 \ddot{\text{C}} + \text{H}$.

Monoclinohedric; $C=61^\circ 49'$, $\infty P 103^\circ 42'$; crystals $\infty P (M) \cdot \infty P \infty (s) \cdot 0P (P)$, in macles (fig. 191). In general acicular, scaly, or reniform, stalactitic, and radiated fibrous. Cleavage, basal and clinodiagonal very perfect. $H.=3.5 \dots 4$; $G.=3.6 \dots 4.4$. Transparent or translucent on the edges; adamantine, vitreous, silky or dull. Emerald and other shades of green; streak apple-green. B.B., and with acids, like azurite. Chem. com. 71.8 copper protoxide, 20 carbonic acid, and 8.2 water. Crystalline at Rheinbreitenbach on the Rhine, and Zellerfeld in the Harz; fibrous and compact at Chessy in France, Siberia, the Ural, Saalfeld in Thuringia, Moldawa in the Bannat, Sandlodge in Zetland, Cornwall, Wales, and Ireland, and in North America and Australia. It is a valuable ore of copper, and the finer varieties are prized for ornamental purposes.

Fig. 191.

Lime-Malachite.—Reniform, botryoidal, and radiated fibrous; brittle. $H.=2.5$. Silky; verdigris-green. B.B. blackens and fuses to a black slag; soluble in h. acid, leaving gelatinous gypsum. Seems a hydrous carbonate of

Mineralogy.

Mineralogy.

copper and lime, with sulphate of lime and some iron. Lauterberg in the Harz. *Mysorine*, compact, blackish-brown, and soft, $G.=2.62$, is a mixture of a carbonate of copper with iron peroxide. Mysore in the East Indies.

283. *AURICHALCITE*.— $2\text{Cu}\ddot{\text{C}}+3\text{Zn}\ddot{\text{H}}$.

Acicular. $H.=2$. Translucent, pearly, and verdigris-green. B.B. on charcoal in the inner flame forms a deposition of zinc oxide, and with fluxes gives reaction for copper; soluble with effervescence in h. acid. Chem. com. 29.2 copper protoxide, 44.7 zinc oxide, 16.2 carbonic acid, and 9.9 water. Loktetskoi in the Altai; Matlock in Derbyshire.

Buratite, azure-blue, and agrees with aurichalcite, but perhaps mixed with lime. Loktetskoi.

284. *CHALCOPHYLLITE*, $\begin{cases} \text{Cu}^{\ddot{\text{S}}}\ddot{\text{As}}+23\ddot{\text{H}}, \text{ or} \\ \text{Copper-mica.} \end{cases} \begin{cases} \text{Cu}^{\ddot{\text{S}}}\ddot{\text{As}}+12\ddot{\text{H}}. \end{cases}$

Rhombohedral; $R\ 69^{\circ}48'$. Crystals, OR (o). R (fig. 192). Cleavage, basal very perfect; sectile. $H.=2$; $G.=2.4$; $\dots 2.6$. Translucent or transparent; vitreous inclining to adamantine; pearly on OR. Emerald to grass or verdigris green; streak light-green. B.B. decrepitates violently, emits arsenical vapours, and fuses to a gray metallic grain; easily soluble in acids and ammonia. Chem. com. 49.6 copper protoxide, 18 arsenic acid, and 32.4 water; or 51.6 copper protoxide, 25 arsenic acid, and 23.4 water; but also 2 alumina, and 1.5 phosphoric acid. Tingtang, Huel Golland and Huel Unity Mines near Redruth; also Saïda in Saxony, and Moldawa in the Bannat.

Fig. 192.

285. *TIROLITE*.— $(\text{Cu}^{\ddot{\text{S}}}\ddot{\text{As}}+10\ddot{\text{H}})+\text{Ca}\ddot{\text{C}}$. Rhombic; reniform, or radiating foliated. Cleavage, basal very perfect; sectile. Thin laminæ flexible. $H.=1.5\dots 2$; $G.=3\dots 3.1$. Translucent; pearly or vitreous. Verdigris-green to azure-blue; streak paler. B.B. decrepitates violently and fuses to a steel-gray bead; soluble in acids, evolving carbonic acid. Chem. com. 43.88 copper oxide, 25.01 arsenic acid, 17.46 water, and 13.65 carbonate of lime, by analysis. The carbonate of lime is perhaps accidental. Falkenstein in Tyrol, in Hungary, Reichelsdorf, Saalfeld, Piombino in Italy, in Asturia and at Linares in Spain, and Matlock in Derbyshire.

286. *ERINITE*.— $\text{Cu}^{\ddot{\text{S}}}\ddot{\text{As}}+2\ddot{\text{H}}$.

Reniform and foliated; conchoidal fracture. $H.=4.5\dots 5$; $G.=4\dots 4.1$. Translucent on the edges; dull resinous. Emerald or grass green; streak similar. Chem. com. 59.9 copper protoxide, 34.7 arsenic acid, and 5.4 water. Limerick in Ireland. *Cornwallite*, is similar, but dark-green, and 5 $\ddot{\text{H}}$. Cornwall.

287. *LIROCONITE*.— $\text{Cu}^{\ddot{\text{S}}}\ddot{\text{As}}+\ddot{\text{Al}}\ddot{\text{As}}+24\ddot{\text{H}}$.

Rhombic; $\infty P\ 119^{\circ}20'$, $\bar{P}\infty\ 72^{\circ}22'$ (fig. 193). Cleavage, $\bar{P}\infty$ imperfect, and $P\infty$ more so. $H.=2\dots 2.5$; $G.=2.8\dots 3.0$. Translucent; vitreous, or resinous on fracture. Azure-blue to verdigris-green; streak paler. In the closed tube does not decrepitate, but becomes green; then ignites and brown. B.B. on charcoal emits arsenical vapours and fuses; soluble in acids and in ammonia. Chem. com. 36.6 copper protoxide, 11.9 alumina, 26.6 arsenic acid, and 24.9 water. Huel Unity and other mines near Redruth; also Herrengrund in Hungary and Ullersreuth in the Voightland.

Fig. 193.

*288. *OLIVENTITE*.— $\text{Cu}^{\ddot{\text{S}}}\ddot{\text{As}}+\ddot{\text{H}}$.

Rhombic; $\infty P\ (r)\ 92^{\circ}30'$, $\bar{P}\infty\ (l)\ 110^{\circ}50'$; $\infty\bar{P}\infty\ (n)$ (fig. 194); also spherical and reniform, and columnar or fibrous. Cleavage, (r) and (l) very imperfect. $H.=3$;

$G.=4.1\dots 4.4$. Pellucid in all degrees; vitreous, resinous, or silky. Leek, olive, or blackish-green, also yellow and brown; streak olive-green or brown. B.B. in the forceps fuses easily to a dark-brown adamantine bead covered with radiating crystals; on charcoal, detonates, emits arsenical vapours, and is reduced; soluble in acids and ammonia. Chem. com. 56.5 copper protoxide, 39.5 arsenic acid, and 4 water, but also 1 to 6 phosphoric acid. Carrarach, Tin Croft, Gwennap, and St Day in Cornwall; also Alston Moor, Thuringia, Tyrol, Siberia, Chili, and other places.

Fig. 194.

289. *EUCHROITE*.— $\text{Cu}^{\ddot{\text{S}}}\ddot{\text{As}}+7\ddot{\text{H}}$.

Rhombic; $\infty P\ (M)\ 117^{\circ}20'$, $\bar{P}\infty\ (n)\ 80^{\circ}52'$, with $\infty\bar{P}2\ (l)$, and $OP\ (P)$, (fig. 195). Cleavage M and n imperfect; rather brittle. $H.=3.5\dots 4$; $G.=3.35\dots 3.45$. Transparent or translucent; vitreous. Emerald or leek-green; streak verdigris-green. B.B. in forceps fuses to a greenish-brown crystallized mass; on charcoal detonates; easily soluble in nitric acid. Chem. com. 47.1 copper protoxide, 34.2 arsenic acid, and 18.7 water. Libethen in Hungary.

Fig. 195.

290. *KLINOCLEASE*, Aphanese, Abichite. — $\text{Cu}^{\ddot{\text{S}}}\ddot{\text{As}}+3\ddot{\text{H}}$. Monoclinohedric; $C=80^{\circ}30'$, $\infty P\ 56^{\circ}$; also wedge-shaped and hemispherical. Cleavage, basal highly perfect. $H.=2.5\dots 3$; $G.=4.2\dots 4.4$. Translucent or opaque; vitreous; pearly on the cleavage. Dark verdigris-green inclining to sky-blue; streak bluish-green. B.B. becomes black, and is reduced; soluble in acids and ammonia. Chem. com. 62.6 copper protoxide, 30.3 arsenic acid, and 7.1 water. Cornwall and the Erzgebirge.

291. *PHOSPHOROCHALCITE*, Lunnite. — $\text{Cu}^{\ddot{\text{S}}}\ddot{\text{P}}+3\ddot{\text{H}}$.

Monoclinohedric; crystals ($\infty P2$) (f) $38^{\circ}56'$, $P\ (P)\ 117^{\circ}49'$, with $OP\ (a)$ and $\infty P\infty\ (e)$ (fig. 196); usually small and indistinct, more common in spherical or reniform, and radiated, fibrous. Cleavage, (e) imperfect; fracture uneven and splintery. $H.=5$; $G.=4.1\dots 4.3$. Translucent, or on the edges; adamantine or resinous. Blackish, emerald, or verdigris green. B.B. decrepitates, or blackens and fuses to a black globule; easily soluble in nitric acid or ammonia. Chem. com. 70.8 copper protoxide, 21.2 phosphoric acid, and 8 water. Rheinbreitenbach, Nishne-Tagilsk, and in Cornwall. *Dihydrate*, with about a fifth less water. *Copperdiaspore* and *Prasin* seem varieties.

Fig. 196.

292. *THROMBOLITE*.— $\text{Cu}^{\ddot{\text{S}}}\ddot{\text{P}}+6\ddot{\text{H}}$.

Porodine. Fracture conchoidal; brittle. $H.=3\dots 4$; $G.=3.38\dots 3.40$. Opaque; vitreous. Emerald, leek, or dark-green. B.B. colours the flame blue and then green; on charcoal fuses easily. Chem. com. 45.1 phosphoric acid, 37.8 copper protoxide, and 17.1 water. Retzbanya in Hungary.

293. *LIBETHENITE*.— $\text{Cu}^{\ddot{\text{S}}}\ddot{\text{P}}+\ddot{\text{H}}$.

Rhombic; $\infty P\ (u)\ 92^{\circ}20'$, $\bar{P}\infty\ (o)\ 109^{\circ}52'$, and P . (fig. 197). Cleavage, brachydiagonal and macrodiagonal imperfect. $H.=4$; $G.=3.6\dots 3.8$. Translucent on the edges; resinous. Leek, olive, or blackish-green; streak olive-green. B.B., and with acids, acts like the phospho-

Mineralogy.

Mineralogy.

rochalcite. Chem. com. 66·37 copper protoxide, 29·86 phosphoric acid, and 3·77 water. Libethen in Hungary, Tagilsk in the Ural, and Gunnislake in Cornwall.

294. TAGILITE.— $\text{Cu}^4 \ddot{\text{P}} + 3\text{H}$.
Fungoid or botryoidal, and radiating fibrous or earthy. $H.=3$; $G.=3\cdot5$. Emerald-green. Chem. com. 61·8 copper protoxide, 27·7 phosphoric acid, and 10·5 water. Nischne-Tagilsk.

Fig. 197.

295. ERLITE.— $\text{Cu}^5 \ddot{\text{P}} + 3\text{H}$.
Botryoidal or reniform, and radiating foliated, or compact. Cleavage in one direction perfect. $H.=1\cdot5 \dots 2$; $G.=3\cdot8 \dots 4\cdot27$. Translucent on the edges; pearly on the cleavage. Verdigris-green; streak paler. B.B. breaks into small fragments thrown about violently. Chem. com. 66·8 copper protoxide, 24·1 phosphoric acid, and 9·1 water. Ehl on the Rhine, Nischne-Tagilsk, and Libethen.

296. ATACAMITE.— $\text{Cu Cl} + 3\text{Cu H}$.
Rhombic; $\infty P (M) 112^\circ 20'$, $\ddot{P} \infty (P) 105^\circ 40'$, and $\infty \ddot{P} \infty (h)$ (fig. 198); also reniform and columnar or granular. Cleavage (h) perfect. $H.=3 \dots 3\cdot5$; $G.=4 \dots 4\cdot3$ (3·7, *Breit.*) Semitransparent or translucent on the edges; vitreous. Olive, grass, or emerald-green; streak apple-green. B.B. fuses, and leaves copper; easily soluble in acids. Chem. com. 55·85 copper protoxide, 14·86 copper, 16·61 chlorine, and 12·68 water; or 74·46 copper protoxide and 17·09 h. acid. Remolinos and Santa Rosa in Chili, Tarapaca in Bolivia, Schwarzenberg, and on lavas of Ætna and Vesuvius. Used as an ore of copper.

Fig. 198.

297. VOLBORTHITE.— $(\text{Cu Ca})^4 \ddot{\text{V}} + \text{H}$.
Hexagonal; small tabular crystals, $OP \cdot \infty P$, single or in groups. $H.=3$; $G.=3\cdot45 \dots 3\cdot89$. Olive-green; streak almost yellow. B.B. on charcoal fuses easily, and forms a graphite-like slag, containing grains of copper; on platina wire, with salt of phosphorus, forms a green glass; soluble in nitric acids, and with water gives a brick-red precipitate. Chem. com. 37 to 38 vanadic acid, 39·4 to 46 copper oxide, 18·5 to 13 lime, 3·6 to 5 water. Syssersk, Nischne-Tagilsk, and Friedericksrode in Thuringia.

298. BROCHANTITE.— $\text{Cu S} + 3\text{Cu H}$.
Rhombic; $\infty P 104^\circ 10'$, $\ddot{P} \infty 151^\circ 52'$, and $\infty \ddot{P} \infty$; also reniform. Cleavage, brachydiagonal very perfect. $H.=3\cdot5 \dots 4$; $G.=3\cdot75 \dots 3\cdot9$. Transparent or translucent; vitreous. Emerald or blackish-green; streak bright-green. B.B. on charcoal fuses, leaving copper; easily soluble in acids. Chem. com. 70 copper protoxide, 18 sulphuric acid, and 12 water. Rezbanya, Katharinenburg, and Roughton-hill in Cumberland; also Krisuvig in Iceland (*Krisuvigite*), and in Siberia (*Königine*).

299. URANITE, Uran-Mica.— $(\text{Ca} + \ddot{\text{U}})^2 \ddot{\text{P}} + 8\text{H}$.
Tetragonal; $P 143^\circ 2'$. Crystals OP , with ∞P or P (fig. 199). Cleavage, basal very perfect; sectile. $H.=1 \dots 2$; $G.=3 \dots 3\cdot2$. Translucent; pearly on OP . Siskin-green to sulphur-yellow; streak yellow. B.B. on charcoal fuses to a black semicrystalline mass; with soda forms a yellow infusible slag; in n. acid forms a yellow solution. Chem. com. 15·5 phosphoric acid, 62·6 uranium peroxide, 6·2 lime, and 15·7 water. Johann-Georgenstadt and Eibenstock in Saxony, Autun and Limoges in France,

Fig. 199.

Chesterfield in Massachusetts, and Lake Onega in Russia.

Mineralogy.

300. CHALCOLITE.— $(\text{Cu} + \ddot{\text{U}})^2 \ddot{\text{P}} + 8\text{H}$.
Tetragonal, and like uranite, but brittle. $H.=2 \dots 2\cdot5$; $G.=3\cdot5 \dots 3\cdot6$. Grass to emerald or verdigris green; streak apple-green. B.B. like uranite, but with soda yields a grain of copper. Chem. com. 15·2 phosphoric acid, 61·1 uranium peroxide, 8·4 copper protoxide, and 15·3 water. Johann-Georgenstadt, Eibenstock, Schneeberg, Bodenmais, near Baltimore in North America, and near Redruth and St Austle.

*301. ERYTHRINE, Cobalt-Bloom.— $\text{Co}^3 \ddot{\text{As}} + 8\text{H}$.
Monoclinohedric; $(\infty P \infty) (P) \cdot \infty P \infty (T) \cdot P \infty (M)$ (like fig. 186), with $M: T=55^\circ 9'$; also $\infty P3 (k) 130^\circ 10'$, and $P (l) 118^\circ 23'$ (fig. 200). Cleavage, clinodiagonal (P) very perfect; sectile; thin laminæ flexible. $H.=1\cdot5 \dots 2\cdot5$; $G.=2\cdot9 \dots 3$. Translucent; vitreous; pearly on the cleavage. Crimson or peach-blossom red. B.B. on charcoal fuses with arsenic fumes to a gray globule; colours borax blue; easily soluble in acids. Chem. com. 24 water, 38·2 arsenic acid, and 37·8 cobalt protoxide; but often with 0 to 8 lime, or the protoxides of iron 1 to 4, and nickel 0 to 9. Schneeberg, Saalfeld, Allemont, Riechelsdorf, the Pyrenees, and Modum in Norway; also Cornwall, Alston in Cumberland, at Alva in Stirlingshire, and Tyndrum in Perthshire. Used in preparing blue colours.

Fig. 200.

Köttigite.—White or peach-blossom red incrustations of minute crystals like erythrine, with which it agrees, except that the cobalt is almost wholly replaced by zinc. Schneeberg.

Kobaltbeschlag, or Earthy-encrusting Cobalt, reniform or spheroidal, is a mixture of erythrine with arsenious acid.

Lavendulan.—Thin reniform lavender-blue crusts; translucent; resinous or vitreous. $H.=2\cdot5 \dots 3$; $G.=2\cdot95 \dots 3\cdot1$. B.B. fuses very easily, colouring the outer flame blue. Consists of arsenic acid, protoxides of cobalt, nickel and copper, and water. Annaberg.

302. NICKELINE, Nickel-Ochre.— $\text{Ni As} + 8\text{H}$.
Monoclinohedric (P); capillary and massive; earthy, rather sectile. $H.=2 \dots 2\cdot5$; $G.=3 \dots 3\cdot1$. Dull or glistening. Apple-green or greenish-white; streak greenish-white and shining. B.B. on charcoal fuses with arsenical vapours; easily soluble in acids. Chem. com. 38·7 arsenic acid, 37·8 nickel protoxide, and 24 water, but with a little cobalt or iron. Andreasberg, Annaberg, Saalfeld, Riechelsdorf, Joachimsthal, and Leadhills. Used in preparing blue colours.

FAMILY IV.—LEAD-SALTS.

Crystallization predominantly rhombic and monoclinohedric in the salts of lead, but several tetragonal and hexagonal. Hardness moderate, or from 2...4·5, or generally about calc-spar. All have a high specific gravity, or from 5·3...8, —this family including all minerals without metallic lustre and aspect, with $G.$ above 5·5. They are all soluble in nitric acid, and form coloured solutions or precipitates. They are all easily fusible, and mostly readily reduced alone, or with soda, to lead. They are mostly compounds of lead, and the cerussite is an ore of this metal. The others are not abundant, but often show fine colours. Occur chiefly in veins and mines with other ores of lead.

Lead B.B. on charcoal forms a greenish or sulphur-yellow coating round the assay. Solutions in nitric acid

Mineralogy.

give, with sulphuric acid, a white precipitate; reduced B.B., and with chromate of potassa, a yellow precipitate.

*303. CERUSSITE, Lead Spar.— $\text{Pb } \ddot{\text{C}}$.

Rhombic; isomorphous with arragonite and nitre; $\infty \text{P } (M) 117^\circ 14'$, $\ddot{\text{P}} \infty 108^\circ 13'$, $2\ddot{\text{P}} \infty (u) 69^\circ 18'$; also 0P , $\text{P } (t)$, $\frac{1}{2}\ddot{\text{P}} \infty (s)$, $\infty \ddot{\text{P}} \infty (l)$, $\infty \ddot{\text{P}} 3 (e)$ (figs. 201, 202).

Fig. 201.

Fig. 202.

Fig. 203.

Macles are very common (fig. 203); also granular or earthy. Cleavage, ∞P and $2\ddot{\text{P}} \infty$ rather distinct; fracture conchoidal; brittle and easily frangible. $H. = 3 \dots 3.5$; $G. = 6.4 \dots 6.6$ (earthy 5.4). Transparent or translucent; adamantine or resinous. Colourless and often white, but also gray, yellow, brown, black, rarely green, blue, or red; streak white. B.B. decrepitates violently, but easily fused and reduced; soluble with effervescence in nitric acid. Chem. com. 83.6 protoxide of lead and 16.4 carbonic acid. Very common at Przibram, Mies, and Bleistadt, Tarnowitz, Johann-Georgenstadt, Zellerfeld, Klausthal, Beeralston in Devonshire, St Minver's in Cornwall, Alston Moor, Keswick, Leadhills and Wanlockhead, and many other places.

304. ANGLESITE.— $\text{Pb } \ddot{\text{S}}$.

Rhombic; $\infty \text{P } 103^\circ 43'$, $\ddot{\text{P}} \infty 75^\circ 35'$. The crystals (fig. 204) short prismatic, or pyramidal, or tabular. Cleavage, prismatic along ∞P and basal, neither very perfect; fracture conchoidal; very brittle. $H. = 3$; $G. = 6.2 \dots 6.3$. Transparent or translucent; adamantine or resinous. Colourless and white, but occasionally yellow, gray, brown, or blue; streak white. Decrepitates in candle; B.B. on charcoal fuses in the ox. flame to a milk-white bead; very difficultly soluble in acids, wholly in solution of potash. Chem. com. 73.7 lead protoxide and 26.3 sulphuric acid, in some with a little silver. Zellerfeld, Clausthal, Badenweiler, Siegen, Silesia, Linares, Southampton in Massachusetts, Parys Mine in Anglesea, St Ives in Cornwall, Derbyshire, Leadhills and Wanlockhead. Compact (*Bleiglas*), Alston Moor in Cumberland.

Fig. 204.

305. LEADHILLITE.— $3 \text{Pb } \ddot{\text{C}} + \text{Pb } \ddot{\text{S}}$.

Rhombic; P middle edge 137° , $\infty \text{P } 120^\circ 20'$, $2\ddot{\text{P}} \infty 43^\circ 12'$. Crystals, 0P . ∞P . $\infty \ddot{\text{P}} \infty$ (fig. 205), mostly tabular; also macles. Cleavage, basal very perfect; slightly brittle. $H. = 2.5$; $G. = 6.2 \dots 6.4$ (6.0). Transparent or translucent; resinous or adamantine-pearly on 0P . Yellowish-white, inclining to gray, green, yellow, or brown. B.B. on charcoal intumesces, and becomes yellow, but again white when cold, and easily reduced; soluble with effervescence in nitric acid, leaving sulphate of lead. Chem. com. 72.6 carbonate and 27.4 sulphate of lead. Leadhills; also Grenada in Spain, and the Greek island Serpho.

Fig. 205.

306. SUSANNITE.— $3 \text{Pb } \ddot{\text{C}} + \text{Pb } \ddot{\text{S}}$.

Rhombohedral; $R 72^\circ 30'$. Cleavage, basal perfect. $H. = 2.5$; $G. = 6.55$. White, green, yellow, or brown. Otherwise like Leadhillite. Susannah Mine, Leadhills.

307. LANARKITE.— $\text{Pb } \ddot{\text{S}} + \text{Pb } \ddot{\text{C}}$.

Monoclinohedric; $\infty \text{P } 85^\circ 48'$, $\text{P} \infty 120^\circ 45'$. Cleavage, basal very perfect; sectile, thin laminæ flexible. $H. = 2$

Mineralogy.

$\dots 2.5$; $G. = 6.3 \dots 7$. Transparent; resinous or adamantine; on 0P pearly. Greenish or yellowish-white, inclining to gray; streak white. B.B. on charcoal fuses to a white globule containing some metallic lead; partially soluble in nitric acid with effervescence. Chem. com. 53.15 sulphate and 46.85 carbonate of lead. Leadhills in Scotland.

308. CALEDONITE.— $3 \text{Pb } \ddot{\text{S}} + 2 \text{Pb } \ddot{\text{C}} + \text{Cu } \ddot{\text{C}} (?)$.

Rhombic; $\ddot{\text{P}} \infty 95^\circ$, $\infty \text{P } 109^\circ$. Crystals $\infty \ddot{\text{P}} \infty$. $\infty \ddot{\text{P}} \infty$. $\ddot{\text{P}} \infty$ (fig. 206). Cleavage, $\ddot{\text{P}} \infty$ brachydiagonal and macrodiagonal all imperfect. $H. = 2.5 \dots 3$; $G. = 6.4$. Transparent or translucent; resinous. Verdigris to mountain green; streak greenish-white. B.B. on charcoal easily reduced; soluble in nitric acid, leaving sulphate of lead. The solution is greenish, and shows reaction for lead and copper. Chem. com. 55.8 sulphate of lead, 38.8 carbonate of lead, and 11.4 carbonate of copper. Leadhills, Roughton Gill in Cumberland, and Rezbanya.

Fig. 206.

309. LINARITE.— $\text{Pb } \ddot{\text{S}} + \text{Cu } \ddot{\text{H}}$.

Monoclinohedric; $\infty \text{P } 61^\circ 0'$, $\text{P} \infty 77^\circ 15'$, $\text{P} \infty 74^\circ 25'$. Crystals $\infty \text{P} \infty$. 0P , with the above or other forms; macles united by $\infty \text{P} \infty$. Cleavage, orthodiagonal very perfect, and $\text{P} \infty$ less so; fracture conchoidal. $H. = 2.5 \dots 3$; $G. = 5.2 \dots 5.45$. Translucent; adamantine. Azure-blue; streak pale-blue. Chem. com. 75.7 sulphate of lead, 19.8 copper protoxide, and 4.5 water. Wanlockhead, Leadhills, Roughton Gill, and Linares.

310. PHOSGENITE, Corneous Lead, } $\text{Pb Cl} + \text{Pb } \ddot{\text{C}}$.
Cerasine.

Tetragonal; $\text{P } 113^\circ 48'$. Crystals of ∞P , 0P , $\infty \text{P} \infty$, with P or $2\text{P} \infty$. Cleavage, ∞P rather perfect; fracture conchoidal. $H. = 2.5 \dots 3$; $G. = 6 \dots 6.2$. Transparent or translucent; resinous adamantine. White, yellow, green, or gray. B.B. fuses easily to an opaque yellow globule, citron-yellow or white and crystalline on cooling; soluble with effervescence in nitric acid. Chem. com. 51 chloride and 49 carbonate of lead. Very rare near Matlock in Derbyshire, and Elgin in Scotland.

311. MENDIPITE, Berzelite.— $\text{Pb Cl} + 2 \text{Pb}$.

Rhombic; but chiefly massive. Cleavage, along $\infty \text{P } 102^\circ 36'$ highly perfect; fracture conchoidal or uneven. $H. = 2.5 \dots 3$; $G. = 7.0 \dots 7.1$. Translucent; adamantine-pearly on the cleavage. Yellowish-white to straw-yellow and pale-red; streak white. B.B. decrepitates, fuses easily, and becomes more yellow; easily soluble in nitric acid. Chem. com. 40 chloride and 60 protoxide of lead = 85.8 lead, and 9.8 chlorine. Churchill in the Mendip Hills, and Brilon in Westphalia.

312. MATLOCKITE.— $\text{Pb Cl} + \text{Pb}$.

Tetragonal; $\text{P } 136^\circ 17'$. Crystals, 0P , $\text{P} \infty$, small, thin, tabular. Cleavage, basal indistinct; fracture uneven conchoidal. $H. = 2.5$; $G. = 7.21$ (*Greg*), 5.39 (*Ram.*) Transparent or translucent; adamantine. Yellowish or greenish. B.B. decrepitates and fuses to a grayish-yellow globule. Chem. com. 55.6 chloride of lead, and 44.4 lead oxide. Matlock, on Galena.

313. COTUNNITE, Cotunnia.— Pb Cl .

Rhombic; $\infty \text{P } 118^\circ 38'$, $\ddot{\text{P}} \infty 126^\circ 44'$. Small acicular crystals. Transparent; adamantine. White. Easily scratched with the knife. $G. = 5.238$. B.B. on charcoal fuses easily, colours the flame blue, volatilizes as a white vapour, forms a white ring, and leaves a very little metallic lead; soluble in a large amount of water. Chem. com. 74 lead and 26 chlorine. Crater of Vesuvius after the eruption of 1822.

*314. PYROMORPHITE.— $3 \text{Pb } \ddot{\text{P}} + \text{Pb Cl}$.

Hexagonal; $\text{P } 80^\circ 44'$. Crystals ∞P . 0P , with $\infty \text{P} 2$, P

Mineralogy.

(fig. 207) or other pyramids, occasionally thicker in the middle, or spindle-shaped; also reniform or botryoidal. Cleavage, P very imperfect, ∞ P in traces; fracture conchoidal or uneven. $H. = 3.5 \dots 4$; $G. = 6.9 \dots 7$. Translucent; resinous or partly vitreous. Colourless, but generally grass, pistacio, olive, or siskin green, and clove or hair brown. B.B. fuses easily, with a transitory ignition, to a crystalline granule; soluble in nitric acid and in solution of potash. Chem. com. 89.7 phosphate and 10.3 chloride of lead, but with 0 to 9 arseniate of lead, 0 to 11 phosphate of lime, and 0 to 1 fluoride of calcium. Przibram, Mies and Bleistadt in Bohemia, Zschopau, Clausthal, Poullaouen, Beresof, and Mexico; also Cornwall, Derbyshire, Yorkshire, Durham, Cumberland, Wicklow, and Leadhills and Wanlockhead. *Miesite*, *Polysphærite*, and *Nussierite*, from near Beaujeu, are varieties.

Fig. 207.

315. MIMETESITE, $3 \text{Pb}^3 \ddot{\text{As}} + \text{Pb Cl}$.

Hexagonal; $P 81^\circ 48'$. Crystals, ∞P . OP. P, or P. OP. Cleavage, P rather distinct, ∞P very imperfect; fracture conchoidal or uneven. $H. = 3.5 \dots 4.0$; $G. = 7.19 \dots 7.25$. Translucent. Colourless, but usually honey or wax yellow, yellowish-green, or gray. B.B. on charcoal fusible, but less easily than pyromorphite, with strong arsenious vapours. Chem. com. 90.7 arseniate and 9.3 chloride of lead; but part of the arsenic occasionally replaced by phosphoric acid. Johann-Georgenstadt, Zinnwald, Badenweiler, St Prix in France, Nertschinsk, and Zacatecas in Mexico; Huel Alfred and Huel Unity in Cornwall, Caldbeckfell in Cumberland, and Beeralston in Devonshire.

Kampylite.—Orange-yellow; $G. = 6.8 \dots 6.9$; Chem. com. like mimetisite, but contains phosphate of lime and chromate of lead. Alston in Cumberland and Badenweiler.

Hedyphane.—Crystalline masses with an imperfect hexagonal cleavage. $G. = 5.4 \dots 5.5$. Translucent; resinous adamantine. White. Chem. com. like mimetisite, but with 13 arseniate and 15.5 phosphate of lime. Langbanshytta in Sweden.

316. BLENNIERITE.— $\text{Pb}, \ddot{\text{Sb}}, \ddot{\text{H}}$.

Reniform, spheroidal; earthy, or encrusting. $H. = 4$; $G. = 3.9 \dots 4.76$. Opaque; dull resinous, or earthy. Gray, brown, red, or yellow; streak grayish or yellowish-white. B.B. on charcoal reduced with antimony fumes. Chem. com. mixture of protoxide of lead (40 to 62), antimony oxides (31 to 47), and water (6 to 12); some also contain arsenic acid. Nertschinsk in Siberia, Cornwall.

317. VANADINITE.— $3 \text{Pb}^3 \ddot{\text{V}} + \text{Pb Cl}$.

Hexagonal; ∞P . OP. $H. = 3$; $G. = 6.6 \dots 7.2$. Opaque; resinous. Yellow and brown; streak white. B.B. decrepitates violently, and on charcoal fuses to a globule, which emits sparks and is reduced, colouring the support yellow; in the forceps fuses, and retains its yellow colour when cold; in nitric acid forms a yellow solution. Chem. com. 89.7 vanadate, and 10.3 chloride of lead. Zimapan in Mexico, Beresof in the Ural, and Wanlockhead.

318. DECHENITE.— $\text{Pb} \ddot{\text{V}}$.

Botryoidal or thin lamellar. $H. = 3.5 \dots 4$; $G. = 5.81$. Resinous; translucent on the edges. Red or reddish-yellow; streak yellow. B.B. fuses easily to a yellow bead, and on charcoal reduced to lead; easily soluble in nitric acid. Chem. com. 54.7 lead oxide, and 45.3 vanadic acid, but analyses gave 46 to 49 of the latter. Niederschlettenbach in Rhenish Bavaria.

Similar are—*Aræowene*; botryoidal; red, with a brown tinge. Chem. com. vanadic acid, with 48.7 lead oxide, and 16.3 zinc oxide. Dahm on the Rhine.

Eusynchite.—Yellowish-red; opaque. B.B. melts easily to a lead-gray globule. Chem. com. 56 lead oxide, 23 vanadic acid, and 21 deutoxide of vanadium.

Descloizite.— $\text{Pb}^3 \ddot{\text{V}}$. In small rhombic crystals. Cleavage wanting; brittle. Translucent. Olive-green to black; on fracture concentric yellow and brown zones. B.B. fuses and partially reduced. Chem. com. 54.7 lead oxide, and 22.46 vanadic acid, but also oxides of manganese, zinc, iron, and copper. La Plata.

319. WULFENITE.— $\text{Pb} \ddot{\text{Mo}}$.

Tetragonal; $P 131^\circ 35'$; OP (a), $\frac{1}{4} P$ (b), P, ∞P , and P ∞ (fig. 208). Cleavage, P rather perfect, basal imperfect; fracture conchoidal to uneven; rather brittle. $H. = 3$; $G. = 6.3 \dots 6.9$.

Fig. 208.

Pellucid; resinous or adamantine. Colourless, but generally yellowish-gray, wax, honey, or orange yellow. B.B. decrepitates violently; on charcoal fuses and sinks into the support, leaving lead; in con. h. acid forms a yellow solution. Chem. com. 61.5 protoxide of lead and 38.5 molybdic acid. Bleiberg and Windisch Kappel in Carinthia, Retzbanya, Badenweiler, and Zacatecas in Mexico.

320. SCHEELITE, Stolzite.— $\text{Pb} \ddot{\text{W}}$.

Tetragonal and hemihedric; $P 131^\circ 25'$. Crystals, 2 P. P. ∞P , spindle-shaped. Cleavage, P imperfect. $H. = 3$; $G. = 7.9 \dots 8.1$. Semitransparent or translucent; resinous. Gray, brown, yellow, or green. B.B. fuses to a dark crystalline grain; soluble in nitric acid, with a yellow precipitate. Chem. com. 51.6 tungstic acid and 48.4 protoxide of lead. Zinnwald in Bohemia and Coquimbo.

321. PLOMBGOMME.— $\text{Pb}^3 \ddot{\text{P}} + 6 \ddot{\text{Al}} \ddot{\text{H}}$.

Reniform or stalactitic. Fracture conchoidal and splintery. $H. = 4 \dots 4.5$; $G. = 3 \dots 6.4$. Translucent; vitreous, inclining to resinous. Yellowish or greenish white to reddish brown, often in stripes. B.B. on charcoal becomes opaque and white, intumesces, and partially fuses; soluble in nitric acid. Chem. com. 38 protoxide of lead, 35 alumina, 8 phosphoric acid, and 19 water; but with 2 chloride of lead, a little iron peroxide and lime. Poullaouen in Brittany, and at Nussière near Beaujeu. It much resembles gum-arabic.

322. CROCOISITE, Krokoit.— $\text{Pb} \ddot{\text{Cr}}$.

Monoclinohedric; $C = 78^\circ 1'$; $\infty P 93^\circ 44'$ (M), $-P 118^\circ 58'$ (t), ($\infty P 2$) $56^\circ 10'$ (r), ($\infty P \infty$) (g) (fig. 209). Cleavage, ∞P rather distinct; sectile. $H. = 2.5 \dots 3$; $G. = 5.9 \dots 6.1$. Translucent; adamantine. Hyacinth or aurora red; streak orange-yellow. B.B. decrepitates, blackens, and fuses on charcoal, the lower part being reduced; with borax or salt of phosphorus in the ox. flame a green, in the red. flame a gray glass; soluble in warm h. acid. Chem. com. 31.7 chromic acid, and 68.3 lead protoxide. Beresof, Mursinsk, and Nischne-Tagilsk in the Ural; Congonhas do Campo in Brazil, Rezbanya, Moldawa, and Tarnowitz. Used as a pigment, but not permanent.

Fig. 209.

323. MELANOCHROITE, Phœnikochroite.— $\text{Pb}^3 \ddot{\text{Cr}}^2$.

Rhombic; dimensions unknown. Cleavage imperfect. $H. = 3 \dots 3.5$; $G. = 5.75$. Translucent on the edges; resinous or adamantine. Cochineal to hyacinth red; streak brick-red. B.B. on charcoal fuses easily to a dark crystalline mass; in the red. flame yields lead; soluble in h. acid. Chem. com. 23.6 chromic acid, and 76.4 protoxide of lead. Beresof.

324. VAUQUELINITE.— $\text{Cu}^3 \ddot{\text{Cr}}^2 + 2 \text{Pb}^3 \ddot{\text{Cr}}^2$.

Monoclinohedric; $C = 67^\circ 15'$. Crystals OP. $-P$. $-P \infty$,

Mineralogy.

Mineralogy.

always maced (fig. 210), the faces of OP forming an angle of $134^{\circ} 30'$; also botryoidal or reniform. $H.=2.5\ldots 3$; $G.=5.5\ldots 5.8$. Semitranslucent or opaque; resinous. Blackish or dark olive-green; streak siskin-green. B.B. on charcoal intumesces, frothes up, and fuses to a dark-gray metallic globule surrounded by small grains of lead; in nitric acid forms a dark-green solution with a yellow residue. Chem. com. 60.87 lead protoxide, 10.80 copper protoxide, 28.33 chromic acid. Beresof, Congonhas do Campo in Brazil.

Fig. 210.

325. BISMUTHITE. Disseminated or investing. Fracture conchoidal or uneven; very brittle. $H.=4\ldots 4.5$; $G.=6.8\ldots 6.91$. Opaque; weak vitreous. Gray, yellow, or green. B.B. decrepitates, fuses very readily, and is reduced with effervescence; in h. acid it forms a deep-yellow solution. Chem. com. essentially carbonate, with a little sulphate of bismuth. Ullersreuth near Hirschberg, Schneeberg, and Johann-Georgenstadt.

326. KERATE, Hornsilver.— $Ag^{\circ}Cl$.

Tesseral; chiefly $\infty O\infty$; small or very small; also massive. Fracture conchoidal; malleable and yields to the nail. $H.=1\ldots 1.5$; $G.=5.3\ldots 5.4$, or 5.5. Translucent; adamantine resinous; gray, occasionally bluish or greenish. B.B. fuses very easily to a gray, brown, or black bead, which in the inner flame is reduced; slightly affected by acids, and slowly soluble in caustic ammonia. Chem. com. 75 silver and 25 chlorine, but with some (0 to 6) iron peroxide. Johann-Georgenstadt, Joachimsthal, Huelgöet, Kongsberg in Norway, Spain, and Cornwall; now chiefly from Mexico and Peru. At Andreasberg in the Harz, mixed with clay (*Buttermilcherz*).

Carbonate of Silver (Selbte), ash-gray, massive, very soft, effervescing in nitric acid, and B.B. easily reduced, seems a mixture. Wolfach in Baden, and Real de Catorce in Mexico (*Plata azul*, a rich silver ore).

327. CALOMEL.— Hg^2Cl .

Tetragonal; $P 135^{\circ} 50'$. Crystals like fig. 118 above but very small; sectile. $H.=1\ldots 2$; $G.=6.4\ldots 6.5$ (artificial 7.0). Translucent; adamantine. Grayish or yellowish-white. In the closed tube it sublimes as a white mass, and with soda yields mercury. B.B. on charcoal, when pure, wholly volatilizes; in nitric acid not soluble, in h. acid partially. Chem. com. 15 chlorine and 85 mercury. Moschellandsberg in Rhenish Bavaria, also Idria and Almaden.

328. IODITE.— $Ag I$.

Thin flexible plates. Malleable. $H.=1\ldots 1.5$; $G.=5.5\ldots 5.7$. Translucent; lustre inclining to adamantine. Pearl-gray, yellowish-gray, or greenish-yellow. B.B. on charcoal becomes red, fuses easily, colouring the flame purple-red, and leaves a grain of silver. Chem. com. 54 iodine and 46 silver. Albarradon in Zacatecas, Mexico; Arqueros in Chili, and Guadalupe in Spain.

329. COCCINITE.— $Hg I$.

Scarlet-red, easily fusible, and subliming; said to occur at Casas Viejas in Mexico, and to be used as a pigment. Chem. com. probably 44.3 mercury and 55.7 iodine, like the artificial salt, which crystallizes in tetragonal pyramids.

330. BROMITE.— $Ag Br$.

Tesseral; $\infty O\infty$ and O . Crystals very small; also crystalline grains. $H.=1\ldots 2$; $G.=5.8\ldots 6$. Very splendid. Olive-green or yellow, with gray tarnish; streak siskin-green. B.B. very easily fusible; scarcely affected by acids. Chem. com. 57.5 silver and 42.5 bromine. San Onofre in the district of Plateros in Mexico (*Plata verde*), and used as an ore of silver.

331. EMBOLITE.— $2 Ag Br + 3 Ag Cl$.

Tesseral; $\infty O\infty$ and O . $H.=1\ldots 1.5$; $G.=5.3\ldots 5.4$ or 5.8 (*Breit*). Resinous or adamantine. Yellow or green. Chem. com. 67 silver, 20 bromine, and 13 chlorine. Chili, Mexico, and Honduras. Ore of silver.

332. ROMITE, Romeine.— $Ca^{\circ} Sb Sb$.

Tetragonal; $P 110^{\circ} 30'$; consequently very like an octahedron. Scratches glass. $G.=4.6\ldots 4.7$. Honey-yellow or hyacinth-red. B.B. fuses to a blackish slag; not soluble in acids. Chem. com. 41.3 antimonious acid, 37.3 antimony oxide, and 21.4 lime, but with 2 to 3 manganese and iron protoxide. St Marcel in Piedmont.

***333. SCHEELITE, Tungsten.**— $Ca W$.

Tetragonal and hemihedric; $P 112^{\circ} 2'$; often alone. The usual combinations are $P(P) \cdot 2 P\infty(g)$, (fig. 211). Cleavage, $2P\infty 129^{\circ} 2'$ rather perfect, along P and OP less perfect. Fracture conchoidal and uneven. $H.=4\ldots 4.5$; $G.=5.9\ldots 6.2$. Translucent; vitreous, inclining to resinous or adamantine. Colourless, but gray, yellow, or brown; streak white. B.B. fuses difficultly to a translucent glass; decomposed in h. or n. acid, leaving tungstic acid; also in solution of potash. Chem. com. 80.6 tungstic acid and 19.4 lime, but with 0 to 3 silica and 0 to 1.5 iron peroxide, or rarely copper protoxide when the mineral is green. Caldbeckfell near Keswick; Pengilly, Cornwall; at Zinnwald and Schlackenwald in Bohemia; also in the gold mines of Salzburg and of Hungary; Chili and Siberia; also in the Monroe Mines in Connecticut, where used in preparing tungstic acid, a very fine yellow pigment.

Fig. 211.

ORDER IV.—OXIDIZED ORES.

Crystallization rhombic, then tesseral or tetragonal, less frequently hexagonal or rhombohedric. Hardness generally high, or 5...7, most equal to felspar. Gravity also high, or 4...7 or 8. They are generally soluble in acids and solutions coloured. B.B. infusible, or very difficultly so. Chem. com. oxides of the metals alone or in composition. They are mostly opaque, with metallic lustre, and of black, brown, or dark-gray colours. Occur in beds, veins, or large masses, especially in the metamorphic and igneous rocks.

FAMILY I.—OXIDIZED IRON ORES.

Crystallization tesseral, rhombohedric, or rhombic. $H.=5\ldots 6.5$; $G.=3.4\ldots 6.5$; crystalline species 4.5...5.3. Soluble in acids; solution green. B.B. infusible or very difficult, but becomes magnetic in the red. flame. With borax show reaction for iron. Colours black, brown, or red. Occur in beds, veins, or large masses in the older rocks, or as rock constituents.

****334. MAGNETITE, Magnetic Iron.**— $Fe^{\circ} Fe$.

Tesseral; O and ∞O , also $\infty O\infty$, $2O2$ and $2O$. Macles common, united by O (fig. 212). Generally granular or almost compact; often also in loose grains. Cleavage, octahedral perfect, or mere traces; fracture conchoidal or uneven; brittle. $H.=5.5\ldots 6.5$; $G.=4.9\ldots 5.2$. Opaque; lustre metallic. Iron-black, or inclining to brown or gray; highly magnetic. B.B. becomes brown and non-magnetic, and fuses with extreme difficulty; powder soluble in h. acid. Chem. com. 31.03 of the protoxide, and 68.77

Fig. 212.

Mineralogy.

Minera-
logy.

of the peroxide of iron, or 72.4 iron and 27.6 oxygen. Crystals at Traversella in Piedmont, Greiner in Tyrol, Kraubat in Styria; large masses Arendal in Norway; Danne-mora, Utoe, Norberg, Taberg in Sweden; Kurunavara and Gellivara in Lapland; Nischne-Tagilsk, Blagodot, and the Kaschkanar in the Ural; also Scotland, the Harz, Saxony, Bohemia, Silesia, Elba, and Spain; Mexico, Brazil, and North America. Magnetite is the most important ore of iron in Norway, Sweden, and Russia.

***335. CHROMITE.**—(Fe, Mg) (Cr, Al).

Tesseral, only in octahedrons; generally granular. Cleavage, octahedral imperfect; fracture imperfect, conchoidal, or uneven. $H.=5.5$; $G.=4.4...4.5$. Opaque; semi-metallic or resinous. Iron or brownish-black; streak yellowish or reddish-brown. Sometimes magnetic. B.B. infusible and unchanged, but the non-magnetic in the red flame become magnetic; in borax forms an emerald-green bead; scarcely affected by acids. Chem. com. 19 to 37 iron protoxide, 0 to 10 magnesia, 36 to 60 chrome peroxide, and 9 to 21 alumina, with 0 to 10 silica as a mixture. Saxony, Silesia, Bohemia, Styria (Kraubat), Gassin in the Var dept. in France, Røraas in Norway, Katherinenburg in the Ural, near Baltimore, Chester in Massachusetts, and Hoboken; in Scotland in great abundance in Unst and Fetlar in the Zetlands, at Portsoy in Banff, and Tyndrum. Used in the preparation of various pigments.

336. FRANKLINITE.—(Fe, Zn, Mn) (Fe, Mn) (?).

Tesseral; O and O. ∞O ; also granular. Cleavage, octahedral, but very imperfect; fracture conchoidal or uneven; brittle. $H.=6...6.5$; $G.=5.0...5.3$. Opaque; imperfect metallic lustre. Iron-black; streak dark reddish-brown. B.B. infusible, but shines brightly and gives out sparks when strongly heated. On charcoal, with soda, a deposition of zinc; soluble in h. acid with strong extrication of chlorine. Chem. com. 66 to 69 iron and 15 to 18 manganese peroxide (or in part protoxides), and 10 to 17 zinc oxide. Franklin and Sterling in New Jersey.

Dysluite, from Sterling, N. J.; dark or yellowish-brown; vitreous; $G.=4.5$; contains 30 per cent. alumina. *Isophane*, $G.=5.01$, seems also Franklinite.

****337. HÆMATITE, Specular Iron.**—Fe.

Rhombohedral; $R\ 86^\circ$. Crystals rhombohedral, prismatic, or tabular, of $R \cdot OR$, $OR \cdot R$ (fig. 213.), $R \cdot \frac{1}{2}R$, $\infty P2$, $R \cdot \frac{1}{2}P2$, OR , $\frac{1}{2}P2$, $R \cdot \frac{1}{2}R$, (or n , P , s .), (fig. 214).

Fig. 213.

Fig. 214.

Macles with parallel axes, and mostly intersecting. Cleavage, R and OR , but seldom distinct; fracture conchoidal or uneven; brittle. $H.=5.5...6.5$; $G.=5.1...5.3$. Opaque, or in very thin laminae translucent and deep blood-red. Metallic; iron-black to steel-gray, but often tarnished, also red; streak cherry-red or reddish-brown. Usually weak magnetic. B.B. in the red flame black and magnetic; slowly soluble in acids. Chem. com. 70.03 iron and 29.97 oxygen, but sometimes contains oxide of titanium, chrome, or silica.

Specular Iron Ore, varieties with crystalline structure and high metallic lustre, includes *micaceous iron*, thin lamellar, and *red iron froth*, finer or scaly. The *Red Hematite* or *red iron*, with inferior lustre, lower specific gravity (4.5...4.9), and hardness (3...5), and deeper blood-red or brownish-red colours; comprises the *fibrous red iron*, reniform, botryoidal, and stalactitic, often with an irregular concentric

structure; the *compact* and *ochrey* iron ores, more earthy or minute; the *reddle* or red chalk, still more earthy, and used as a drawing material; and the *jaspers*, *columnar*, and *lenticular clay iron*, mere impure varieties.

Crystals, Elba, St Gotthardt, Framont in the Vosges, Arendal, Langbanshytta, Tilkeroide in the Harz, Altenberg, Capas in Brazil, Katherinenburg and Nischne-Tagilsk. Micaceous, Zorge in the Harz, Tincroft in Cornwall, Tavistock in Devonshire, Wales, Cumberland, and Birnam in Perthshire; also in Auvergne, on Vesuvius, Ætna, and Stromboli. The *Red Hematite*, the Harz, Ulverstone in Lancashire, near Edinburgh, and in many other parts of Britain. A most abundant ore of iron.

Martite.—Tesseral, O, O. ∞O and O. ∞O . $H.=6$; $G.=4.6...5.33$. Iron-black, with reddish-brown streak. Either pseudomorphs after magnetite, or a dimorphous form of hæmatite. Brazil, Monroe in New York, Framont, and Auvergne.

338. IRITE.—(Ir, Os, Fe) (Ir, Os, Cr).

Tesseral; O; but in fine iron black scales, with strong metallic lustre, which mark paper. $G.=6.506$. Strongly magnetic. B.B. fused with nitre gives out the odour of osmium; insoluble in acids. Chem. com. 62.86 peroxide of iridium, 10.30 osmium protoxide, 12.50 iron protoxide, 13.7 chrome oxide, with traces of manganese. Ural, with platina.

***339. LIMONITE, Brown Iron Ore.**— $2\text{Fe} + 3\text{H}$.

Fine fibrous, in spherical, reniform, and stalactitic masses; also compact and earthy. $H.=5...5.5$; $G.=3.4...3.95$. Opaque; lustre weak silky, glimmering, or dull. Colour brown, especially yellowish, clove, hair, and blackish-brown, also yellow and green; streak yellowish-brown. In the closed tube yields water, and the powder becomes red. B.B. in the outer flame red on ignition; in the inner flame thin splinters fuse to a black magnetic glass. Chem. com. 85.6 peroxide of iron (=60 iron), and 14.4 water; but occasionally with silica, alumina, or phosphoric acid. Harz, Thuringia, Siegen near Bonn, Naussau, Styria, Carinthia, Pyrenees, Siberia, Brazil, and the United States; in Britain in Cornwall, at Clifton near Bristol, Sandlodge in Zetland, and in many other places. A valuable ore of iron, the iron usually uniting hardness with tenacity. *Stilpnosiderite*, *Lepidokrokit*, and *Yellow ochre* seem partly this mineral, partly Götheite, or mixtures.

Bog-Iron Ore is also an hydrated oxide of iron, with no definite composition, and often containing thirty to fifty per cent. of impurities. Phosphoric acid to 11 per cent. Occurs chiefly in bogs, meadows, and lakes, as in North Germany, Sweden, and Britain; especially the northern and western islands of Scotland.

***340. GÖTHEITE, Pyrrhosiderite.**— $2\text{Fe} + \text{H}$.

Rhombic; P with polar edges $121^\circ 5'$ and $126^\circ 18'$, $\infty P(g) 94^\circ 53'$, $\infty \bar{P}2 (d) 130^\circ 40'$, $\bar{P}\infty (b) 117^\circ 30'$, with $\infty \bar{P}\infty (M)$ and $P(P)$, (fig. 215); also columnar, fibrous, or scaly. Cleavage, brachydiagonal very perfect; brittle. $H.=5...5.5$; $G.=3.8...4.4$. Opaque, or in fine lamellae, translucent, and hyacinth-red; lustre adamantine or silky. Colour yellowish, reddish, or blackish-brown; streak brownish or reddish-yellow. In the closed tube the powder yields water, and becomes reddish-brown. B.B. in the ox. flame also brown; in the red flame black and magnetic; difficultly fusible; soluble in h. acid, often leaving a little silica. Chem. com. 90 peroxide of iron and 10 water, with silica and manganese peroxide. Foliated, Eiserfeld near Siegen. Crystals, Lostwithiel in Cornwall, and Clifton near Bristol. Capillary, Przibram, Hüttenberg in Carinthia, and Norway. Compact,

Fig. 215.

Minera-
logy.

Mineralogy.

Saxony, the Pyrenees, Ural, North America, and many other localities.

Turgite, with 94.15 peroxide of iron and 5.85 water; compact reddish-brown; $G.=3.54...3.74$; Turginsk in the Ural; is probably a mixture.

*341. **ILMENITE**, Titanitic Iron.— Fe^{Ti} , Ti .

Rhombohedral, and isomorphous with hæmatite, but sometimes tetartohedral; $R\ 86^\circ$ ($85^\circ 40'$ to $86^\circ 10'$). Crystals tabular or rhombohedral, of OR (a) and R , with $-\frac{1}{2}R$ (e), $-2R$ (d), and $\frac{1}{2}P$ (2) (b'), (fig. 216.) Also in macles, granular or foliated, or in loose grains. Cleavage, basal more or less perfect, and rhombohedral R less distinct; fracture conchoidal or uneven. $H.=5...6$; $G.=4.66...5$. Opaque; semimetallic. Iron-black, often inclining to brown, rarely to steel-gray; streak generally black, but sometimes reddish-brown. Slightly or not at all magnetic. B.B. infusible alone, but with salt of phosphorus in the red. flame a red glass; soluble, but often with much difficulty in h. acid. Chem. com. peroxide of iron with 8 to 53 blue oxide of titanium. Ilmen Mountains; Gastein in Salzburg (*Kibdelophan*); Egersund in Norway; near Arendal (*Hystatit*); Menaccan in Cornwall (*Menaccanite*); Bourg d'Oisans in Dauphiné (*Crichtonite*). *Mohs*ite is the same, or connected.

Fig. 216.

Iserine, or magnetic iron sand, in cubes, octahedrons, and dodecahedrons, generally with rounded edges or in loose grains; strongly magnetic in chemical action and composition; resembles ilmenite, but is perhaps only magnetite mixed with peroxide of titanium. Iserweise in Bohemia, the Eifel, Auvergne, near Rome and Naples; also in Northern Germany; Cornwall, sands of the Don in Aberdeenshire, and Loch of Tristan in Zetland.

FAMILY II.—TIN ORE.

Crystallization tetragonal, rhombic, or rarely monoclinohedric, with prismatic forms. Hardness 5.5...6.5 or 7. Gravity 3.4...4.3 in the titanium compounds, 4.6...4.8 in the remainder. Mostly not soluble, or very difficultly, in acids, and also B.B. very difficultly, or not fusible. Colours dark, as black, brown, or red. Lustre resinous, semimetallic, or adamantine. Occur chiefly in the older crystalline strata, or in granite and syenite.

342. **CASSITERITE, Tin Ore.— Sn .

Tetragonal; $P\ 87^\circ 5'$, $P\infty\ 67^\circ 50'$. Crystals ∞P (P); ∞P (g) $\cdot P$ (s) $\cdot \infty P\infty$ (l), or with $P\infty$ (P), (fig. 217); and also $\infty P\ 2$ (r), and $5 P\ 2$ (z), (fig. 218). Macles very

Fig. 217.

Fig. 218.

common, combined by a face of $P\infty$, with the chief axis $112^\circ 10'$ (figs. 219, 220); also granular or fibrous (*wood tin*), or in rounded fragments and grains (*stream tin*). Cleavage, prismatic along ∞P and $\infty P\infty$, rather imperfect; brittle. $H.=6...7$; $G.=6.8...7$. Translucent or opaque; adamantine or resinous. White, but usually gray, yellow, red, brown, and black; streak white, light-gray, or brown.

B.B. in the forceps infusible; on charcoal, in the inner flame, more easily with soda, reduced to tin. Not affected by acids. Chem. com. 79 tin and 21 oxygen, but often

Mineralogy.

Fig. 219.

Fig. 220.

mixed with peroxide of iron or manganese, tantalic acid, or silica. Cornwall, Bohemia, Saxony, Galicia in Spain, and Portugal; also Silesia, the Haute Vienne in France, Greenland, Sweden, Russia, North and South America, Malacca, and Banca. The only ore of tin. The produce of the Cornish mines is about 100,000 cwts. annually.

Stannite.—Compact; brittle. $H.=6.75$; $G.=3.5$. Translucent only on thinnest edges; weak resinous. Yellowish white to yellow. B.B. infusible. Chem. com. 36.5 tin oxide with silica and alumina. Probably a mixture. Cornwall.

*343. **WOLFRAM**.—(Fe , Mn) W .

Rhombic; $\infty P\ 101^\circ 45'$, $\frac{1}{2}P\infty\ 123^\circ 57'$, $P\infty\ 98^\circ 27'$.

Crystals ∞P (r) $\cdot \frac{1}{2}P\infty$ (t) $\cdot \infty P\infty$ (M) $\cdot P\infty$ (u), (fig. 221). Macles rather common, also columnar, laminar, or coarse granular. Cleavage, brachydiagonal very perfect; macrodiagonal imperfect; fracture uneven. $H.=5...5.5$; $G.=7.1...7.5$. Opaque; resinous, metallic-adamantine on the cleavage. Brownish-black; streak reddish-brown to black. Sometimes weak magnetic. B.B. on charcoal fuses to a magnetic globule covered with small crystals; soluble in warm h. acid, leaving a yellow residue. Chem. com. 76 tungstic acid, 9.5 to 20 protoxide of iron, and 4 to 15 protoxide of manganese, in some with a little lime or magnesia. Altenberg, Geyer, Ellenfriedersdorf, Schlackenwald, Zinnwald, the Harz, Cornwall, near Redruth, Rona in the Hebrides; also the Ural, Ceylon, and North America.

Fig. 221.

344. **COLUMBITE**, Niobite.—(Fe , Mn) Nb .

Rhombic; $\infty P\ 100^\circ 40'$, $2 P\ 8\ 59^\circ 20'$. Tabular, or broad prismatic (fig. 222). Macles with chief axes at $59^\circ 20'$; also foliated or granular. Cleavage, brachydiagonal very distinct, macrodiagonal less so, and basal imperfect. $H.=6$; $G.=5.4...6.4$. Opaque; metallic adamantine. Brownish or iron-black; streak reddish brown or black. B.B. infusible; not affected by acids. Chem. com. 14 to 17 protoxide of iron, 3.7 to 4.8 protoxide of manganese, and 78 to 81 niobic (or columbic) acid, with a little oxide of tin or copper. Middletown and Haddam in Connecticut, and Chesterfield in Massachusetts; Rabenstein near Bodenmais, and Ilmen Mountains.

Fig. 222.

345. **SAMARSKITE**, Uranotantalite, Yttrilmenite.

Rhombic; isomorphous with columbite; mostly flat, somewhat polygonal grains. Fracture conchoidal; brittle. $H.=5.5$; $G.=5.625$. Opaque; strong semi-metallic. Velvet-black; streak dark reddish-brown. B.B. fuses on the edges to a black glass. In the closed tube decrepitates, yields water, incandescs, and becomes brown. Soluble in h. acid with difficulty, but wholly to a greenish fluid. Chem. com. 56 niobic acid, 15 to 16 iron protoxide, 14 to 17 ura-

Mineralogy.

anium oxide, and 8 to 11 yttria with lime and magnesia. Ilmen Mountains in miascite.

346. TANTALITE.—(Fe, Mn) Ta.

Rhombic; P with polar edges 126° and $112^\circ 30'$, middle $91^\circ 42'$. Cleavages all very indistinct; fracture conchoidal or uneven. $H.=6\ldots6.5$; $G.=7.1\ldots8$. Opaque; semimetallic, adamantine, or resinous. Iron-black; streak cinnamon or coffee brown. B.B. infusible; scarcely affected by acids. Chem. com. 7 to 14 protoxide of iron, 1 to 7 protoxide of manganese, and 67 to 84 tantalic acid, with tin oxide and lime. Kimito and Tammela in Finland, Broddbo and Finbo near Fahlun.

Cassiterotantalite, varieties with much tin oxide, have $G.=6.2\ldots6.5$, and with soda yield tin.

347. YTTROTANTALITE.—(Y, Ca, Fe, U)³ (Ta, W.)

Crystallization unknown; indistinct four or six sided prisms; also in grains and lamellæ. Cleavage in one direction; fracture conchoidal or uneven. Opaque, or in thin splinters translucent. Three varieties are distinguished—(a.) *Black Y*, iron-black, semimetallic, and greenish-gray streak; $H.=5.5$; $G.=5.4\ldots5.7$. (b.) *Dark or Brown Y*, brownish-black, bright brown streak, vitreous or resinous. (c.) *Yellow Y*, yellowish-gray, or brown, often striped or spotted; streak white; resinous or vitreous. $H.=5$; $G.=5.88$. B.B. infusible, but become brown or yellow; not affected by acids. Chem. com. 57 to 60 tantalic acid, 1 to 8 tungstic acid, 20 to 38 yttria, 0.5 to 6 lime, 0.5 to 6 uranium peroxide, and 0.5 to 3.5 iron peroxide. Ytterby, and near Fahlun.

348. EUXENITE.—Ta, Ti, Y, Ce, Ca, H.

Monoclinohedric probably; also compact, with no trace of cleavage. Fracture imperfect conchoidal. $H.=6.5$; $G.=4.6$. Opaque; thin splinters reddish-brown translucent; metallic vitreous. Brownish-black; streak reddish-brown. B.B. infusible; not affected by acids. Chem. com. uncertain. Jölster and Arendal in Norway.

349. FERGUSONITE.—(Y, Ce, Zr)⁶ Ta.

Tetragonal and hemihedric; P $128^\circ 28'$ (fig. 223). Cleavage, traces along P; fracture imperfect conchoidal; brittle. $H.=5.5\ldots6$; $G.=5.8\ldots5.9$. Translucent in thin splinters; semimetallic. Brownish-black; streak pale-brown. B.B. infusible. Chem. com. 48 tantalic acid, 42 yttria, 5 cerium protoxide, 3 zirconia, with tin oxide, uranium, and iron peroxide. Cape Farewell in Greenland.

Fig. 223.

Tyrite, brown, resinous or semimetallic; $H.=6.5$; $G.=5.13\ldots5.86$; Helle, near Arendal; is similar or identical. *Azorite*, minute, greenish or yellowish white tetragonal pyramids from the Azores, seems a tantalate of lime.

350. SPHENE, Titanite.—Ca Si² + Ca Ti².

Monoclinohedric; $C=85^\circ 6'$; ∞P (l) $133^\circ 54'$, $\frac{1}{2}P \infty$ (x) $52^\circ 21'$, $P \infty$ (y) $34^\circ 27'$, OP (P), ($\infty P \infty$) (q), ($\infty P 3$) (M), and ($\frac{1}{2}P 2$) (n) $136^\circ 6'$. Crystals horizontal prismatic or tabular, or very often oblique prismatic (figs. 224, 225). Macles frequent; also granular or foliated.

Fig. 224.

Fig. 225.

Cleavage, in many ∞P ; in others ($P \infty$) (r) $113^\circ 30'$, imperfect. $H.=5\ldots5.5$; $G.=3.4\ldots3.6$. Semitransparent or

opaque; adamantine or often resinous. Brown, yellow, or green. B.B. fuses on the edges to a dark glass; with salt of phosphorus in the red. flame reaction for titanate acid; wholly soluble in s. acid, which forms sulphate of lime. Chem. com. 31.3 silica, 40.4 titanate acid, and 28.3 lime, with 0 to 5 iron protoxide in the brown varieties. Dauphiné near Mont Blanc, St Gotthard, Tyrol, Arendal, Sweden, Saxony, France, America, and the Ural; also Lake Laach and Vesuvius; in Scotland, in Criffell, near King's House, Ben Nevis, Strontian, Loch Ness, Aberdeenshire, Fetlar and Burra in Zetland.

Greenovite, flesh-red, from St Marcel in Piedmont, with much protoxide of manganese, is not distinct. *Schorlamite*, black shining; $H.=7\ldots7.5$; $G.=3.78\ldots3.86$; from Arkansas, is related.

351. BROOKITE.—Ti.

Rhombic; P with polar edges $135^\circ 37'$ and $101^\circ 3'$, $\infty P 2$ $99^\circ 50'$ (fig. 226). Cleavage macrodiagonal. $H.=5.5\ldots6$; $G.=3.86\ldots4.2$. Opaque or translucent; metallic adamantine. Yellowish, reddish, or hair-brown; streak yellowish-white. B.B. infusible; with salt of phosphorus forms a brownish-yellow glass. Chem. com. titanate acid, with 1.4 to 4.5 per cent. peroxide of iron. Bourg d'Oisans, Chamouni, and near Amstäg in the Canton Uri, Miask, Magnet Cove in Arkansas (*Arkansite*); Snowdon and Tremadoc in North Wales.

Fig. 226.

*352. RUTILE, Nigrine.—Ti.

Tetragonal; P $84^\circ 40'$, $P \infty$ $65^\circ 35'$. Crystals ∞P , $\infty P \infty$, P, and $\infty P 3$. P (fig. 227). Macles very common (like fig. 220) with chief axis at $114^\circ 26'$; also imbedded or granular. Cleavage, ∞P and $\infty P \infty$ perfect. $H.=6\ldots6.5$; $G.=4.2\ldots4.3$. Translucent or opaque; metallic adamantine. Reddish-brown to red, also yellowish and black (*Nigrine*); streak yellowish-brown. B.B. unchanged alone; with borax in the ox. flame forms a greenish, in the red. flame a violet glass; not affected by acids. Chem. com. titanate acid, with 1.5 per cent. or more peroxide of iron. Alps, in Spain, St Yrieux near Limoges, Norway, the Ural, Brazil, and North America; Craig Cailleach near Killin, Ben-y-gloe and Crianlarich in Perthshire, and Burra in Zetland. Used in painting porcelain to produce a yellow colour.

Fig. 227.

353. ANATASE, Octædrite.—Ti.

Tetragonal; P $136^\circ 36'$. Crystals P. OP (fig. 228), or P. $\frac{1}{2}P$. Cleavage, basal and P both perfect; brittle. $H.=5.5\ldots6$; $G.=3.8\ldots3.93$. Semitransparent or opaque; metallic adamantine. Indigo-blue, almost black, red, yellow, or brown, rarely colourless; streak white. B.B. infusible; only soluble in warm con. s. acid. Chem. com. titanate acid with a little peroxide of iron, or rarely tin oxide. The Alps, as Bourg d'Oisans, Dauphiné, Valois, and Salzburg; Hof in Bavaria, at Slide in Norway, Ural, Minas Geraes in Brazil, and in Cornwall.

Fig. 228.

354. POLYMIGNITE.

Rhombic; P with polar edges $136^\circ 28'$ and $116^\circ 22'$, ∞P $109^\circ 46'$. Crystals long prismatic, rather broad, and vertically striated. Cleavage imperfect; fracture conchoidal. $H.=6.5$; $G.=4.806$. Opaque; semimetallic. Iron-black; streak dark-brown. B.B. infusible alone, or with soda; soluble in con. h. acid. Analysis by Berzelius—46.30 titanate acid, 14.14 zirconia, 12.20 iron peroxide, 2.70 manganese peroxide, 5.00 cerium peroxide, 11.50 yttria, 4.20 lime (=96.04). Fredriksvärn, Norway.

355. POLYKRASE.—Zr, Y, Fe, U, Ce, Ti, Ta.

Rhombic, six-sided tables, ∞P 140° . Cleavage not observable; fracture conchoidal. $H.=5\ldots6$; $G.=5.0\ldots5.15$. Opaque, or in very fine splinters translucent yel-

Mineralogy.

Mineralogy.

lowish-brown. Black; streak grayish-brown. B.B. decrepitates violently, incandesces, and becomes grayish-brown, but is infusible; imperfectly soluble in warm h. acid, wholly in s. acid. Hitterö in Norway.

356. PERROWSKITE.— Ca Ti .

Tesseral; especially ∞O , also O , ∞O . Cleavage hexahedral. $\text{H.}=5.5$; $\text{G.}=4$. Opaque, or translucent on the edges; adamantine. Grayish or iron-black, or dark reddish-brown. B.B. infusible; slightly affected by acids. Chem. com. 58.9 titanic acid, and 41.1 lime, with 2 to 5 iron protoxide. Slatoust, Kaiserstuhl in Baden.

357. AESCHYNITE.— $2(\text{Ce, La, Fe})(\text{Nb, Ti}) + \text{Ce}(\text{Nb, Ti})$.

Rhombic; $\infty\text{P } 127^\circ 19'$, $2\bar{\text{P}} \infty 73^\circ 44'$. Crystals long prismatic (fig. 229). Cleavage, only in traces; fracture imperfect conchoidal. $\text{H.}=5.5$; $\text{G.}=4.9$. Opaque; submetallic or resinous. Iron black or brown; streak yellowish-brown. B.B. swells and becomes yellow or brown, but is infusible; not soluble in h. acid, partially in con. s. acid. Miask in the Ural.

Fig. 229.

358. MENGITE.— Fe, Zr, Ti .

Rhombic; $\infty\text{P } 136^\circ 20'$. The crystals small, prismatic; fracture uneven. $\text{H.}=5.5$; $\text{G.}=5.48$. Opaque; semi-metallic. Iron-black; streak chestnut-brown. B.B. infusible, but becomes magnetic; almost wholly soluble in warm con. s. acid. Ilmen Mountains.

359. PECHURANE, Pitch-Blende.— U U .

Tesseral; O ; also granular, reniform, columnar or lamellar. $\text{H.}=5.6$; $\text{G.}=6.5$ or 7.9 . Opaque; imperfect metallic or resinous. Grayish, greenish, or brownish-black; streak greenish-black. B.B. infusible; not soluble in h. acid, but easily in warm n. acid. Chem. com. proto-peroxide of uranium, 84.78 uranium, and 15.22 oxygen, but with lead, iron, arsenic, lime, magnesia, silica, and other impurities. Some contain vanadium, others also selenium (*Gummierz*, $\text{H.}=2.5$). *Pittinerz*, olive-green streak; $\text{H.}=3.0$; $\text{G.}=4.8$. and *Coracite*, from Lake Superior, seem mixtures. Johann-Georgenstadt, Marienberg, Annaberg, Przibram, Rezbanya, and near Redruth in Cornwall. Used in porcelain-painting.

360. PLATTNERITE.— Pb .

Hexagonal; $\infty\text{P. OP. P}$. Cleavage indistinct; fracture uneven; brittle. $\text{G.}=9.39$. Opaque; metallic adamantine. Iron-black; streak brown. Chem. com. 86.2 lead and 13.8 oxygen, with trace of sulphuric acid. Leadhills in Scotland.

FAMILY III.—MANGANESE ORES.

Crystallization rhombic, tetragonal, and monoclinohedric. Crystals often prismatic. $\text{H.}=1$...7; $\text{G.}=2.3$...5. Opaque; lustre more or less perfect metallic. Colour black or brown. B.B. infusible, mostly give out much oxygen, and do not become magnetic; soluble in hydrochloric acid, with fumes of chlorine. The solution, saturated with carbonate of lime and filtered, gives, with chloride of lime, a copious dark-brown precipitate which acts like manganese oxide. Occur chiefly in veins in the older rocks, often along with barytes.

*361. PYROLUSITE.— Mn .

Rhombic; $\infty\text{P } 93^\circ 40'$; $\bar{\text{P}} \infty 140^\circ$. Crystals short, prismatic, or pointed (fig. 230); generally massive or reniform, and radiating, fibrous, earthy, or compact. Cleavage, ∞P , also macro- and brachydiagonal; rather brittle or friable. $\text{H.}=2$...2.5; $\text{G.}=4.7$...5. Opaque; semimetallic or silky. Dark steel-gray, bluish, or iron-black; streak black and soiling. B.B. infusible, loses oxygen, and becomes brown; soluble in h. acid, with large evolution of chlorine. Chem.

Fig. 230.

com. 63.6 manganese and 36.4 oxygen. Ilmenau, Ihlefeld, Goslar, Johann-Georgenstadt; also France, Hungary, Brazil, Cornwall and Devon. Used for producing oxygen, chlorine, and chloride of lime, removing the brown and green tints in glass, in painting glass and enamel-work, and for glazing and colouring pottery.

Varvacite.—With 5 water, pseudomorphs after calc-spar; also crystals with $\infty\text{P}=99^\circ 36'$, or columnar, and fibrous. $\text{G.}=4.5$...4.6. Semimetallic. Iron-black to steel-gray; streak black. Warwickshire.

362. POLIANITE.— Mn .

Rhombic; $\infty\text{P } 92^\circ 52'$, $\bar{\text{P}} \infty 118^\circ$. Crystals generally short, prismatic, and vertically striated; also granular. Cleavage, brachydiagonal perfect. $\text{H.}=6.5$...7; $\text{G.}=4.84$...4.88. Opaque; weak metallic. Light steel-gray. B.B. acts like pure hyperoxide of manganese. Chem. com. identical with pyrolusite, which seems thus a less hard variety or product of decomposition. Platten, Schneeberg, and Johann-Georgenstadt.

*363. MANGANITE.— $\text{Mn} + \text{H}$.

Rhombic, sometimes hemihedric; $\infty\text{P } (M) 99^\circ 40'$, $\infty\bar{\text{P}} 2 (l) 118^\circ 42'$, $\bar{\text{P}} \infty (e) 114^\circ 19'$; also $\bar{\text{P}} 3 (g)$, $\infty\bar{\text{P}} 2 (r)$, $2\bar{\text{P}} (m)$, and $2\bar{\text{P}} 2 (n)$, (fig. 231). Crystals prismatic, vertically striated, and in bundles; also columnar or fibrous, rarely granular. Cleavage, brachydiagonal very perfect, basal and ∞P less perfect; rather brittle. $\text{H.}=3.5$...4; $\text{G.}=4.3$...4.4. Opaque; imperfect metallic. Dark steel-gray to iron-black, or often brownish-black and tarnished; streak brown. B.B. infusible; soluble in warm con. h. acid. Chem. com. 89.9 manganese peroxide and 10.1 water. Ihlefeld, in the Harz, Thuringia, Christiansand in Norway, Undenæs in Sweden, Nova Scotia, and Danestown near Aberdeen.

Fig. 231.

364. HAUSMANNITE.— $\text{Mn} + \text{Mn}$, or $\text{Mn}^2 \text{Mn}$.

Tetragonal; $\text{P } 117^\circ 54'$, $\text{P} \infty 99^\circ 11'$. Crystals P or $\text{P. } \frac{1}{2}\text{P}$. Macles common (fig. 77); also granular. Cleavage, basal rather perfect, less distinct P and $\text{P} \infty$; fracture uneven. $\text{H.}=5.5$; $\text{G.}=4.7$...4.8. Opaque; strong metallic. Iron-black; streak brown. B.B. like peroxide of manganese; soluble in h. acid, with escape of chlorine; powder colours con. s. acid bright-red in a short time. Chem. com. 31 protoxide and 69 peroxide of manganese, or 72.4 manganese and 27.6 oxygen. Ihlefeld, and near Ilmenau.

365. BRAUNITE.— Mn .

Tetragonal; $\text{P } 108^\circ 39'$; hence almost an octahedron. Crystals P and P. OP . Cleavage, P rather perfect; brittle. $\text{H.}=6$...6.5; $\text{G.}=4.818$. Opaque; imperfect metallic. Colour and streak dark brownish-black. B.B., and with acids like manganite. Chem. com. 70 manganese and 30 oxygen. Elgersburg, Oehrenstock, Ihlefeld, and St Marcel (*Marceline*).

366. PSILOMELANE.— $(\text{Mn, Ba, K, Cu}) \text{Mn} + \text{H}$.

Massive, botryoidal, or stalactitic. Fracture conchoidal or uneven. $\text{H.}=5.5$...6; $\text{G.}=4.1$...4.2. Opaque; dull or glimmering. Iron-black or bluish-black; streak brownish-black and glistening. B.B. infusible. Chem. com. 4.7 to 11 protoxide of manganese, 80 hyperoxide (but 20 to 50 mixed), 6 to 16 baryta, 2 to 5 potash, 0 to 1 copper, and 0.5 cobalt protoxide; and thus a mixture. Schneeberg, Ilmenau, France, Vermont, Cornwall, and Devon.

367. CREDNERITE.— $\text{Cu}^2 \text{Mn}^2$.

Monoclinohedric; granular, foliated. Cleavage, basal very distinct, prismatic imperfect. $\text{H.}=4.5$...5; $\text{G.}=4.9$...5.05. Opaque; metallic. Iron-black; streak brownish-

Mineralogy.

Mineralogy.

black. B.B. very thin foliæ scarce fusible on the edges; with salt of phosphorus in the inner flame forms a glass first green, then copper-red; in h. acid it forms a green solution. Chem. com. 42·85 copper protoxide and 57·15 peroxide of manganese. Freidrichsroda in Thuringia.

368. CUPREOUS MANGANESE.—(Mn, Cu) $\text{Mn}^{2+} + 2 \text{H}$.

Amorphous; botryoidal, stalactitic, or earthy. Rather brittle or friable. H.=3·5 or less; G.=3·1...3·2. Opaque; vitreous. Black, inclining to brown or blue; streak similar. Gives off much water in the closed tube. B.B. fusible, and yields copper. Contains 14 to 17 copper protoxide, 1·6 baryta, 2·5 lime, 0·2 to 0·6 protoxide of cobalt and nickel, 15 to 17 water, and other substances; thus scarcely a true species. Silesia, Saxony, the Harz, and Cornwall.

Black copper, with 28 iron peroxide, 29·5 water, is similar. Harz.

369. EARTHY COBALT.—(Co, Cu) $\text{Mn}^{2+} + 4 \text{H}$.

Amorphous; reniform, sectile. H.=1...1·5; G.=2·1...2·2. Opaque; dull. Bluish or brownish-black; streak black, shining, and leaves a mark. B.B. infusible. Contains about 20 cobalt protoxide, 4·5 copper protoxide, and 21 water. Saalfeld, Glücksbrun, Riechelsdorf, and Alderley Edge in Cheshire. *Horn-cobalt*, Siegen, is a mixture with quartz.

*370. WAD.—Mn (Ca, Ba, K) $\text{Mn}^{2+} + 3 \text{H}$.

Massive; reniform, stalactitic, or froth-like; also scaly, earthy, or compact. Very soft and sectile (rarely brittle, and H.=3); G.=2·3...3·7; or porous, and swims on water. Opaque; semimetallic, and shining or dull. Colour and streak brown or black. B.B. like peroxide of manganese; soluble in h. acid. Chem. com. very uncertain. Saxony, Harz, France, Devonshire, and Cornwall. *Grorolite* is a variety, and *Newhirkite* related.

FAMILY IV.—OCHRES.

The following substances, chiefly products of decomposition, and all compact, earthy, or disseminated, and scarcely true mineral species, may be described here:—

371. COBALT-OGHRE, Earthy Cobalt.— $\ddot{\text{Fe}}$, $\ddot{\text{As}}$, $\ddot{\text{Co}}$, $\ddot{\text{Ca}}$, $\ddot{\text{H}}$. H.=1...2; G.=2...2·65. Yellowish-gray or brown to liver-brown; streak brown or yellowish-gray and shining. In the closed tube yields water. B.B. emits odour of arsenic, and fuses to a black magnetic slag. Saalfeld, Riechelsdorf, Dauphiné, and other localities.

372. MOLYBDENA-OGHRE.— $\ddot{\text{Mo}}$.

Opaque; dull. Straw, sulphur, or orange yellow. B.B. fuses and smokes; soluble in h. acid. Sweden, Norway, the Tyrol, and on Corybuy, near Loch Creran in Scotland.

373. BISMUTH-OGHRE.— $\ddot{\text{Bi}}$.

Very soft and friable. G.=4·36...4·7. Opaque; dull, or glimmering. Straw-yellow to light-gray or green. B.B. fusible and easily reduced; easily soluble in nitric acid. Schneeberg, Siberia, and St Agnes in Cornwall.

374. ANTIMONY-OGHRE.— $\ddot{\text{Sb}}$, $\ddot{\text{H}}$.

Soft and friable. G.=3·7...3·8. Opaque; dull or glimmering, with glistening streak. Yellow, yellowish-gray, or white. B.B. easily reduced. Harz, Hungary, Saxony, France, Spain, and Padstow in England.

375. STIBLITE.— $\ddot{\text{Sb}}$, $\ddot{\text{H}}$.

H.=5·5; G.=5·28. Resinous or dull. Yellowish-white or yellow. B.B. not reduced alone, but easily with soda. Chem. com. 75 antimony, 20·5 oxygen, and 5·5 water. Kremnitz, Felsöbanya, and Mexico.

376. TUNGSTEN-OGHRE.— $\ddot{\text{W}}$.

Soft. Opaque; dull. Yellow or yellowish-green. Soluble in caustic ammonia. Huntington in North America.

377. URANIUM-OGHRE.— $\ddot{\text{U}}$, $\ddot{\text{H}}$.

Sectile, soft, and friable. Opaque; dull. Straw, sulphur,

or orange yellow. In the closed tube yields water, and becomes red. B.B. in the red. flame becomes green, but does not fuse; easily soluble in acids. Joachimsthal, Johann-Georgenstadt, and St Symphorien in France.

Mineralogy.

378. MINIMUM (Native).— $\ddot{\text{Pb}} + 2 \text{Pb}$.

H.=2...3; G.=4·6. Opaque, dull or weak resinous. Aurora-red; streak orange-yellow. B.B. fuses easily, and reduced; in h. acid loses its colour, and changed into chloride of lead. Chem. com. 90·7 lead and 9·3 oxygen. Schlangenberg in Siberia, Badenweiler, Anglesea, Grassington Moor and Weirdale in Yorkshire.

379. LEAD-OGHRE.— $\ddot{\text{Pb}}$.

G.=8·0. Opaque; dull. Sulphur or lemon yellow. Pococatepetl in Mexico.

380. CHROME-OGHRE.— $\ddot{\text{Cr}}$.

Opaque, or translucent on the edges; dull. Grass-green to siskin or yellowish green. B.B. infusible; soluble to a green fluid in solution of potash. Unst in Zetland, Creuzat in France, and Sweden. *Wolchonskoite*, emerald or blackish green, from Okhansk in Perm, is similar.

381. TELLURITE.— $\ddot{\text{Te}}$.

Spherical, and radiated fibrous. Yellowish or grayish-white. Siebenbürg.

FAMILY V.—THE RED COPPER ORES.

Tesseral and hexagonal. H.=3·5...4·5; G.=5·4...6. Translucent; metallic. Red or dark-gray. Soluble in acids, and B.B. fusible, except zincite. Are oxides of copper or zinc.

*382. CUPRITE, Red Copper Ore.— $\ddot{\text{Cu}}$.

Tesseral; O, αO , and $\alpha\text{O}\infty$; granular or compact. Cleavage, octahedral rather perfect; brittle. H.=3·5...4; G.=5·7...6. Translucent or opaque; metallic-adamantine. Cochineal to brick red, with a lead-gray tarnish; or crimson in transmitted light; streak brownish-red. B.B. on charcoal becomes black, fuses, and reduced; soluble in acids and ammonia. Chem. com. 88·9 copper and 11·1 oxygen. Siberia, the Bannat, Chessy near Lyons, Linares in Spain, and in the Huel Gorland, Huel Muttrel, Carvath, and United Mines in Cornwall.

383. CHALCOTRICHITE.

Rhombic or tesseral; in fine capillary crystals (prisms or cubes). Cochineal and crimson red. In other characters like cuprite. Rheinbreitenbach, Moldawa, and Huel Gorland, Carharrack, and St Day, in Cornwall.

Tile-ore.—Reddish-brown, or brick-red and earthy. Chem. com. suboxide of copper, mixed with much peroxide of iron and other substances. Bannat, Thuringia, Cornwall, and Shropshire.

384. TENORITE.— $\ddot{\text{Cu}}$.

Hexagonal, in thin tables; also fine scaly or earthy. Translucent and brown; metallic. Dark steel-gray or black. On lava, Vesuvius.

385. ZINCITE, Red Zinc.— $\ddot{\text{Zn}}$.

Hexagonal; granular or foliated. Cleavage, basal and αP very perfect. H.=4...4·5; G.=5·4...5·5. Translucent on the edges; adamantine. Blood or hyacinth red; streak orange-yellow. B.B. infusible, but phosphoresces. Chem. com. 80·26 zinc and 19·74 oxygen, but with 3 to 12 manganese peroxide. Franklin and Sterling in New Jersey. Ore of zinc.

FAMILY VI.—THE WHITE ANTIMONY ORES.

386. VALENTINITE, White Antimony.— $\ddot{\text{Sb}}$.

Rhombic; ∞P 137°, $\ddot{\text{P}}\infty$ 70½°. Crystals $\infty\ddot{\text{P}}\infty$. αP . $\ddot{\text{P}}\infty$ (fig. 232); broad prismatic, or long tabular; also granular, columnar, or foliated. Cleavage, αP very per-

Mineralogy.

fect, brachydiagonal imperfect. $H.=2.5...3$; $G.=5.5...5.6$. Translucent; adamantine or pearly. and grayish-white, brown, gray, and rarely peach-blossom red; streak white. B.B. becomes yellow, and fuses (in the flame of a candle) to a white mass. In the closed tube wholly sublimes; on charcoal forms a thick white coating; easily soluble in h. acid; the solution yields with water a white precipitate. Chem. com. 83.6 antimony and 16.4 oxygen. Przibram, Braunsdorf in Saxony, Harz, Hungary, Allemont in Dauphiné, and Siberia.

Fig. 232.

387. SENARMONTITE.— $\ddot{S}b$.

Tesseral; O; also massive. Cleavage, O imperfect. $G.=5.22...5.30$. Transparent to translucent; brilliant resinous or adamantine. White or gray. B.B. and chem. com. like valentinite. Sensa, near Constantine in Algeria, Perneck in Hungary.

388. CERVANTITE.— $\ddot{S}b \ddot{S}b$.

Acicular or incrusting. $G.=4.1$. Resinous. Yellow or white. B.B. infusible, but reduced on charcoal; soluble in h. acid. Chem. com. 79.5 antimony, 20.5 oxygen. Cervantes in Spain, Auvergne, Hungary, and Pereta in Tuscany.

389. ARSENITE.— $\ddot{A}ss$.

Tesseral; O; usually capillary, flaky, or pulverulent. Cleavage octahedral. $H.=1.5$ (3, *Breit.*); $G.=3.6...3.7$. Translucent; vitreous. Colourless and white. Tastesweetish astringent; highly poisonous. B.B. in closed tube sublimes in small octahedrons; on charcoal volatilizes with strong smell of garlic. Chem. com. arsenious acid, with 75.76 arsenic and 24.24 oxygen. Andreasberg, Joachimsthal, Kapnik, Alsace, and Pyrenees.

ORDER V.—NATIVE METALS.

Form only one family. Crystallization either tesseral in regular octahedrons, as gold, silver, copper, and lead; or rhombohedric, with $R=86^\circ$ to 88° , as antimony, arsenic, tellurium, and bismuth (tin is tetragonal). $H.$ ranges from 1.5 in lead to 6...7 in iridium; $G.$ from 5.7 in arsenic to 23 in iridium. Some (platina, palladium, iridium, and iron) are infusible; gold and the others easily fusible; antimony, arsenic, and tellurium, burn and fume.

They are all opaque, metallic lustre, and pure metallic colours (not lead-gray nor black); streak similar and shining. Are simple metals or their combinations.

*390. PLATINA.—Pt, Fe.

Tesseral; very rarely in small cubes, commonly in minute, flat, or obtuse grains and roundish lumps. Cleavage wanting; fracture hackly; malleable and ductile. $H.=4...5$; $G.=17...19$ (hammered 21.23). Steel-gray, inclining to silver-white. Sometimes slightly magnetic. Very difficultly or not fusible; in nitrochloric acid forms a red coloured solution. Chem. com. platina, but generally alloyed with 4 to 13 iron, 1 to 5 iridium, and many other metals. Found in diluvial deposits in Columbia, Brazil, and St Domingo; in the Ural; also in California, Canada, Borneo, the Harz, and France. The largest mass from South America weighs 1 lb. 9½ oz.; from the Ural, 18½ lb. English avoirdupois. Its hardness, infusibility, power of resisting acids, and other properties, render platina a very important material for chemical, mathematical, and philosophical instruments. In Russia also used for money.

391. PALADIUM.—Pd.

Tesseral; in very minute octahedrons; mostly small grains or scales. Malleable. $H.=4.5...5$; $G.=11.8...12.2$. Light steel-gray or silvery-white. B.B. infusible; in nitric acid forms slowly a brownish-red solution. Chem. com.

VOL. XV.

palladium, alloyed with platinum and iridium. Brazil, in gold sands; Tükerode in the Harz, in very small, brilliant, hexagonal tables;—hence rhombohedric and dimorphous. Used for astronomical and other instruments.

392. OSMIUM-IRIDIUM.—Ir, Os.

Hexagonal; $P 124^\circ$; or rhombohedric, $R 84^\circ 52'$, $OP . P . \infty P$ (fig. 233), more common in small flat grains. Cleavage, basal rather perfect. Slightly malleable. Not affected by acids.

Fig. 233.

(a.) *Osmiridium*.—Tin-white. $H.=7$; $G.=19.38...19.47$. B.B. not altered. Analysis, 46.77 iridium, 49.34 osmium, 3.15 rhodium, 0.74 iron, and trace of palladium. Katherinenburgh.

(b.) *Iridosmium*.—Lead-gray. $H.=7$; $G.=21.118$ (*G. Rose*). B.B. on charcoal becomes black, with a very strong odour of osmium; in the flame of a spirit-lamp shines brightly and colours it yellowish-red. In one variety Berzelius found 25 iridium and 75 osmium, or $Ir Os^3$; in another, 20 iridium and 80 osmium, or $Ir Os^4$. Nischne-Tagilsk, Ural, Brazil, and Borneo.

393. IRIIDIUM, PLATIN-IRIDIUM.—Ir, Pt.

Tesseral; $\infty O \infty . O$; also small rounded grains. Cleavage, traces; slightly malleable. $H.=6...7$; $G.=21.57...23.46$. Silver-white, inclining to yellow on the surface. B.B. unalterable; insoluble in acids, even the nitrochloric. Chem. com., by Svanberg's analysis, 76.80 iridium, 19.64 platina, 0.89 palladium, and 1.78 copper. Nischne-Tagilsk and Newjansk. Used in porcelain-painting.

*394. GOLD.—Au.

Tesseral; O, $\infty O \infty$, ∞O , 303, $\infty O 2$, and other forms. Crystals small, often elongated, deformed, and indistinct; also capillary, wire-like, arborescent, and in plates and grains. Remarkably ductile and malleable. $H.=2.5...3$; $G.=17.0...19.4$. Gold-yellow to brass or bronze yellow. B.B. easily fusible; soluble in aqua regia, often with a precipitate of chloride of silver. The solution is yellow, and colours the skin deep purple-red. Chem. com. gold with silver to 38 per cent., and copper and iron under 1 per cent. In beds, veins, and alluvial deposits in many parts of the world,—the Ural, Brazil, California, Australia; in the sand of many rivers, as Rhine and Tagus; in Britain in many of the Cornish stream-works; in mineral lodes near Dolgelly, North Wales; in Scotland at Leadhills, Tyndrum, and Glen Coich, Perthshire; and in Ireland in Wicklow.

*395. SILVER.—Ag.

Tesseral; cubes and octahedrons; also ∞O , 303, and $\infty O 2$. Crystals small and often misshapen; also capillary, filiform, arborescent, or tooth-like, and in leaves, plates, or crusts. Malleable and ductile. $H.=2.5...3$; $G.=10.1...11.1$. Silver-white, but often tarnished yellow, red, brown, or black. B.B. easily fusible; easily soluble in nitric acid; the solution colours the skin black. Chem. com. silver, often with copper, iron, gold (28 per cent.), platina, antimony, and arsenic. Chiefly in veins, as at Andreasberg, Freiberg, Johann-Georgenstadt, and Kongsberg in Norway; Mexico and Peru; St Mewan, St Stephens, Huel Mexico, and Herland in Cornwall; and at Alva in Stirlingshire.

396. ANTIMONY-SILVER, DISCRASITE.— $Ag^4 Sb$.

Rhombic; P with polar edges $132^\circ 42'$ and 92° , $\infty P 120^\circ$ nearly. Crystals short prismatic or thick tabular, and vertically striated; macles united by a face of ∞P ; often in stellar groups (fig. 234); also massive or granular. Cleavage, basal and $P \infty$ distinct; ∞P imperfect; rather brittle, and slightly malleable. $H.=3.5$; $G.=9.4...9.8$. Silver-white to tin-white, with a yellow or blackish tarnish. B.B. fuses easily; fumes, staining the charcoal white, and

Fig. 234.

P

Mineralogy.

Mineralogy.

leaves a grain of silver; soluble in nitric acid. Chem. com. 78 silver and 22 antimony. Andreasberg, Allemont in Dauphiné, Spain, and Arqueras in Coquimbo. A valuable ore of silver.

397. MERCURY. Native Quicksilver.—Hg.

Fluid; but at -40° congeals, and forms tesseral crystals. $G.=13.545$ fluid, 15.612 solid. Bright metallic; tin-white. B.B. wholly volatile, or leaves a little silver. Chem. com. mercury, sometimes with a little silver. Idria, Almaden, Wolfstein, and Mörsfeld on the Rhine, the Harz, Peru, China, and California.

398. AMALGAM.—Ag Hg², and Ag Hg³.

Tesseral; ∞O , with $2O_2$, O , $\infty O\infty$, $3O_3$, and ∞O_3 ; also compact, or in crusts and plates. Cleavage, traces along ∞O ; rather brittle. $H.=3...3.5$; $G.=13.7...14.1$. Silver-white, and leaves the same colour on copper. In the closed tube yields mercury and leaves silver; easily soluble in nitric acid. Chem. com. 35 and 26.5 per cent. silver. Mörsfeld and Moschellandsberg in Rhenish Bavaria, Hungary, Sala, Allemont, and Almaden. *Arquerite* in small octahedrons and arborescent; ductile and malleable. $H.=2...2.5$; $G.=10.8$. Chem. com. 86.5 silver. Forms the chief ore in the rich silver mines of Arqueras near Coquimbo.

399. ANTIMONY.—Sb.

Rhombohedral; $R\ 87^{\circ}\ 35'$, but very rarely crystallized, generally massive or spherical, and botryoidal. Cleavage, basal highly perfect; R perfect, and $-2R$ imperfect; rather brittle and sectile. $H.=3...3.5$; $G.=6.6...6.8$. Tin-white, with a grayish or yellowish tarnish. B.B. easily fusible; on charcoal burns with a weak flame; volatilizes and forms a white deposit. Chem. com. antimony, with a little silver, iron, or arsenic. Andreasberg, Przibram, Sala, and Allemont.

400. ARSENIC-ANTIMONY.—Sb As³.

Rhombohedral; spherical or reniform. $H.=3.5$; $G.=6.1...6.2$. Tin-white to lead-gray, and tarnished with brownish-black. B.B. gives out a strong smell of arsenic. Chem. com. 35.2 antimony and 64.8 arsenic; but the two metals are isomorphous, and form indefinite compounds. Allemont; also Przibram, Schladming, and Andreasberg.

401. ARSENIC.—As.

Rhombohedral; $R\ 85^{\circ}\ 26'$; OR , R , $-\frac{1}{2}R$ (fig. 235); usually fine granular, rarely columnar, botryoidal, or reniform. Cleavage, basal perfect, R and $-\frac{1}{2}R$ imperfect; brittle. $H.=3.5$; $G.=5.7...5.8$. Whitish lead-gray, but in a few hours acquires a grayish-black tarnish.

Fig. 235.

When broken or heated gives out arsenical odours. B.B. easily fusible, but on charcoal gives off dense white vapours, and may be wholly volatilized without fusing. Chem. com. arsenic, with some antimony, and traces of iron, silver, or gold. Andreasberg, Annaberg, Schneeberg, Marienberg, Freiberg, Joachimsthal, Kapnik, Orawitz, Allemont, St Marie aux Mines in Alsace, and Königsberg; Tyndrum in Perthshire; also the Altai, North America, and Chili.

Arsenic-silver is a compound with silver; Königsberg. *Arsenic-glance*, with 3 bismuth; $H.=2$; $G.=5.36...5.39$; dark lead-gray; takes fire at the flame of a candle, and burns; Marienberg. Arsenic is used in various pharmaceutical preparations and metallurgical processes.

402. TELLURIUM.—Te.

Rhombohedral; $R\ 86^{\circ}\ 57'$; ∞R . OR . R . $-R$; usually massive, and fine granular. Cleavage, ∞R perfect, basal imperfect; slightly sectile. $H.=2...2.5$; $G.=6.1...6.3$. Tin-white. B.B. very easily fusible; burns with a greenish flame and much smoke, which forms a white ring with a reddish margin on charcoal. In con. s. acid forms a bluish-red solution. Chem. com. tellurium, with a little gold or iron. Facebay in Siebenburg.

403. LEAD.—Pb.

Tesseral, but only capillary, filiform, or in thin plates. Ductile and malleable. $H.=1.5$; $G.=11.3...11.4$. Blu-

ish-gray with a blackish tarnish. B.B. very easily fusible; on charcoal volatilizes and forms a sulphur-yellow coating; soluble in nitric acid. In lava on Madeira; also near Bristol and Kenmare in Ireland; in meteoric iron from Chili.

404. TIN.—Sn.

This metal has not certainly been found native, though quoted from Cornwall. The fused metal crystallizes in regular octahedrons. That formed by galvanic action is described as tetragonal, with $P\ 57^{\circ}\ 13'$.

*405. BISMUTH.—Bi.

Rhombohedral; $R\ 87^{\circ}\ 40'$. Crystals R . OR , but often misshapen, also aborescent or reticulated; often massive and granular. Cleavage, $-2R\ 69^{\circ}\ 28'$, and basal perfect. Not malleable; very sectile. $H.=2.5$; $G.=9.6...9.8$. Reddish silver-white, often with a yellow, red, brown, or parti-colour tarnish. B.B. very easily fusible, even in the flame of a candle. On charcoal volatilizes, leaving a citron-yellow coating. Soluble in nitric acid. Chem. com. bismuth; sometimes with a little arsenic. Schneeberg, Annaberg, Marienberg, Joachimsthal; Bieber in Hanau; Wittichen; also Modum and Fahlun; near Redruth in Cornwall, Carrick-Fell in Cumberland, and Alva in Stirlingshire.

*406. COPPER.—Cu.

Tesseral; O , $\infty O\infty$, ∞O , ∞O_2 . Crystals small, and generally irregular and deformed. Macles united by a face of O . Often filiform and arborescent, or in plates and laminae. Malleable and ductile. $H.=2.5...3$; $G.=8.5...8.9$. Copper-red, with yellow or brown tarnish. B.B. rather easily fusible, colouring the flame green; readily soluble in nitric acid. In large masses (200 tons) near Lake Superior, with native silver. Cornwall, near Redruth and the Lizard; Yell in Zetland, Chessy near Lyons, the Bannat, and Hungary; Faroe Islands, Siberia, China, Canada, Mexico, Brazil, and Chili.

*407. IRON.—Fe.

Tesseral; chiefly the octahedron. Cleavage hexahedral, but often mere traces; fracture hackly; malleable and ductile. $H.=4.5$; $G.=7...7.8$. Steel-gray or iron-black, often with a blackish tarnish. Very magnetic. B.B. infusible, or only in thin plates with a strong heat; soluble in h. acid. Two varieties are distinguished.

(a.) *Telluric Iron*.—In grains and plates, or disseminated. Almost pure iron, or contains carbon, graphite, lead, or copper, but not nickel. Said to occur at Gross Camtsdorf, Oule in Dauphiné; in the gold sands of Brazil, the Ural and Olahpian; in veins in South Africa; also at Leadhills in Scotland, and in basalt in north of Ireland.

(b.) *Meteoric Iron*.—Steel-gray and silver-white; contains nickel, with cobalt, copper, and other substances. Polished and etched with nitric acid, the surface is marked by lines intersecting at 60° or 120° , named Widmanstadt's figures. Has fallen from the sky in very many countries. Siberia, Brazil, North America, South Africa, Hungary, Britain and Ireland.

ORDER VI.—SULPHURETTED METALS.

Crystallization often tesseral ($\frac{2}{3}$ ths), rhombic ($\frac{1}{2}$ d), or hexagonal and rhombohedral ($\frac{1}{3}$ th), rarely other forms. $H.=1...7$; $G.=3.4...9$. Soluble in acids, and mostly B.B. easily fusible, many yielding fumes characteristic of sulphur, arsenic, or antimony. All (with one or two exceptions of blends) are opaque, and show metallic lustre and colour. Are all compounds of sulphur, arsenic, or antimony with metals. Occur frequently in veins, more rarely disseminated in rocks.

FAMILY I.—PYRITES.

Crystallization tesseral, rhombic, or hexagonal, one tetragonal. Brittle, except bornite. $H.=3...6.5$, the iron

Mineralogy.

Mineralogy.

pyrites being the harder, the copper ores the softer; $G.=4.1...8.1$, but sulphur compounds $=4.1...5.3$, arsenic or antimony $6...8.1$, sulphur with arsenic or antimony $6...6.5$. Colour mostly yellow, becoming lighter or more gray in those with less sulphur. They are all soluble in nitric acid; solutions generally coloured, and all fusible, and give out fumes.

****408. PYRITE, Iron Pyrites.—Fe²⁺.**

Tesseral, and dodecahedral-semiteesseral. The cube $\infty O\infty$, then $O, \frac{\infty O2}{2}$ (fig. 236), and others (fig. 237), and macles (fig. 238). In druses or groups, spheroidal or reniform, and massive. Cleavage, hexahedral or octahedral very imperfect, or scarcely perceptible; brittle: $H.=6...6.5$; $G.=4.9...5.2$. Bronze-yellow, inclining to gold-yellow, often with a brown or rarely variegated tarnish; streak brownish-black. When broken emits a smell of sulphur. B.B. on charcoal burns

Fig. 236.

Fig. 237.

Fig. 238.

with a bluish flame, and a strong smell of sulphur. In the red. flame fuses to a blackish magnetic bead. Soluble in nitric acid with deposition of sulphur; scarcely affected by h. acid. Chem. com. 46.7 iron and 53.3 sulphur. Very often contains gold, silver, or silicium, the gold occasionally in visible grains. Common in rocks of all ages and classes. Fine varieties, Elba, Cornwall, Persberg, Traversella; also Alston Moor and Derbyshire. Auriferous pyrites, Beresof, Marmato, Mexico, Aedelfors in Sweden, and many parts of England and Scotland. Used for the manufacture of sulphur, sulphuric acid, and alum.

***409. MARCASITE, White Iron Pyrites.—Fe²⁺.**

Rhombic; $\infty P 106^\circ 5'$, $\frac{1}{2} P \infty 136^\circ 54'$, $P \infty 80^\circ 20'$, $P \infty 64^\circ 52'$. Crystals like figs. 193 and 158; tabular or thin prismatic, or pyramidal. Macles frequent; also cockscomb-like groups, or spherical, reniform, and stalactitic. Cleavage, ∞P indistinct, P traces; fracture uneven; brittle. $H.=6...6.5$; $G.=4.65...4.9$. Pale, or grayish bronze-yellow, sometimes almost greenish-gray; streak dark greenish-gray or brownish-black. B.B. and with acids acts like pyrite. Varieties are:—*Radiated pyrites*, radiated, fibrous masses. *Spear pyrites*, macles, very fine at Littmitz, Przibram, Schemnitz, and Freiberg. *Hepatic pyrites*, or *Leberkies*, liver-brown, generally decomposing; Harz, Saxony, Sweden, Derbyshire, and Cornwall. *Cockscomb pyrites*, compound, comb-like crystals, often greenish, or with a brown tarnish; Derbyshire and the Harz. *Waserkies* or *Hydrous pyrites* contains water; the *Kyrosite* copper and arsenic; *Lonchidite* also arsenic.

***410. PYRRHOTINE, Magnetic Pyrites.—Fe²⁺, or Fe⁵⁺ Fe³⁺.**

Hexagonal; $P 126^\circ 50'$. Crystals OP , ∞P , or with P (fig. 239) tabular or short prismatic, but rare. Commonly massive, granular, or compact. Cleavage, $8P$ imperfect, laminar structure along OP ; brittle. $H.=3.5...4.5$; $G.=4.4...4.7$. Colour between bronze-yellow and copper-red, with a pinchbeck-brown tarnish; streak grayish-black; more or less magnetic. Unaltered in the closed tube; in the open tube yields sulphurous fumes, but

Fig. 239.

no sublimation. B.B. on charcoal on the red. flame fuses to a black strongly-magnetic globule; soluble in h. acid. Chem. com. 63.65 iron and 36.35 sulphur, or 60.44 iron and 39.56 sulphur, in some with 2 to 3 nickel. Bodenmais, Fahlun, Kongsberg, Andreasberg, Moel Elion and Llanrwst in Caernarvonshire, Cornwall, Appin in Argyleshire, and Vesuvius; also in some meteoric stones.

***411. LEUCOPYRITE, Arsenical Pyrites, Lölingite.** } $Fe As$, or $Fe^4 As^3$.

Rhombic; $\infty P 122^\circ 26'$, $P \infty 51^\circ 20'$, $P \infty 86^\circ 10'$. Crystals ∞P . $P \infty$ (fig. 240). Generally massive, granular, or columnar. Cleavage, basal rather perfect, $P \infty$ imperfect; fracture uneven; brittle. $H.=5...5.5$; $G.=7.0...7.4$. Silver-white to steel-gray, with a darker tarnish; streak grayish-black. B.B. on charcoal emits a strong smell of arsenic, and fuses to a black magnetic globule. Chem. com. 27.2 iron and 72.8 arsenic, or 32.2 iron and 66.8 arsenic, but always 1.3 to 21 sulphur, and sometimes 13.4 nickel, and 5 cobalt. Reichenstein in Silesia; Schladming in Styria; Löling in Carinthia; Andreasberg, in the Harz, and Fossum in Norway. Used for the manufacture of arsenious acid.

Fig. 240.

***412. MISPICKEL.—Fe S² + Fe As.**

Rhombic; $\infty P 111^\circ 12'$, $\frac{1}{2} P \infty 146^\circ 28'$, $P \infty 79^\circ 22'$, $P \infty 59^\circ 2'$. Crystals ∞P . $\frac{1}{2} P \infty$. Macles short prismatic or tabular; also massive, granular, or columnar. Cleavage, ∞P rather distinct; fracture uneven; brittle. $H.=5.5...6$; $G.=6...6.2$. Silver-white, almost steel-gray, with a grayish or yellowish tarnish; streak black. In the closed tube yields first a red then a brown sublimate of sulphuret of arsenic, and then metallic arsenic. B.B. on charcoal fuses to a black magnetic globule. Chem. com. 19.9 sulphur, 46.6 arsenic, and 33.5 iron, but some contain silver or gold, others 5 to 9 cobalt. Freiberg, Altenberg, Joachimsthal, Zinnwald, Schlackenwald, Andreasberg, Sweden, North America, and in many Cornish tin mines; Cobalt-mispickel, from Skutterud in Norway. *Danaite* and *Plinian* seem the same mineral. Used as an ore of arsenic or of silver.

***413. COBALTINE.—Co S² + Co As.**

Tesseral and semiteesseral, like pyrite; also massive or granular, disseminated. Cleavage, hexahedral perfect; brittle. $H.=5.5$; $G.=6.0...6.3$. Brilliant, silver-white, inclining to red, often with a grayish or yellowish tarnish; streak grayish-black. B.B. on charcoal fuses with strong smell of arsenic to a gray, weak magnetic globule; after roasting shows reaction for cobalt with borax. Chem. com. 35.9 cobalt (with 3.6 iron), 44.9 arsenic, and 19.2 sulphur. Skutterud in Norway, Tunaberg, Querbach in Silesia, Siegen, and St Just in Cornwall.

Glaukodote.—Rhombic like mispickel. Dark tin-white; streak black; with 11.9 iron, 24.8 cobalt. Huasco and Valparaiso in Chili, Orawitza.

***414. SMALTINE.—Co As.**

Tesseral; chiefly the cube and octahedron, the faces of the cube convex or cracked; also reticulated, reniform, or granular compact. Cleavage, traces along $\infty O\infty$ and O ; fracture uneven; brittle. $H.=5.5$; $G.=6.4...7.3$. Tin-white or steel-gray, with a dark-gray or iridescent tarnish; streak grayish-black. Gives out an odour of arsenic when broken. In the closed tube gives no sublimate of arsenic. B.B. fuses easily, with a strong smell of arsenic, to a white or gray magnetic globule. Chem. com. 71.4 arsenic and 28.6 cobalt, but with 3 to 19 iron and 1 to 12 nickel; others 1 to 3 bismuth. Schneeberg, Annaberg; Riechelsdorf, Allemont in Dauphiné; Tunaberg in Sweden; Chatham in Connecticut; Huel Sparnon, Doalcoath, and Redruth in Cornwall. *Gray Smaltine* has 10 to 18 iron,

Mineralogy.

Mineralogy.

and $G. = 6.9$ to 7.3 . Smaltine and cobaltine are used in preparing blue colours for painting porcelain and stoneware.

415. MODUMITE, Skutterudite.— $\text{Co}^2 \text{As}^3$.

Tesseral; O and ∞O , or granular. Cleavage, hexahedral distinct; fracture conchoidal or uneven; brittle. $H. = 6$; $G. = 6.74 \dots 6.84$. Tin-white to pale lead-gray, sometimes with an iridescent tarnish. Lustre rather brilliant. In the closed tube it gives a sublimate of metallic arsenic; in other respects acts like smaltine. Chem. com. 79 arsenic, and 21 cobalt. Skutterud, near Modum in Norway.

416. LINNÉITE.— $(\text{Ni}', \text{Co}', \text{Fe}') + (\text{Ni}''', \text{Co}''', \text{Fe}''')$.

Tesseral; in octahedrons and cubes, or maced; also massive. Cleavage, hexahedral imperfect; brittle. $H. = 5.5$; $G. = 4.9 \dots 5.0$. Silver-white inclining to red, often with a yellowish tarnish; streak blackish-gray. B.B. on charcoal fuses in the red. flame to a gray magnetic globule, bronze-yellow when broken. Chem. com. 11 to 53 cobalt, 0 to 42.6 nickel, 2 to 5 iron, and 1 to 15 copper. Bastnæs in Sweden, and Mûsen near Siegen.

417. SYEPOORITE.— Co .

Massive. Steel-gray or yellowish. $G. = 5.45$. Chem. com. 65.2 cobalt, and 34.8 sulphur. Syepoor near Rajpootanah in North-West India. The Indian jewellers use it to give a rose colour to gold.

418. GRUNAUITE, Saynite.

Tesseral; O and ∞O ; also granular. Cleavage octahedral; brittle. $H. = 4.5$; $G. = 5.14$. Light steel-gray inclining to silver-white, with a yellow or grayish tarnish. B.B. fuses to a gray, brittle, magnetic bead, yellow on the fracture, and colours the support yellow. The solution in nitric acid is green. Chem. com. nickel, bismuth, sulphur, iron, cobalt, copper, lead, in variable proportions. Grünau in Sayn-Altenkirchen.

419. GERSDORFFITE.— $(\text{Ni}, \text{Fe}) \text{As} + (\text{Ni}, \text{Fe}) \text{S}^2$.

Tesseral; O , ∞O ; usually granular. Cleavage, hexahedral rather perfect; fracture uneven; brittle. $H. = 5.5$; $G. = 5.6 \dots 6.13$ ($6.64?$). Silver-white to steel-gray, with a grayish tarnish. In the closed tube decrepitates violently. B.B. fuses to a brittle, black, slag-like globule; partially soluble in nitric acid. Chem. com. 35.2 nickel (with 2.4 to 6 iron, 0 to 3 cobalt), 45.4 arsenic, and 19.4 sulphur; but others give different formula, with 10 to 15 iron and 14 cobalt. Harzgerode and Tanne, Schlading, Camsdorf, Loos in Helsingland, Sweden; also Spain and Brazil. Used as an ore of nickel.

Amoibite, *Tombazite*, and *Wodankies*, are similar.

420. ULLMANNITE.— $\text{Ni Sb} + \text{Ni S}^2$, or $\text{Ni}^2 (\text{Sb}, \text{As}, \text{S})^3$.

Tesseral; O , ∞O , ∞O ; usually granular. Cleavage, hexahedral perfect; fracture uneven. $H. = 5 \dots 5.5$; $G. = 6.2 \dots 6.5$. Lead-gray to tin-white or steel-gray; with a grayish-black or iridescent tarnish. B.B. fuses with dense fumes, and slight odour of arsenic; soluble in con. nitric acid. Chem. com. 27.4 nickel, 57.5 antimony, and 15.1 sulphur, with 2 to 12 arsenic. Westerwald, Siegen, Harzgerode, and Lobenstein.

421. BREITHAUPTITE.— $\text{Ni}^2 \text{Sb}$.

Hexagonal; $P 112^\circ 10'$. Crystals, thin striated hexagonal tables of OP . ∞P . $H. = 5$; $G. = 7.54$. Brilliant. Light copper-red, with violet-blue tarnish. B.B. fumes and fuses with great difficulty. Chem. com. 32.2 nickel, and 67.8 antimony, but mixed with 6 to 12 sulphuret of lead. Andreasberg.

422. NICKELINE, Copper Nickel.— $\text{Ni}^2 \text{As}$.

Hexagonal; $P 86^\circ 50'$. Crystals, ∞P , OP (fig. 241), very rare and indistinct; also arborescent, reniform, or generally massive. Fracture conchoidal and uneven; brittle. $H. = 5.5$; $G. = 7.5 \dots 7.7$. Light copper-red, with a tarnish first gray then blackish. It forms no sublimate in the closed tube. B.B. fuses with strong fumes to a white, brittle,

Fig. 241.

metallic globule. Chem. com. 43.6 nickel and 56.4 arsenic, but with 0 to 2 cobalt, 0.2 to 9 iron, 0.1 to 4 sulphur, and 0 to 29 antimony. Freiberg, Schneeberg, Joachimsthal, Andreasberg, Chatham in Connecticut, Pengelly and Huel Chance in Cornwall, and Leadhills in Scotland. Used as an ore of nickel.

Plakodine is a furnace product, not a native mineral.

423. RAMMELSBERGITE, White Nickel.— Ni As .

Tesseral; O , ∞O , ∞O ; also fine granular or compact. Fracture uneven; brittle. $H. = 5.5$; $G. = 6.4 \dots 6.6$. Tin-white, but first a gray, then a blackish tarnish, and loses its lustre. Yields an odour of arsenic when broken. In the closed tube forms a sublimate of metallic arsenic, and becomes copper-red. B.B. on charcoal fuses easily with much smoke, continues long ignited, becomes invested with crystals of arsenious acid, and leaves a brittle grain of metal. Chem. com. 28 nickel and 72 arsenic, but often with cobalt; and many smaltines belong to this species. Schneeberg, Riechelsdorf, Allemont.

424. CHLOANTHITE.— Ni As .

Rhombic; $\infty \text{P } 123^\circ \dots 124^\circ$. $G. = 7.099 \dots 7.188$. Colour tin-white, inclining to red on the fresh fracture. Otherwise like Rammelsbergite, with which it occurs. The names are sometimes transposed.

425. MILLERITE.— Ni .

Rhombohedral; $R 144^\circ 8'$, in fine acicular prisms of $\infty \text{P } 2$. R. Brittle. $H. = 3.5$; $G. = 4.6$, or 5.26 , and 5.65 . Brass or bronze-yellow, with a gray or iridescent tarnish. B.B. fuses easily to a blackish metallic globule, which boils and sputters. In nitro-chloric acid forms a green solution. Chem. com. 64.4 nickel and 35.6 sulphur. Johann-Georgenstadt, Joachimsthal, Przibram, Camsdorf, Riechelsdorf, near St Austle in Cornwall, and at Merthyr Tydvil.

426. INVERARITE, Eisennickelkies.— $2 \text{Fe}' + \text{Ni}'$.

Tesseral; massive and granular. Fracture uneven; brittle. $H. = 3.5 \dots 4$; $G. = 4.6$. Light pinchbeck-brown, with darker streak. Not magnetic. B.B. acts in general like pyrrhotine; the roasted powder forms with borax in the red. flame a black opaque glass. Chem. com. 36 sulphur, 42 iron, and 22 nickel; but mixed with pyrrhotine and chalcopryrite. Lillehammer in Southern Norway, near Inverary in Scotland.

*427. CHALCOPYRITE, Yellow } $\text{Cu}' + \text{Fe}'$, or $\text{Cu}' + \text{Fe}''$.
Copper Ore, Copper Pyrites.

Tetragonal and sphenoidal-hemihedral; $\frac{1}{2} \text{P}$ (P) with polar edges $71^\circ 20'$; $\text{P} \infty$ (b), $2 \text{P} \infty$ (c) $126^\circ 11'$, OP (a), P and $\infty \text{P} \infty$. Crystals generally small and deformed (fig. 242); macles very common, like fig. 243. Most

Fig. 242.

Fig. 243.

commonly compact and disseminated; also botryoidal and reniform. Cleavage, pyramidal $2 \text{P} \infty$ sometimes rather distinct; fracture conchoidal or uneven. $H. = 3.5 \dots 4$; $G. = 4.1 \dots 4.8$. Brass-yellow, often with a gold-yellow or iridescent (*peacock copper ore*) tarnish; streak greenish-black. B.B. on charcoal becomes darker or black, and on cooling red. Fuses easily to a steel-gray globule, which at length becomes magnetic, brittle, and grayish-red on the fractured surface. With borax and soda yields a grain of copper. Moistened with h. acid colours the flame blue.

Mineralogy.

Mineralogy.

Chem. com. essentially 1 atom copper, 1 atom iron, and 2 atoms sulphur, with 34.5 copper, 30.5 iron, and 35 sulphur. The most abundant ore of copper. Anglesea (Parys Mine), Derbyshire, Staffordshire, Cumberland; Wicklow in Ireland; also in the Cornish mines (Gunnis Lake and St Austle); in Scotland in Kirkcudbrightshire and Wigtownshire, Tyndrum in Perthshire, Inverness-shire, Zetland, and other places. Of foreign European localities, Fahlun, Roraas, Freiberg, Mansfeld, Goslar, Lauterberg, Musen, may be mentioned; also in Siberia, the United States, and Australia. The ores raised in Cornwall and Devon give 8 per cent. metal on the average; and that picked for sale at Redruth rarely yields 12, sometimes only 3 or 4 per cent. The richness of the ore may in general be judged of by the colour; if of a fine yellow hue, and yielding readily to the hammer, it may be considered a good ore; but if hard and pale yellow, it is assuredly a poor one, being mixed with iron pyrites. From pyrite it is distinguished by yielding readily to the knife, by its tarnish, and by soon forming a green solution in nitric acid.

Cuban.— $\text{Cu Fe}'' + 2 \text{Fe}$. Tesseral in cubes or massive, with a hexahedral cleavage. $G.=4.02...4.04$. B.B. very easily fusible, otherwise like chalcopyrite. Chem. com. 22.96 copper, 42.51 iron, and 34.78 sulphur. Bacarano in Cuba.

*428. BORNITE, Variegated or Purple } $\text{Cu}_3 \text{Fe}''$.
Copper.

Tesseral. Crystals, $\infty\text{O}\infty$, and $\infty\text{O}\infty . \text{O}$, but rare, and generally rough or uneven; also macles. Mostly massive. Cleavage, octahedral very imperfect; fracture conchoidal or uneven; slightly brittle, or almost sectile. $H.=3$; $G.=4.9...5.1$. Colour between copper-red and pinchbeck-brown, with very pale tarnish, especially steel-blue, inclining to red and green; streak grayish-black. B.B. acts like chalcopyrite; soluble in con. h. acid, leaving sulphur. Chem. com. 3 atoms copper, 1 atom iron, and 3 atoms sulphur, with 55.6 copper, 16.4 iron, and 28 sulphur, but often, especially when compact, mixed, and then 56 to 71 copper, and 6 to 17 iron. Crystals near Redruth and St Day in Cornwall; massive at Killarney in Ireland; also Norway, Sweden, Mansfeld, Silesia, Tuscany, and Chili. An ore of copper.

429. DOMEYKITE.— $\text{Cu}^6 \text{As}$.

Botryoidal, reniform, or massive. Fracture uneven or conchoidal; brittle. $H.=3...3.5$. Tin or silver white, inclining to yellow, with an iridescent tarnish. B.B. fuses easily with strong odour of arsenic; not affected by h. acid. Chem. com. 71.63 copper and 28.37 arsenic. Calabazo in Coquimbo and Copiapo in Chili.

Condurrite.—Massive, soft, and soils the fingers. Fracture flat conchoidal. Colour brownish or bluish black. $G.=4.20...4.29$. B.B. on charcoal fuses, with escape of arsenic vapours, to a globule, which, on cooling, cracks, swells, and falls to pieces. With soda and borax leaves a grain of copper. Seems an impure variety. Condurrow Mine and near Redruth in Cornwall.

430. ARSENIURET OF MANGANESE.— $\text{Mn}^3 \text{As}$.

Massive and botryoidal, granular or foliated. Fracture uneven; brittle. $G.=5.55$. Grayish-white, with a black tarnish. B.B. burns with a blue flame, and emits fumes of arsenic; soluble in nitro-chloric acid. Chem. com. 42.75 manganese, 57.25 arsenic, with trace of iron. Saxony.

FAMILY II.—LEAD GLANCE.

Crystallization, chiefly tesseral; also rhombic and rhombohedral. $H.=1...2.5$, rarely more; $G.=4.6...8.9$, and mostly 5.5, or higher. Colours generally lead-gray, and more or less dark. All soluble in acids. B.B. all fusible, and mostly very easily, and easily reduced. They are compounds with sulphur, arsenic, or selenium; known by their fumes. Chiefly occur in veins.

*431. GALENA, Sulphuret of Lead.— Pb' .

Tesseral; $\infty\text{O}\infty$, ∞O ; seldomer 2O, and 2O2. Crystals, $\infty\text{O}\infty . \text{O}$. Also massive and granular, compact, or laminar. Cleavage, hexahedral very perfect; fracture scarcely observable; sectile. $H.=2.5$; $G.=7.2...7.6$. Lead-gray, with darker, or rarely iridescent tarnish; streak grayish-black. B.B. decrepitates, fuses, and leaves a globule of lead; soluble in nitric acid. Chem. com. 86.7 lead, and 13.3 sulphur, but usually contains a little silver,—ranging from 1 to 3, or 5 parts in 10,000; rarely 1 per cent. or more. Some contain copper, zinc, or antimony, others selenium, and others (the *supersulphuret*) probably free sulphur (2 to 8 per cent.). Most common ore of lead in many countries. Cornwall, Derbyshire (Castletown), Wales, Cumberland, Alston Moor, Durham (Altonhead); Isle of Man; Leadhills, Pentland Hills, Linlithgow, Inverkeithing, Monaltrie, Strontian, Islay, and many other places in Scotland. In 1855 the produce was,—England, 66,265 tons; Wales, 18,204; Isle of Man, 3573; Ireland, 2005; and Scotland, 1587 tons.

432. CUPROPLUMBITE.— Cu Pb^2 .

Tesseral; massive, with distinct hexahedral cleavage. Rather sectile and brittle. $H.=2.5$; $G.=6.408...6.428$. Blackish lead-gray; streak black. B.B. does not decrepitate; with soda gives a grain of metal. Chem. com. 65 lead, 19.9 copper, and 15.1 sulphur (with 0.5 silver). Chili.

433. CLAUSTHALITE.— Pb Se .

Tesseral; but massive and fine granular, with hexahedral cleavage. $H.=2.5...3$; $G.=8.2...8.8$. Lead-gray; streak gray. B.B. on charcoal fumes, smells of selenium, colours the flame blue, stains the support red, yellow, and white; and volatilizes, except a small remainder, without fusing. Chem. com. 72.7 lead (with 11.6 silver), and 27.3 selenium. Lerbach, Zorge and Tilkerode in the Harz.

Tilkerodite, with 3 cobalt; $G.=7.7$; colours borax glass smalt-blue. *Lehrbachite*; Lerbach and Tilkerode; with 17 to 45 mercury, seems a mixture.

434. SELENCOPPERLEAD.— $(\text{Cu, Pb}) \text{Se}$.

Massive and fine granular. Sectile. $H.=2.5$; $G.=7...7.5$. Light lead-gray inclining to brass-yellow, or with a bluish tarnish; streak darker. B.B. like clausthalite, only some fuse slightly on the surface, others easily forming a gray metallic mass. Chem. com. 30 to 35 selenium, 47 to 64 lead, and 4 to 16 copper (with 0 to 1.3 silver). Tilkerode, Zorge, and near Gabel in Thuringia.

435. ONOFRITE.— $\text{Hg Se} + 4 \text{Hg S}$.

Massive, and granular. $H.=2.5$. Blackish lead-gray or steel-gray; streak shining. In the closed tube wholly volatile with a black sublimate. With soda gives metallic mercury. Chem. com. 82.8 mercury, 6.6 selenium, and 10.6 sulphur. St Onofre in Mexico, Zorge in the Harz.

436. TIEMANNITE.— Hg Se , or $\text{Hg}^6 \text{Se}^5$.

Fine granular; brittle. $H.=2.5$; $G.=7.1...7.4$. Brilliant. Dark lead-gray. In the closed tube decrepitates, swells, fuses, and volatilizes to a black and brown deposit. Only soluble in nitro-chloric acid. Chem. com. 75 mercury, 25 selenium. Clausthal.

437. NAUMANNITE.— Ag Se .

In thin plates and granular. Cleavage, hexahedral perfect. Malleable. $H.=2.5$; $G.=8$. Iron-black; splendid. B.B. on charcoal fuses; with soda a grain of silver; easily soluble in con. nitric acid. Chem. com. 73 silver and 27 selenium, with 4.91 lead. Tilkerode.

Silverphyllinglanz.—Massive, foliated; perfect cleavage; thin lamina flexible. $H.=1...2$; $G.=5.8...5.9$. Dark-gray. Chem. com. antimony, lead, tellurium, gold, and sulphur (*Plattner*). Deutsch-Pilsen in Hungary.

*438. ARGENTITE, Sulphuret of Silver.— Ag' .

Tesseral; $\infty\text{O}\infty$, O , ∞O , and 2O2 (fig. 244). Crystals generally misshapen, with uneven or curved faces;

Mineralogy.

Mineralogy.

in druses, or linear groups; also arborescent, capillary, or in crusts. Cleavage, very indistinct traces along ∞O and $\infty O\infty$; fracture uneven and hackly; malleable and flexible. $H.=2\ldots2.5$; $G.=7\ldots7.4$. Rarely brilliant; more so on the streak. Blackish lead-gray, often with a black, brown, or rarely iridescent tarnish. B.B. on charcoal fuses, intumesces greatly, and leaves a grain of silver; soluble in con. nitric acid. Chem. com. 87 silver, and 13 sulphur. Freiberg, Marienberg, Annaberg, Schneeberg, Johann-Georgenstadt; Joachimsthal; Schemnitz and Kremnitz; Kongsberg; Huel Duchy, Dolcoath, Herland, and near Callington, in Cornwall; Alva in Stirlingshire. Common ore at Guanajuato and Zacatecas in Mexico, in Peru, and Blagodot in Siberia. Valuable ore of silver.

Fig. 244.

439. STROMAYERITE.— $Cu' + Ag'$.

Rhombic; isomorphous with redruthite. Crystals rare; usually massive, or in plates; fracture flat, conchoidal, or even; very sectile. $H.=2.5\ldots3$; $G.=6.2\ldots6.3$. Bright. Blackish lead-gray. B.B. fuses easily to a gray metallic semimalleable globule. Chem. com. 52.9 silver, 31.4 copper, and 15.7 sulphur, but often indeterminate proportions of silver 3 to 53, and copper 30 to 75. Schlängenberg in Siberia, Rudelstadt in Silesia, and Catemo in Chili. Ore of silver and copper.

*440. REDRUTHITE, Copper Glance.— Cu' .

Rhombic; $\infty P(o)$ $119^\circ 35'$, $P(P)$ middle-edge $125^\circ 22'$, $\frac{1}{2}P(a)$ middle-edge $65^\circ 40'$, $2P\infty(d)$ middle-edge $125^\circ 40'$, $\frac{3}{2}P\infty(e)$ middle-edge $65^\circ 48'$. Crystals $OP.(s)$ $\infty P.(o)$ $\infty P\infty(p)$, (fig. 245). Mostly thick tabular; also macles, and massive, in plates or lumps. Cleavage, ∞P imperfect; fracture conchoidal or uneven; very sectile. $H.=2.5\ldots3$; $G.=5.5\ldots5.8$. Rather dull; brighter on the streak. Blackish lead-gray, with a blue or other tarnish. B.B. colours the flame blue; on charcoal in the ox. flame sputters and fuses easily; in the red. flame becomes solid. With soda gives a grain of copper. Green solution in nitric acid. Chem. com. 79.8 copper, and 20.2 sulphur. Saxony, Silesia, Norway, the Bannat, Siberia, and the United States; near Redruth and Land's End in Cornwall; Fassnet Burn in Haddingtonshire, in Ayrshire, and in Fair Island, Orkney. Important copper ore.

Fig. 245.

Digenite.—Massive. $G.=4.568\ldots4.680$; in other respects like redruthite. Contains 70.20 copper, 29.56 sulphur, and 0.24 silver. Sangerhausen in Thuringia, and Chili.

441. KUPFERINDIG, Covellite.— Cu' .

Hexagonal. Crystals ∞P . OP rare; usually reniform, and fine granular. Cleavage, basal often very perfect; sectile, and thin laminæ flexible. $H.=1.5\ldots2$; $G.=3.8\ldots3.85$. Dull resinous, inclining to metallic. Indigo-blue, inclining to black; streak black. B.B. burns with a blue flame; on charcoal like redruthite, but remains fluid in the inner flame; soluble in nitric acid. Chem. com. 66.7 copper, and 33.3 sulphur. Vesuvius, Sangerhausen, Badenweiler, Schwarzwald; Kielce in Poland, Leogang in Salzburg, and Cairn Beg in Cornwall.

442. EUKAIRITE.— $Cu^2 Se + Ag Se$.

Massive and fine granular. Soft (cuts with the knife). Lead-gray; streak shining. B.B. fuses to a brittle gray metallic grain. Chem. com. 43 silver, 25.2 copper, and 31.8 selenium. Skrikerum in Smoland.

443. BERZELINE.— $Cu^2 Se$.

Crystalline, in thin dendritic crusts. Soft. Silver-white;

streak shining. B.B. on charcoal fuses to a gray, slightly malleable bead. With soda a grain of copper. Chem. com. 61.5 copper and 38.5 selenium. Skrikerum in Sweden, Lerbach in the Harz.

444. NAGYAGITE, Black or Foliated Tellurium.

Tetragonal; P $137^\circ 52'$, $P\infty$ $122^\circ 50'$, and OP . Crystals tabular, but rare; in general thin plates or foliated. Cleavage, basal very perfect; very sectile; the thin laminæ flexible. $H.=1\ldots1.5$; $G.=6.85\ldots7.2$. Splendent. Blackish lead-gray. B.B. fuses easily, with white fumes, and forms a yellow deposit on the charcoal; with soda leaves a grain of gold; soluble in nitric acid, with residue of gold. Chem. com. 51 to 63 lead, 6.7 to 9 gold, 1 to 1.3 copper and silver, 13 to 32 tellurium, 3 to 12 sulphur, and 0 to 4.5 antimony. Nagyag in Siebenburg, and Offenbanya.

445. ALTAITE.— $Pb Te$.

Tesseral and granular; hexahedral cleavage. Fracture uneven; sectile. $H.=3\ldots3.5$; $G.=8.1\ldots8.2$. Tin-white inclining to yellow, with yellow tarnish. B.B. on charcoal colours the flame blue; in the red. flame fuses to a globule that almost wholly volatilizes. Chem. com. 61.9 lead with 1.28 silver, and 38.1 tellurium. Sawodinski mine in the Altai.

446. HESSITE.— $Ag Te$.

Massive and granular; slightly malleable. $H.=2.5\ldots3$; $G.=8.31\ldots8.88$. Blackish lead gray to steel-gray. B.B. on charcoal fumes, fuses to a black grain with white spots, and leaves a brittle grain of silver. Chem. com. 62.8 silver, and 37.2 tellurium, but some (*Petzite*) 0.7...18 gold. Sawodinski mine in the Altai, Nagyag in Siebenburg.

447. TETRADYMITTE.— $2 Bi Te + Bi S^2$.

Rhombohedral; $3 R$ $66^\circ 40'$. Crystals $3 R$. OR ; almost always macles, with the faces of OR at 95° ; also granular foliated. Cleavage, basal very perfect; sectile, and in thin laminæ flexible. $H.=1\ldots2$; $G.=7.2\ldots7.5$. Dull. Tin-white to steel-gray. B.B. on charcoal fuses easily, occasionally with odour of selenium, staining the support yellow and white; at length yields a white grain of metal, almost entirely volatile; soluble in nitric acid. Chem. com. 59.66 bismuth, 35.86 tellurium, and 4.48 sulphur, with traces of selenium; but the tellurium and bismuth are isomorphous, and probably in indeterminate proportions, the sulphur and selenium not essential. Schubkau near Schemnitz, Deutsch-Pilsen in Hungary, San Jose in Brazil, Virginia and Carolina.

*448. MOLYBDENITE.— Mo'' .

Hexagonal; but only tabular or short prismatic crystals of OP . ∞P or $OP.P$. Generally scaly or curved foliated. Cleavage, basal very perfect; very sectile, and thin laminæ flexible. Feels greasy. $H.=1\ldots1.5$; $G.=4.6\ldots4.9$. Reddish lead-gray; makes a gray mark on paper, a greenish mark on porcelain. B.B. in the forceps colours the flame siskin-green, but is infusible. On charcoal yields sulphurous fumes, and forms a white coating, but burns slowly and imperfectly. In warm nitrochloric acid forms a greenish, in boiling sulphuric acid a blue solution. Chem. com. 59 molybdena and 41 sulphur. Arendal, Altenberg, Ehrenfriedersdorf, Zinnwald, Schlackenwald, Mont Blanc, Shutesbury in Massachusetts, in Maine, Haddam in Connecticut; Caldbeckfell in Cumberland, Shap in Westmoreland, Huel Gorland, and many Cornish mines; Peterhead, Corybuey on Loch Creran, and Glenelg. Readily distinguished from graphite by its streak, lustre, gravity, and action before the blowpipe. Used for preparing blue carmine for colouring porcelain.

FAMILY III.—GRAY ANTIMONY ORE.

Crystallization rhombic, rarely tesseral or hexagonal. $H.=3\ldots3.5$, or less; $G.\approx 4\ldots6.8$ (sylvanite 8.1). Colour

Mineralogy.

Mineralogy.

steel or lead gray. All soluble in acids with precipitates; generally very easily fusible, even in the flame of a candle, and give out fumes.

*449. STIBINE, Antimonite.— Sb^{III} .

Rhombic; P polar edges $109^{\circ} 16'$, and $108^{\circ} 10'$, $\infty P 90^{\circ} 45'$. Crystals $\infty P (m)$, $\infty \bar{P} \infty (o)$, $P (P)$, or with $\frac{1}{2} \bar{P} \infty (a)$, $2 \bar{P} 2 (b)$, $\frac{2}{3} \bar{P} 2 (c)$, $\frac{1}{3} P (s)$, (fig. 246). Mostly long prismatic or acicular, with strong vertical striae, often in druses, or stellar groups; also radiating, fibrous, or fine granular. Cleavage, brachydiagonal (o) highly perfect, and often horizontally striated; also basal, ∞P , and macrodiagonal imperfect; sectile. $H.=2$; $G.=4.6 \dots 4.7$. Brilliant. Lead-gray, with a blackish or iridescent tarnish. B.B. fuses easily, colouring the flame green, and volatilizes, leaving a white coating on the support; soluble in warm h. acid. Chem. com. 71.8 antimony and 28.2 sulphur. Near Freiberg in Saxony, Wolfsberg in the Harz, Przibram, Felsöbanya, Kremnitz, Schemnitz, Auvergne, Spain, and North and South America; St Stephen's, Padstow, and Endellion in Cornwall; Glendinning in Dumfriesshire, New Cumnock in Ayrshire, and in Banffshire. Chief ore of antimony.

Fig. 246.

450. JAMESONITE.— $\text{Pb}^3 + \text{Sb}^{\text{III}}$.

Rhombic; $\infty P 101^{\circ} 20'$. Crystals ∞P , $\infty \bar{P} \infty$, long prismatic, parallel or radiating. Cleavage, basal very perfect, ∞P and brachydiagonal imperfect; sectile. $H.=2 \dots 2.5$; $G.=5.5 \dots 5.7$. Steel-gray to dark lead-gray. B.B. decrepitates, fuses easily, and wholly volatilizes, except a small slag; soluble in warm h. acid. Chem. com. 44.6 lead, with 2 to 4 iron, 34.8 antimony, and 20.6 sulphur. Cornwall, Estremadura, Hungary, Siberia, and Brazil.

451. ZINCKENITE.— $\text{Pb}^2 \text{Sb}^{\text{III}}$.

Rhombic; $\infty P 120^{\circ} 39'$, $\bar{P} \infty 150^{\circ} 36'$. Crystals, prismatic or acicular, vertically striated, and maced in threes. Cleavage, prismatic very imperfect; fracture uneven; rather sectile. $H.=3 \dots 3.5$; $G.=5.30 \dots 5.35$. Dark steel-gray to lead-gray, with a steel-blue or iridescent tarnish. B.B. decrepitates violently, fuses, emits fumes of antimony, and wholly volatilizes, except a small remainder; soluble in warm h. acid. Chem. com. 35.9 lead, 42 antimony, 22.1 sulphur, with 0.42 copper. Wolfsberg in the Harz.

452. PLAGIONITE.— $\text{Pb}^4 \text{Sb}^{\text{III}}$.

Monoclinohedric; $C=72^{\circ} 28'$, $P 134^{\circ} 30'$ and $142^{\circ} 3' - 2 P 120^{\circ} 49'$. Crystals thick tabular, minute, and in druses. Cleavage, $-2 P$ rather perfect; brittle. $H.=2.5$; $G.=5.4$. Blackish lead-gray. B.B. decrepitates violently, fuses easily, sinking into the charcoal, and leaves metallic lead. Chem. com. 42 lead, 37 antimony, and 21 sulphur. Wolfsberg in the Harz.

453. BOULANGERITE.— $\text{Pb}^6 \text{Sb}^{\text{III}}$.

Fine granular, columnar, radiating, or fibrous. Slightly sectile. $H.=3$; $G.=5.8 \dots 6$. Silky, metallic. Blackish lead-gray, with darker streak. B.B. fuses easily, forming a coating of protoxide of lead; soluble in warm h. acid. Chem. com. 55.4 lead, 25.9 antimony, and 18.7 sulphur. Molières in France, Ober-Lahr, Lapland, and Siberia. *Plumbostib*, with arsenic, and *Embrithite*, seem varieties; Nertschinsk.

*454. GEOKRONITE.— $\text{Pb}^5 (\text{Sb}^{\text{III}}, \text{As}^{\text{III}})$.

Rhombic; P polar edges 153° and $64^{\circ} 45'$; $\infty \bar{P} 2=119^{\circ} 44'$, mostly massive, or lamellar. Cleavage, $\infty \bar{P} 2$; fracture conchoidal or even; sectile. $H.=2 \dots 3$; $G.=6.45 \dots 6.54$. Pale lead-gray, with a slight tarnish. B.B. fuses easily and volatilizes. Chem. com. 67 lead, with 1 to 2 copper and iron, 16 antimony, with 4.7 arsenic, and 17 sul-

phur. Sala in Sweden, Mérédo in Spain, and near Pietrosanto in Tuscany. *Kilbrickenite*, massive, granular, or foliated; County Clare in Ireland.

455. STEINMANNITE.— $\text{Pb}^2 \text{Sb}^{\text{III}}$.

Tesseral; O; also botryoidal and reniform. Cleavage, hexahedral rather imperfect; sectile. $H.=2.5$; $G.=6.833$. Lead-gray. B.B. decrepitates violently; on charcoal fuses readily, leaving lead and silver. Przibram.

456. PLUMOSITE, Feather Ore.— $\text{Pb}^2 \text{Sb}^{\text{III}}$.

Rhombic (?); acicular or capillary, in felt-like masses. $H.=1 \dots 3$; $G.=5.7 \dots 5.9$. Dull or glimmering. Dark-lead or steel-gray, sometimes iridescent. B.B. and with acids acts like zinckenite; fuses even in the flame of a candle. Chem. com. 51.8 lead, 29.7 antimony, and 19.5 sulphur. Wolfsberg, Andreasberg, and Clausthal; Neudorf in Anhalt, Freiberg, and Schemnitz.

457. ENARGITE.— $3 \text{Cu}^3 + \text{As}^{\text{III}}$.

Rhombic; $\infty P 97^{\circ} 53'$, $P \infty 100^{\circ} 58'$, mostly massive and granular. Cleavage, ∞P perfect, brachy- and macrodiagonal less so; brittle. $H.=3$; $G.=4.43 \dots 4.45$. Iron-black. In the closed tube yields first sulphur, then fuses and gives out sulphuretted arsenic. B.B. with borax, gives a bead of copper. Chem. com. 48.3 copper, 19.1 arsenic, and 32.6 sulphur. Morocacha in Peru.

458. DUFRENOYSITE.— $\text{Cu}^2 \text{As}^{\text{III}} + \text{Cu}^2 \text{As}^{\text{III}}$.

Tesseral. Crystals $\infty O.202$. Fracture uneven; brittle. $H.=2 \dots 3$; $G.=4.48$. Steel-gray; streak reddish-brown. In the closed tube gives a reddish-brown sublimate. B.B. fuses easily, leaving a grain of copper readily soluble in warm acid. Chem. com. 38.4 copper, 2.8 lead, 1.3 silver, 30.5 arsenic, and 27 sulphur. Binnenthal, St Gotthardt.

459. SKLEROKLASE.— $\text{Pb}^2 \text{As}^{\text{III}}$.

Rhombic; $\bar{P} \infty 115^{\circ} 16'$, $\bar{P} \infty : \bar{P} \infty = 134^{\circ} 59'$. Crystals broad prismatic, acicular or fibrous; very brittle and friable. $G.=5.39 \dots 5.55$. Bright metallic. Pale lead-gray, steel-gray, and iron-black; streak reddish-brown. Chem. com. 57.12 lead, 20.74 arsenic, 22.14 sulphur, with traces of silver, copper, and iron. St Gotthardt, with Dufrenoyite, for which it was analyzed.

460. WOLFSBERGITE.— $\text{Cu}^1 \text{Sb}^{\text{III}}$.

Rhombic; $\infty P 135^{\circ} 12'$, $\infty \bar{P} 2 111^{\circ}$. Crystals tabular; also fine granular. Cleavage, brachydiagonal very perfect, basal imperfect; fracture conchoidal or uneven. $H.=3.5$; $G.=4.748$. Lead-gray to iron-black, sometimes iridescent; streak black, dull. B.B. decrepitates, fuses easily, and with soda gives a grain of copper. Chem. com. 25.4 copper, 49 antimony, and 25.6 sulphur. Wolfsberg in the Harz.

461. BERTHIERITE.— $\text{Fe}^1 \text{Sb}^{\text{III}}$.

Massive; columnar or fibrous, with indistinct cleavage. $H.=2 \dots 3$; $G.=4.0 \dots 4.3$. Dark steel-gray, yellowish or reddish; easily tarnished. B.B. on charcoal fuses easily, with fumes of antimony, to a black magnetic slag; soluble in h. acid. Chem. com. sulphurets of iron and antimony in variable proportions, or 9.8 to 16 iron, 52 to 61.6 antimony, and 29.1 to 31 sulphur. Auvergne and Anglar in France, Bräunsdorf in Saxony, Tintagel and Padstow in Cornwall. In France used as an ore of antimony.

462. BISMUTHINE.— Bi^{III} .

Rhombic; $\infty P 91^{\circ} 30'$. Crystals long prismatic or acicular, with strong striae; also granular or columnar, foliated or radiated. Cleavage, brachydiagonal perfect, macrodiagonal less distinct; sectile. $H.=2 \dots 2.5$; $G.=6.4 \dots 6.6$. Light lead-gray to tin-white, with a yellowish or iridescent tarnish. B.B. on charcoal fuses easily in the inner flame, sputters, and yields a yellow coating with a grain of bismuth; soluble in nitric acid. Chem. com. 81.2 bismuth and 18.8 sulphur. Riddarhyttan, Bastnaes, Johann-Georgenstadt, Altenberg, Joachimsthal; Haddam in Connecticut; near Redruth, Botallack, Dolcoath, and Herland in Cornwall, and Caldbeckfell in Cumberland.

Mineralogy.

Mineralogy.

463. **ACICULITE**, Needle-ore.— $\text{Pb}^4 \text{Bi}''' + \text{Cu}^2 \text{Bi}'''$. Rhombic; long thin crystals imbedded in quartz, often bent or broken, with strong vertical striae. Cleavage imperfect; fracture conchoidal or uneven; rather brittle. $H.=2.5$; $G.=6.7\ldots6.8$. Blackish lead-gray or steel-gray, with a brownish tarnish. B.B. fuses very easily, smokes, stains the charcoal white and yellow, and leaves a metallic globule; soluble in nitric acid. Chem. com. 35.8 lead, 11 copper, 36.7 bismuth, and 16.5 sulphur. Beresof in Siberia.

464. **KOBELLITE**.— $3 \text{Pb}^3 \text{Bi}''' + \text{Fe}^3 \text{Sb}'''$. Radiated columnar; soft. $G.=6.29\ldots6.32$. Blackish lead-gray to steel-gray; streak black. B.B. fuses (at first boiling, then quietly), and stains the charcoal white and yellow, and leaves a white grain of metal; soluble in con. h. acid, evolving sulphuretted hydrogen. Chem. com. 46 sulphuret of lead, 33.3 sulphuret of bismuth, 5.7 sulphuret of iron, and 15 sulphuret of antimony. Hvena in Nerike, Sweden.

465. **SILVANITE**.— $\text{Ag Te}^4 + \text{Au Te}^3$. Rhombic; crystals generally small, short acicular, and often grouped in rows like letters. Cleavage in two directions, one very perfect; sectile, but friable. $H.=1.5\ldots2$; $G.=7.99\ldots8.33$. Steel-gray to tin-white, silver-white, and pale bronze-yellow. B.B. on charcoal forms a white coating, and fuses to a dark-gray globule, with soda reduced to a malleable grain of argentiferous gold; soluble in nitrochloric acid, depositing chloride of silver; and in nitric acid, leaving gold. Chem. com. 59.6 tellurium, with 0.5 to 8.5 antimony, 26.5 gold (in some 30), and 13.9 silver, with 0.2 to 19.5 lead. Offenbanya (*Graphic Tellurium*), Nagyag (*Yellow Tellurium*).

FAMILY IV.—GRAY COPPER ORE.

Crystallization rhombic and tesseral. $H.=1\ldots4$, the ores of copper being above 3, the ores of silver below 3; $G.=4.2\ldots6.3$. Colour steel or lead-gray, in a few inclining to black or brown. All soluble in nitric acid. B.B. fusible, often easily, with fumes of sulphur or arsenic. Mostly sulphurets of copper and silver, with sulphurets of arsenic or antimony.

*466. **FAHLORE**, } $(\text{Cu}', \text{Ag}', \text{Fe}', \text{Zn}', \text{Hy}')^4 (\text{Sb}''', \text{As}''')$.
Gray Copper. }

Tesseral and tetrahedral. In crystals $\frac{O}{2}, -\frac{O}{2}, \infty O, \frac{2O}{2}$

(fig. 247, and figs. 19, 20). Macles (fig. 248), not uncommon; most abundant massive and disseminated. Cleavage,

Fig. 247.

Fig. 248.

octahedral imperfect, with traces in other directions; fracture conchoidal, uneven, or fine granular; brittle. $H.=3\ldots4$; $G.=4.5\ldots5.2$. Steel-gray to iron-black; streak black (dark-red when containing zinc). B.B. on charcoal boils slightly, and fuses to a steel-gray slag, usually magnetic, and with soda gives copper. In nitric acid the powder forms a brownish-green solution. Chem. com. very variable; but 15 to 40 copper, 0 to 31 silver, 1 to 6 iron, 1 to 7 zinc, 0 to 7.5 mercury, 12 to 29 antimony, 0 to 10 arsenic, and 23 to 27 sulphur; those with much arsenic are

paler coloured; those with little or no arsenic dark-coloured; those with 17 to 31 silver are the silver fahlore (Freiberg). Harz, Müsen, Freiberg, Camsdorf, Alsace, Kremnitz, Kapnik; Crinnis and other Cornish mines near St Austle; Airthrie near Stirling, and Sandlodge in Zetland. Ore of copper and silver.

467. **TENNANTITE**.— $(\text{Cu}', \text{Fe}') \text{As}'''$.

Tesseral; like fahlore. Cleavage, ∞O very imperfect; brittle. $H.=4$; $G.=4.3\ldots4.5$. Blackish lead-gray to iron-black; streak dark reddish-gray. B.B. decrepitates, burns with a bluish flame and odour of arsenic, and fuses to a magnetic slag. Chem. com. 49 copper, 4 iron, 19 arsenic, and 28 sulphur. Redruth and St Day, Cornwall, and Skutterud. *Copperblende*, with brownish-red streak; $G.=4.3$; contains 8.9 zinc; Freiberg.

468. **BOURNONITE**.— $\text{Pb}^4 \text{Sb}''' + \text{Cu}^2 \text{Sb}'''$.

Rhombic; $\infty P (d) 93^\circ 40'$, $\bar{P} \infty (n) 96^\circ 13'$, $\bar{P} \infty (e) 92^\circ 34'$, $OP (r)$, $\infty \bar{P} \infty (s)$, $\infty \bar{P} \infty (h)$, as in fig. 249. Crystals generally thick tabular, very often maced by a face of ∞P , and several times repeated; also granular or disseminated. Cleavage, brachydiagonal imperfect, traces in other directions; fracture uneven to conchoidal; rather brittle. $H.=2.5\ldots3$; $G.=5.7\ldots5.9$. Lustre brilliant metallic. Steel-gray, inclining to lead-gray and iron-black. B.B. usually decrepitates and fuses easily to a black globule, staining the charcoal first white, then yellow, and with soda leaves a grain of copper. In nitric acid a blue solution. Chem. com. 41.8 lead, 12.9 copper, 26 antimony, and 19.3 sulphur. Harz (Neudorf), Bräunsdorf, Kapnik, Servoz, Alais and Pontgibaud, Redruth and Bealston.

469. **WÖLCHITE**.— $\text{Cu}^4 \text{Sb}''' + \text{Pb}^2 \text{As}''' (?)$.

Rhombic; in short prisms. Cleavage, brachydiagonal rather distinct; fracture imperfect conchoidal; brittle. $H.=3$; $G.=5.7\ldots5.8$. Blackish lead-gray. B.B. on charcoal fuses with effervescence to a lead-gray metallic grain. Chem. com. 29.90 lead, 17.35 copper, 1.40 iron, 16.65 antimony, 6.04 arsenic, and 28.60 sulphur. Wölch, near St Gertraud, Carinthia.

470. **FREIESLEBENITE**.— $\text{Ag}^2 \text{Sb}''' + \text{Pb}^3 \text{Sb}'''$.

Monoclinohedric; $C=87^\circ 46'$; $\infty P 119^\circ 12'$, $P \infty 131^\circ 41'$, in prisms with curved reed-like faces and strong vertical striae. Macles intersecting; also massive. Cleavage, ∞P perfect; fracture conchoidal or uneven; rather brittle. $H.=2\ldots2.5$; $G.=6.2\ldots6.4$. Steel-gray to dark lead-gray; streak the same. B.B. on charcoal fuses to a grain of silver. Chem. com. 22.5 silver, 32.4 lead with copper, 26.8 antimony, and 18.3 sulphur. Rare. Freiberg in Saxony; also Kapnik and Ratiborschitz (?).

471. **STEPHANITE**.— $\text{Ag}^6 \text{Sb}'''$.

Rhombic; $\infty P (o) 115^\circ 39'$, $P (P)$ middle edge $104^\circ 20'$, $2 \bar{P} \infty (d)$ middle edge $107^\circ 48'$, $OP' (s)$, $\infty \bar{P} \infty (p)$, (fig. 250), thick tabular or short prismatic, Macles frequent, repeated three or four times; also massive. Cleavage (d and p), both imperfect; fracture conchoidal or uneven; sectile. $H.=2\ldots2.5$; $G.=6.2\ldots6.3$. Iron-black to blackish lead-gray, rarely iridescent. B.B. on charcoal (odour of arsenic) fuses to a dark-gray globule; with soda, a grain of silver. Chem. com. 70.9 silver, 13.5 antimony, and 16.6 sulphur, but with 0 to 5 iron, or 0.5 to 4 copper, and 0 to 3.3 arsenic. Freiberg, Schneeberg, Johann-Georgenstadt, and Annaberg; Joachimsthal and Przibram, Schemnitz, the

Fig. 250.

Mineralogy.

Mineralogy.

Harz, Mexico, Peru, Siberia, and Cornwall. Valuable ore of silver.

472. POLYBASITE.— $(Ag', Cu')^9 (Sb'', As'')$.

Hexagonal; $P 117^\circ$. Crystals $OP \cdot \infty P$ and $OP \cdot P$, tabular, and often very thin; also massive. Cleavage, basal imperfect; sectile, and easily frangible. $H.=2...2.5$; $G.=6.0...6.25$. Iron-black. B.B. decrepitates slightly and fuses very easily. Chem. com. 64 to 72 silver, 3 to 10 copper, 16 to 17 sulphur, 0.2 to 8 antimony, and 1 to 6 arsenic. Freiberg, Joachimsthal, Schemnitz, and Guanajuato. An ore of silver.

473. STERNBERGITE.— $Ag' + 2 Fe''' (?)$.

Rhombic; P middle edge 118° , section (*or* ∞P) $119^\circ 30'$. Crystals usually thin tabular, in macles or in fan-like and spheroidal groups. Cleavage, basal very perfect; sectile, and flexible in thin laminae. $H.=1...1.5$; $G.=4.2...4.25$. Dark pinchbeck-brown, often a violet-blue tarnish; streak black. B.B. on charcoal fuses to a magnetic globule covered with silver, with borax, a grain of silver; decomposed by nitrochloric acid. Zippe found 33.2 silver, 36 iron, and 30 sulphur; or nearly 1 atom silver, 4 iron, and 6 sulphur. Joachimsthal, Schneeberg and Johann-Georgenstadt.

Flexible Sulphuret of Silver is identical; Hungary and Freiberg.

474. STANNINE, Tin Pyrites.— $Cu'^2 Sn'' + (Fe', Zn)^2 Sn''$.

Tesseral; in cubes very rare, generally massive and granular. Cleavage, hexahedral very imperfect; fracture uneven or small conchoidal; brittle. $H.=4$; $G.=4.3...4.5$. Steel-gray (yellowish from copper pyrites); streak black. B.B. on charcoal fuses, forming round the assay a white coating; with soda, a grain of copper; easily decomposed by nitric acid, leaving tin peroxide and sulphur; the solution is blue. Chem. com. 26 to 32 tin, 24 to 30 copper, 5 to 12 iron, 2 to 10 zinc, and 30 sulphur. Huel Rock near St Agnes, St Michael's Mount, and Carn Brea, Cornwall; and Zinnwald. Bell-metal ore.

475. WITTICHITE, Cupreous Bismuth.— $Cu'^3 Bi'''$.

Rhombic (?); massive. Cleavage, vertical distinct; fracture uneven and fine granular; sectile. $H.=3.5$; $G.=5$. Steel-gray, pale lead-gray tarnish; streak black. B.B. fuses very readily, frothes, and stains the charcoal yellow; with soda, a grain of copper. Chem. com. 38.5 copper, 42 bismuth, and 19.5 sulphur. Wittichen in Schwarzwald, Huel Buller in Cornwall.

476. BISMUTHIC SILVER.

Acicular, capillary, or massive; sectile and soft. Pale lead-gray, darker tarnish. B.B. fuses easily, and forms a large deposit on the charcoal. Klaproth found 33 lead, 27 bismuth, 15 silver, 4.3 iron, 0.9 copper, and 16.3 sulphur. Schapbach Valley in Baden.

FAMILY V.—BLENDES.

Crystallization mostly tesseral; cleavage distinct. $H.=3.5...4.5$; $G.=3.5...4.9$. Lustre adamantine or resinous; more or less *translucent*. Colours and streak red, yellow, brown, or black. All soluble in acids. B.B. often decrepitate, but fuse with difficulty.

*477. BLENDE, Zinc-blende.— Zn' .

Tesseral and tetrahedral; $\frac{O}{2}$, $-\frac{O}{2}$ (sometimes as O), ∞O , $\frac{303}{2}$ and $\infty O \infty$. Macles remarkably

common, united by a face of O (fig. 251) and several times repeated; frequently massive and granular. Cleavage, ∞O very perfect; very brittle. $H.=3.5...4$; $G.=3.9...4.2$. Semitransparent to opaque; adamantine and resinous. Brown or black, also red, yellow, and green. B.B. decrepitates often violently, but only fuses on very thin edges; soluble in con. nitric acid, leaving sul-

Fig. 251.

phur. Chem. com, 66.8 zinc and 33.2 sulphur, but generally with 1 to 15 iron, 0 to 3 cadmium. Very abundant, the Harz, Freiberg, Przibram, Schemnitz, Kapnik, North America, Peru, Cornwall, Derbyshire, Cumberland, Leadhills, and Stotfield, near Elgin. Used as an ore of zinc, but with little success.

478. VOLTZINE.— $4 Zn' + Zn$.

Hemispherical, curved-lamellar incrustations. Fracture conchoidal. $H.=4.5$; $G.=3.66$. Brick-red to yellow or brown. Opaque or semitranslucent; vitreo-resinous; pearly. B.B. like zinc-blende; soluble in l. acid. Chem. com. 82.8 sulphuret and 17.2 oxide of zinc. Pontgibaud in Auvergne, and Joachimsthal.

479. ALABANDINE.— Mn' .

Tesseral; O and $\infty O \infty$; usually massive and granular. Cleavage, hexahedral perfect; fracture uneven; rather brittle. $H.=3.5...4$; $G.=3.9...4$. Opaque; semimetallic. Iron-black to dark steel-gray, brownish-black tarnish; streak dark green. B.B. fuses on thin edges to a brown slag; soluble in h. acid. Chem. com. 63.6 manganese and 36.4 sulphur. Nagyag and Kapnik, Mexico and Brazil.

480. HAUERITE.— Mn'' .

Tesseral; O , $\infty O \infty$, and ∞O . Crystals single or in spherical groups. Cleavage, hexahedral perfect. $H.=4$; $G.=3.463$. Semitranslucent on very thin edges; metallic-adamantine. Reddish-brown to brownish-black; streak brownish-red. In the closed tube yields sulphur, and leaves a green mass, which B.B. becomes brown on the surface, and is soluble in h. acid. Chem. com. 46.28 manganese and 53.72 sulphur. Kalinka, near Neusohl in Hungary.

481. GREENOCKITE.— Cd' .

Hexagonal and hemimorphic; $P 87^\circ 13'$, $2P 124^\circ 34'$. Crystals $2P \cdot OP \cdot \infty P \cdot P$, or $P \cdot 2P \cdot \infty P$; attached singly. Cleavage, ∞P imperfect, basal perfect. $H.=3...3.5$; $G.=4.8...4.9$. Translucent; brilliant resinous, or adamantine. Honey or orange-yellow, rarely brown; streak yellow. B.B. decrepitates and becomes carmine-red, but again yellow when cold; fused with soda forms a reddish-brown coating on charcoal; soluble in h. acid. Chem. com. 77.6 cadmium, and 22.4 sulphur. Bishoptown in Renfrewshire.

FAMILY VI.—RUBY-BLENDES.

Crystallization rhombohedral, monoclinohedric, or rhombic. Cleavage rarely distinct. $H.=1.5...2.5$; $G.=3.5...8.2$. Lustre adamantine. Colour yellow, red or gray; streak deep red, rarely brownish or yellow. Soluble in nitric acid. B.B. fusible and reduced often with fumes, or sublime.

*482. PYRRARGYRITE, Red Silver.— $Ag^3 Sb'''$.

Rhombohedral; $R (P) 108^\circ 42'$, $-\frac{1}{2} R 137^\circ 58'$, OR , $-2R$ (r), R^3 , $\infty P2$ (s), and ∞R (l). Crystals prismatic (figs. 252, 253); macles common of various kinds; also massive, den-

Fig. 252.

Fig. 253.

dritic, or investing. Cleavage, R rather perfect; fracture conchoidal to uneven and splintery; slightly sectile, sometimes almost brittle. $H.=2...2.5$; $G.=5.75...5.85$. Translucent on the edges to opaque; crimson-red to blackish lead-gray; streak cochineal to cherry-red. B.B. on charcoal

Mineralogy.

Minera-
logy.

fuses easily, gives out sulphurous acid and antimony fumes, and leaves a grain of silver; soluble in nitric acid, leaving sulphur and antimony protoxide; solution of potash extracts sulphuret of antimony. Chem. com. 59.8 silver, 22.5 antimony and 17.7 sulphur. Andreasberg, Freiberg, Johann-Georgenstadt, Annaberg, Schneeberg, and Marienberg; Przibram, Schemnitz and Kremnitz, Markirchen, Kongsberg and Mexico; Huel Brothers and Huel Duchy in Cornwall.

483. PROUSTITE.— $\text{Ag}^3 \text{As}^m$.

Rhombohedral, like pyrrargyrite, except R, $107^\circ 50'$. G. 5.5...5.6. Semitransparent to translucent on the edges. Cochineal to crimson red; streak aurora-red to cochineal-red. B.B. arsenical odour, and leaves a brittle metallic grain difficultly reduced to pure silver; soluble in nitric acid, with remainder of sulphur and arsenious acid; solution of potash extracts sulphuret of arsenic. Chem. com. 65.4 silver, 15.1 arsenic, and 19.4 sulphur. In the same localities with pyrrargyrite; and both valuable ores of silver. Red orpiment has a lower specific gravity and yellow streak; cinnabar volatilizes before the blowpipe.

484. MARGYRITE.— $\text{Ag}^3 \text{Sb}^m$.

Monoclinohedric; C = $81^\circ 36'$, P $90^\circ 53'$, —P $95^\circ 59'$. Crystals pyramidal, short prismatic, or tabular (fig. 254); also massive. Cleavage, indistinct traces; fracture imperfect conchoidal or uneven; sectile. H. = 2...2.5; G. = 5.3...4. Opaque; thin splinters dark blood-red, translucent; metallic adamantine. Blackish lead-gray to iron-black and steel-gray; streak cherry-red. B.B. with soda, a grain of silver; with acids, like pyrrargyrite. Chem. com. 35.9 silver, 42.9 antimony, and 21.2 sulphur. Bräunsdorf near Freiberg.

Fig. 254.

Rittingerite.—Monoclinohedric; C = $88^\circ 26'$, ∞ P $126^\circ 18'$. Crystals small tabular. Cleavage basal imperfect; brittle. H. = 2.5...3. Translucent honey-yellow to red. Colour iron-black, on OP brown tarnished; streak orange-yellow. B.B. melts easily, with arsenic fumes, leaving much silver. Joachimsthal.

485. XANTHOKON.— $\text{Ag}^3 \text{As}^m + \text{Ag}^3 \text{As}^m$.

Rhombohedral. Crystals very thin hexagonal tables, with R : OR $110^\circ 30'$, —2R : OR $100^\circ 35'$. Cleavage, R and OR more or less perfect; rather brittle, very easily frangible. H. = 2...2.5; G. = 5.0...5.2. Translucent and transparent; adamantine. Orange-yellow or yellowish-brown; streak slightly darker. In the closed tube fuses very easily, becomes lead-gray. Chem. com. 63.4 silver, 14.7 arsenic, and 21.9 sulphur. Himmelsfürst Mine at Freiberg.

Fireblende.—In thin tabular crystals (like heulandite), with one perfect cleavage; sectile and slightly flexible. G. = 4.2...4.3. Hyacinth-red. B.B. like pyrrargyrite. Contains sulphur, antimony, and silver. Freiberg and Andreasberg.

486. KERMES.— $\text{Sb}^m \text{Sb}$.

Monoclinohedric (?). Crystals acicular, capillary, and diverging; also radiating fibrous. Cleavage, very perfect along the axis of the crystals, less perfect at right angles; sectile. H. = 1...1.5; G. = 4.5...4.6. Semitranslucent; adamantine. Cherry-red; streak similar. B.B. acts like stibine; soluble in h. acid; in solution of potash the powder becomes yellow and dissolves. Chem. com. 75.3 antimony, 19.8 sulphur, and 4.9 oxygen; or 70 sulphuret and 30 protoxide of antimony. Bräunsdorf near Freiberg, Przibram, and Allemont.

Zundererz, or Tinder-ore, soft, flexible, tinder-like masses, dirty cherry-red or blackish-red, is a mixture; Andreasberg.

487. CINNABAR.— Hg^2 .

Rhombohedral; R $71^\circ 48'$, OR $\frac{1}{2}$ R, $\frac{1}{2}$ R, ∞ R. Crystals rhombohedral or thick tabular; also disseminated and granular, compact, or earthy. Cleavage, ∞ R rather perfect; fracture uneven and splintery; sectile. H. = 2...2.5; G. = 8...8.2. Semitransparent or opaque; adamantine.

Cochineal-red, with lead-gray and scarlet-red tarnish; streak scarlet-red. In the open tube sublimes, partly as cinnabar, partly as metallic mercury; perfectly soluble in nitrochloric acid, but not in hydrochloric acid, nitric acid, or solution of potash. Chem. com. 86.2 mercury and 13.8 sulphur. Idria in Carniola, Almaden and Almadenejos in Spain, Wolfstein and Moschellandsberg in Rhenish Bavaria, Hartenstein in Saxony, Szlana and Rosenau in Hungary, Ripa in Tuscany; New Almaden in California, Mexico, and Peru. Principal ore of mercury; also used as a pigment. *Fibrous and Hepatic Cinnabar* are mixtures.

488. REALGAR, Red Orpiment.—As.

Monoclinohedric; C = $66^\circ 5'$ (P), ∞ P (M) $74^\circ 26'$, (P ∞) $132^\circ 2'$, ∞ P2 (I) $113^\circ 16'$. Crystals prismatic (fig. 255); also massive and investing. Cleavage, basal and clinodiagonal rather perfect, prismatic imperfect; fracture small conchoidal to uneven or splintery; sectile. H. = 1.5...2; G. = 3.4...3.6. Semitransparent or opaque; resinous. Aurora-red; streak orange-yellow. In the closed tube sublimes as a dark-yellow or red mass; B.B. on charcoal fuses and burns with a yellowish-white flame; acids act on it with difficulty. Chem. com. 70 arsenic and 30 sulphur. Kapnik, Nagyag, Felsobanya, and Tajowa, Andreasberg, St Gotthardt, Vesuvius and the Solfatara.

Fig. 255.

489. DIMORPHINE.—As.

Rhombic, in two types; more common short prismatic, with ∞ P $96^\circ 34'$ and $\bar{P} \infty 108^\circ 50'$; the other more pyramidal. Very fragile. H. = 1.5; G. = 3.58. Splendent adamantine; translucent or transparent. Orange-yellow; streak similar. Chem. com. 75.5 arsenic, and 24.5 sulphur. Solfatara, Naples.

490. ORPIMENT.—As.

Rhombic; ∞ P $117^\circ 49'$, $\bar{P} \infty 83^\circ 37'$. Crystals short prismatic (fig. 256), disseminated, columnar or foliated. Cleavage, brachydiagonal very perfect, striated vertically; sectile, and in thin laminae flexible. H. = 1.5...2; G. = 3.4...3.5. Semi-transparent or opaque; resinous or pearly. Citron-yellow to orange-yellow. In the closed tube yields a dark-yellow or red sublimate; fused with soda it yields metallic arsenic; soluble in nitrochloric acid, in potash, and in ammonia. Chem. com. 61 arsenic and 39 sulphur. Tajowa near Neusohl, Servia, Wallachia, Natolia, Felsobanya, Kapnik, and Andreasberg; the Solfatara, and Zimapan in Mexico.

Fig. 256.

ORDER VII.—THE INFLAMMABLES.

Named from the substances all burning before the blowpipe, whereas the former minerals only fused or gave out fumes, and left a residue. Few of them are crystallized, and many rather organic remains or rocks than simple minerals. In chemical composition they are either simple elements, as sulphur and carbon, or mostly formed not on the plan of the mineral kingdom, but of organic nature. Except the diamond, their hardness is low, or less than 2.5; and their specific gravity also 2.2, or under.

FAMILY I.—SULPHUR.

*491. SULPHUR.—S.

Rhombic; P polar edges $106^\circ 38'$, $84^\circ 58'$, middle edge $148^\circ 17'$; ∞ P $101^\circ 58'$, OP, $\frac{1}{2}$ P, $\bar{P} \infty$. Crystals pyramidal (fig. 257), single or in druses; also reniform, spherical, stalactitic, disseminated, incrusting, or pulverulent. Cleavage, basal and ∞ P imperfect; fracture conchoidal to uneven or splintery; rather brittle. H. = 1.5

Mineralogy.

...2.5; G.=1.9...2.1. Transparent or translucent on the edges; resinous or adamantine. Sulphur-yellow, passing into brown and red, or into yellowish-gray and white. In the closed tube it sublimes; at 227° Fahr. fuses, and at 518° takes fire and burns with a blue flame, forming sulphurous acid. Chem. com. sulphur, occasionally more or less mixed with other substances. Sicily, at Girgenti, Cataldo, &c.; the Lipari Islands, the Solfatara near Naples, Poland, Iceland, Java, Sandwich Islands, Peru, and Chili; from springs at Aix-la-Chapelle, and in Scotland.

Fig. 257.

492. SELEN-SULPHUR.

Orange-yellow or yellowish-brown. Fuses readily in the closed tube, and volatilizes. B.B. on charcoal burns, and gives out fumes of selenic and sulphurous acids. Consists of sulphur and selenium. Vulcano, Lipari, and Kilauea in Hawaii.

Native Selenium.—Brownish-black or lead-gray. Thin splinters red translucent. H.=2; G.=4.3. Culebras in Mexico.

FAMILY II.—DIAMOND.

493. DIAMOND.—C.

Tesseral and tetrahedral-semiteaseral; $\frac{O}{2}$ and $-\frac{O}{2}$, mostly conjoined, ∞O , ∞On , mO , mOn ; or the octahedron, rhombic dodecahedron, and hexakisoctahedron (figs. 2, 3, 7, and 5). The crystals have often curved faces, and occur loose or imbedded singly. Macles common, united by a plane of O, like fig. 251. Cleavage, octahedral perfect; fracture conchoidal; brittle. H.=10; G.=3.5...3.6. Transparent or translucent when dark-coloured. Refracts light strongly; brilliant adamantine. Colourless, but often white, gray, or brown tints, also green, yellow, red, blue, and rarely black. Becomes positive electric by friction; burns in oxygen gas, and forms carbonic acid. Chem. com. pure carbon. Hindostan on the east of the Deccan, between Pennar, Sonar, and the delta of the Ganges (lat. 14° to 25°); Borneo and Malacca; Brazil in the district of Serro do Frio in Minas Geraes; also in Borneo, Malacca, the Ural, Georgia, and North Carolina, and the Sierra Madre, south-west from Mexico.

FAMILY III.—THE COALS.

494. GRAPHITE, Plumbago.—C.

Hexagonal or monoclinohedric; but only thin tabular or short prismatic crystals of OP. ∞P . Usually foliated, radiating, scaly, or compact. Cleavage, basal perfect; very sectile, flexible in thin laminæ. Feels greasy. H.=0.5...1; G.=1.9...2.2. Opaque; metallic. Iron-black. Leaves a mark on paper. Is a perfect conductor of electricity. B.B. burns with much difficulty; and heated with nitre in a platina spoon only partially detonates. Chem. com. carbon, but mixed with iron, lime, alumina or other matter. Pargas, Arendal, Passau, Spain, Ticonderoga in New York, Ceylon, Borrowdale in Cumberland, Glenstrathfarrer in Inverness-shire, Kirkcudbright, and Craigman in Ayrshire. At the latter it is evidently common coal altered by contact with trap. Is used for making pencils, and to form crucibles.

*495. ANTHRACITE.—Glance-Coal.

Massive and disseminated; rarely columnar, or fibrous and pulverulent. Fracture conchoidal; brittle. H.=2...2.5; G.=1.4...1.7. Opaque; brilliant metallic. Iron-black or grayish-black; streak unaltered. Perfect conductor of electricity. Burns difficultly with a very weak or no flame, and does not cake; in the closed tube yields a little moisture, but no empyreumatic oil; detonates with nitre. Chem. com. carbon above 90 per cent., with 1 to 3

Mineralogy.

oxygen, 1 to 4 hydrogen, and 0 to 3 nitrogen; and ashes chiefly of silica, alumina, lime, and peroxide of iron. Very common in some parts of the English, Scottish, and Irish coal-fields; in the Alps, as the Valais, Piedmont, Savoy, and Dauphiné; in the Pyrenees, and in various parts of France; in Silesia, Bohemia, Saxony, and the Harz; and in the United States, as in Rhode Island, Massachusetts, and above all in Pennsylvania. Used for manufacturing metals, and for economic and household purposes.

496. COMMON COAL, Black, Stone, Bituminous Coal.

Compact, slaty, or confusedly fibrous; often dividing into columnar, cubical, or rhomboidal fragments. Fracture conchoidal, uneven, or fibrous; rather brittle or sectile. H.=2...2.5; G.=1.2...1.5. Vitreous, resinous, or silky in the fibrous variety. Blackish-brown, pitch-black, or velvet-black. Burns easily, emitting flame and smoke, with a bituminous odour; heated in the closed tube with powdered sulphur gives out sulphuretted hydrogen. Chem. com. 74 to 90 carbon, with 0.6 to 8 or 15 oxygen, 3 to 6 hydrogen, 0.1 to 2 nitrogen, 0.1 to 3 sulphur, and 1 to 11 earthy matters or ash, in 100 parts.

Slate-coal has a thick slaty structure, and an uneven fracture in the cross direction. *Cannel coal*, a resinous, glimmering lustre, and a large or flat conchoidal fracture; breaks into irregular cubical fragments, but more solid, and takes a higher polish than the other varieties. It burns with a bright flame, and yields much gas. *Coarse or foliated coal*, massive or lamellar, breaks into cubical or irregular angular masses, with a more splendid lustre, and less compact texture than the former, and more easily frangible. *Earthy coal*, loose powdery masses, often brown or dirty in colour, and apparently semi-decomposed. Abundant in many lands, as in England, South Wales, Scotland, and Ireland; in Belgium and France, in Germany and Southern Russia. The United States possess immense fields in the valley of the Mississippi. Also found in China, Japan, Hindostan, Australia, Borneo, and several of the Indian Islands. Its uses are too well known to need notice.

497. BROWN COAL.—Lignite, Jet.

Distinctly vegetable in origin, the external form, and very often the internal woody structure, being preserved. The texture is compact, woody, or earthy. Fracture conchoidal, woody, or uneven; soft and often friable. G.=0.5...1.5. Lustre sometimes resinous, mostly glimmering or dull. Brown, black, or rarely gray. Burns easily with an unpleasant odour; colours solution of potash deep-brown; heated with sulphur evolves much sulphuretted hydrogen. Chem. com. 47 to 73 carbon, 2.5 to 7.5 hydrogen, 8 to 33 oxygen (with nitrogen), and 1 to 15 ashes. *Jet* is pitch-black, with conchoidal fracture and resinous lustre. Brown coal occurs at Bovey Tracy in Devonshire, in Yorkshire, Antrim, Brora, Mull, and Skye; Germany, Hungary, France, Italy, and Greece. The *Surturbrand* of Iceland seems a variety. Used as fuel, but much inferior to common coal.

*498. PEAT.

A mass of more or less decomposed vegetable matter of a brown or black colour, closely connected with coal, and, like it, rather a rock than a simple mineral. Contains 50 to 60 carbon, 5 to 6 hydrogen, 30 to 39 oxygen, 0 to 2 nitrogen, and 1 to 14 ashes in 100 parts. Common everywhere in the colder parts of the earth.

FAMILY IV.—THE MINERAL RESINS.

*499. BITUMEN, Naphtha.—CH².

Liquid. Colourless, yellow, or brown; transparent or translucent. G.=0.7...0.9. Volatilizes in the atmosphere with an aromatic bituminous odour. Chem. com. 84 to 88 carbon, and 12 to 16 hydrogen.

Naphtha.—Very fluid, transparent, and light-yellow. Tegern Lake in Bavaria, Amiano near Parma, Salies in

Mineralogy.

the Pyrenees, Rangun in Hindostan, Baku on the Caspian Sea, China, Persia, and North America. Used for burning and preparing varnishes. *Petroleum*.—Darker yellow or blackish-brown; less fluid or volatile. Ormskirk in Lancashire, at Coalbrookdale, Pitchford, and Madeley in Shropshire; St Catherine's Well, south of Edinburgh; Isle of Pomona; and in many other parts of Europe and the United States.

*500. ELATERITE, Elastic Bitumen, } $C H^2$.
Mineral Caoutchouc.

Compact; reniform or fungoid; elastic and flexible like caoutchouc; very soft. $G.=0.8...1.23$. Resinous. Blackish, reddish, or yellowish brown. Strong bituminous odour. Chem. com. 84 to 86 carbon, 12 to 14 hydrogen, and a little oxygen. Derbyshire, Montrelais near Nantes, and Woodbury in Connecticut.

501. ASPHALTUM.

Compact and disseminated. Fracture conchoidal, sometimes vesicular; sectile. $H.=2$; $G.=1.1...1.2$. Opaque, resinous, and pitch-black; strong bituminous odour, especially when rubbed. Takes fire easily, and burns with a bright flame and thick smoke; soluble in ether, except a small remainder, which is dissolved in oil of turpentine. Chem. com. 76 to 88 carbon, 2 to 10 oxygen, 6 to 10 hydrogen, and 1 to 3 nitrogen. Limmer near Hanover, Seyssel on the Rhone; Val Travers in Neuchâtel, Lobsann in Alsace, in the Harz; Cornwall, Haughmond Hill, Shropshire; East Lothian, Burntisland in Fifeshire; Dead Sea, Persia, and Trinidad.

502. PIAUZITE.

Massive; imperfect conchoidal; sectile. $H.=1.5$; $G.=1.22$. Dimly translucent on very thin edges; resinous. Blackish-brown; streak yellowish-brown. Fuses at 600° Fahr., and burns with an aromatic odour, lively flame, and dense smoke; soluble in ether and caustic potash. Piauze in Carniola.

503. IXOLITE.

Massive; conchoidal fracture. $H.=1$; $G.=1.008$. Resinous. Hyacinth-red; streak ochre-yellow. Rubbed between the fingers it emits an aromatic odour, and becomes soft at 119° , but is still viscid at 212° . Oberhart near Gloggnitz in Austria.

*504. AMBER, Succinite.— $C^{10} H^8 O$.

Round irregular lumps, grains, or drops. Fracture perfect conchoidal; slightly brittle. $H.=2...2.5$; $G.=1...1.1$. Transparent to translucent or almost opaque; resinous. Honey-yellow, but from hyacinth-red or brown to yellowish-white; also streaked or spotted. When rubbed emits an agreeable odour, and becomes negatively electric. It melts at 550° , emitting water, an empyreumatic oil, and succinic acid; it burns with a bright flame and pleasant odour, leaving a carbonaceous remainder; only a small part is soluble in alcohol. Chem. com. 79 carbon, 10.5 hydrogen, and 10.5 oxygen. Derived from an extinct coniferous tree, and found in the diluvial formations of many countries, especially Northern Germany and shores of the Baltic, Sicily, Spain, and Northern Italy; rarely in England, as on the shores of Norfolk, Suffolk, and Essex, and at Kensington near London. Used for ornamental purposes, and for preparing succinic acid and varnishes.

505. RETINITE, Retinasphalt.

Roundish or irregular lumps. Fracture uneven or conchoidal; very easily frangible. $H.=1.5...2$; $G.=1.05...1.15$. Translucent or opaque; resinous or glistening. Yellow or brown. Melts at a low heat, and burns with an aromatic or bituminous odour. Chem. com. in general carbon, hydrogen, and oxygen, in very uncertain amount. Bovey, Halle, Cape Sable, and Osnabrück.

506. WALCHOWITE.— $C^{12} H^9 O$.

Rounded pieces, with a conchoidal fracture. $H.=1.5...2$; $G.=1.035...1.069$. Translucent, resinous. Yellow with

brown stripes; and a yellowish-white streak. It fuses at 482° , and burns readily; soluble partially (7.5 per cent.) in ether, and in sulphuric acid forms a dark-brown solution. Chem. com. 80.4 carbon, 10.7 hydrogen, and 8.9 oxygen. Walchow in Moravia.

507. COPALINE, Fossil Copal, } $C^{40} H^{84} O$.
Highgate Resin.

Irregular fragments. $H.=1.5$; $G.=1.046$. Translucent resinous, and light-yellow or yellowish-brown. Burns easily with a bright-yellow flame and much smoke; alcohol dissolves very little of it, which is precipitated by water; becomes black in sulphuric acid. Chem. com. 85.54 carbon, 11.63 hydrogen, 2.76 oxygen. Highgate near London. A similar resin from Settling Stones in Northumberland, found in flat drops or crusts on calc-spar, is infusible at 500° Fahr.; $G.=1.16...1.54$; and contains 85.13 carbon, 10.85 hydrogen, and 3.26 ashes; or $C^2 H^3$.

508. BERENGELITE.— $C^{40} H^{62} O^3$.

Amorphous; conchoidal fracture. Dark-brown, inclining to green; yellow streak. Resinous; unpleasant odour, and bitter taste. Fuses below 212° , and then continues soft at ordinary temperatures; easily soluble in alcohol. Chem. com. 72.40 carbon, 9.28 hydrogen, 18.31 oxygen. St Juan de Berengela in South America.

509. GUYAQUILLITE.— $C^{20} H^{28} O^3$.

Amorphous; yielding easily to the knife, and very friable. $G.=1.092$. Pale yellow. Slightly resinous. Fluid at 212° , viscid when cold; slightly soluble in water and largely in alcohol, forming a yellow fluid with a bitter taste. Chem. com. 77.01 carbon, 8.18 hydrogen, and 14.80 oxygen. Guyaquil in South America.

Bogbutter, from the Irish peat mosses, is similar; melts at 124° , easily soluble in alcohol, and contains 73.70 carbon, 12.50 hydrogen, and 13.72 oxygen.

510. HARTINE.— $C^{20} H^{34} O^2$.

Spermaceti-like masses. $G.=1.115$. White; without taste or smell. Becomes soft at 392° , and at 410° melts to a clear yellow fluid; burns with a bright flame; it is not soluble in water, very little in ether, and less in alcohol. Chem. com. 78.26 carbon, 10.92 hydrogen, 10.82 oxygen. Oberhart in Austria.

511. MIDDLETONITE.— $C^{20} H^{20} + HO$.

Round masses or thin layers. Brittle, but easily cut with a knife. $G.=1.6$. Resinous. Reddish-brown by reflected, deep-red by transmitted light; streaked, light-brown. It becomes black on exposure to the atmosphere. Chem. com. 86.44 carbon, 8.01 hydrogen, 5.56 oxygen. In the main coal seam at Middleton near Leeds, and at Newcastle.

512. OZOKERITE.— CH .

Amorphous, sometimes fibrous. Very soft, pliable, and easily fashioned with the fingers. $G.=0.94...0.97$. Glimmering or glistening; semitranslucent. Yellowish-brown or hyacinth-red by transmitted, dark leek-green by reflected light. Pleasant aromatic odour; fuses easily (at 144° , *Schrötter*; at 183° , *Malagutti*) to a clear oily fluid, again becoming solid when cold, and at higher temperatures burns with a clear flame, seldom leaving any ashes; readily soluble in oil of turpentine, with great difficulty in alcohol or ether. Chem. com. 85.7 carbon, and 14.3 hydrogen. Slanik and Zietriska in Moldavia, and near Garning in Austria. Also Urpeth coal mine near Newcastle-on-Tyne.

513. HATCHETINE, Mineral Tallow.

Flaky, like spermaceti; or sub-granular, like bees' wax; soft and flexible. $G.=0.6$. Translucent; weak pearly. Yellowish-white, wax-yellow, or greenish yellow. Greasy; inodorous; readily soluble in ether. Chem. com. 85.91 carbon, and 14.62 hydrogen, or similar to ozokerite. Glamorganshire (fusible at 115°); Loch Fyne near Inverary. Also Merthyr-Tydvil (melts at 170°), and Sooldorf in Schaumburg.

Mineralogy.

Mineralogy.

514. FICHELITE.— $C^4 H^6$. Crystalline lamellæ, which swim in water, but sink in alcohol. White and pearly. Fuse at 115° , but again become crystalline on cooling; very easily soluble in ether, and precipitated by alcohol. Chem. com. 89.3 carbon and 10.7 hydrogen. In pine trees in a peat moss near Redwitz in Bavaria.

515. HARTITE.— $C^6 H^6$. Resembles spermaceti or white wax; lamellar, and probably monoclinohedric. Sectile, but not flexible. $H.=1$; $G.=1.046$. Translucent; dull resinous. White. Melts at 165° , and burns with much smoke; very soluble in ether, much less so in alcohol. Chem. com. 87.50 carbon, and 12.10 hydrogen. Oberhart in Austria.

516. KÖNITE.— $C^2 H$. Crystalline foliæ and grains. Soft. $G.=0.88$. Translucent; resinous. White, without smell. Fuses at 120° to 137° Fahr; soluble in nitric acid, and precipitated by water in a white crystalline mass. Chem. com. 92.31 carbon and 7.69 hydrogen. Uznach near St Gallen, Redwitz in Bavaria.

517. SCHEERERITE.— CH^2 . Monoclinohedric; tabular or acicular. Soft and rather brittle. $G.=1.0...1.2$. Translucent; resinous or adamantine. White, inclining to yellow or green. Feels greasy, has no taste, and when cold no smell, but when heated a weak aromatic odour. Insoluble in water; but readily in alcohol, ether, nitric, and sulphuric acid. Chem. com. 75 carbon, and 25 hydrogen. Uznach. *Branchite*, white, translucent, feels greasy, and fuses at 167° , is similar; Monte Vaso in Tuscany.

518. IDRIALITE.—(Idrialine = $C^{42} H^{14} O$). Massive; fracture uneven or slaty. Sectile. $H.=1.0...1.5$; $G.=1.4...1.6$ ($1.7...3.2$). Opaque; resinous. Grayish or brownish-black; streaked blackish-brown, inclining to red. Feels greasy. Burns with a thick smoky flame, giving out sulphurous acid, and leaving some reddish-brown ashes. Chem. com. idrialine = 91.83 carbon, 5.30 hydrogen, and 2.87 oxygen) and cinnabar, with a little silica, alumina, pyrite, and lime. The idrialine may be extracted by warm olive oil or oil of turpentine, as a pearly shining mass. Idria.

FAMILY V.—INFLAMMABLE SALTS.

519. MELLITE, Honey Stone.— $Al \bar{M}^3 + 18 H$. Tetragonal; $P 93^\circ 6'$. Crystals, P alone, or with OP, $P\infty$, and $\infty P\infty$, usually single; also massive and granular. Cleavage, P very imperfect; fracture conchoidal; rather brittle. $H.=2.0...2.5$; $G.=1.5...1.7$. Transparent to translucent; distinct double refraction; resinous or vitreous. Honey-yellow to wax-yellow or reddish; streak whitish. In the closed tube it yields water. B.B. car-

bonizes without any sensible odour, at length burns white, and acts like pure alumina; easily soluble in nitric acid or solution of potash. Chem. com. 40.53 mellic acid ($\bar{M}=C^4 O^3$), 14.32 alumina, and 45.15 water. Artern in Thuringia, Lausnitz in Bohemia, and Walchow in Moravia.

520. OXALITE, Humboldtine.— $2 Fe \ddot{C}^3 + 3 H$. Capillary crystals; also botryoidal or in plates, and fine granular, fibrous, or compact. Fracture uneven or earthy; slightly sectile. $H.=2$; $G.=2.15...2.25$. Opaque; weak resinous or dull. Ochre or straw yellow. B.B. on charcoal becomes first black then red; easily soluble in acids. Chem. com. 42.7 oxalic acid, 41.4 iron protoxide, and 15.9 water. Kolosoruk near Bilin, Duisburg, and Gross Almerode in Hessa.

521. HEWELLITE.— $\dot{Ca} \ddot{C} + 7 H$. Monoclinohedric; $C=72^\circ 41'$, $\infty P 100^\circ 36'$. Cleavage, basal perfect; very brittle. $H.=2.5...2.8$; $G.=1.833$. Transparent to opaque; vitreous. Colourless. Chem. com. 49.31 oxalic acid, 38.36 lime, 12.33 water. Hungary (?).

522. CONISTONITE.— $\dot{Ca} \ddot{C} + 7 H$. Rhombic; $\infty P 97^\circ 5'$. Slightly sectile. $H.=2$; $G.=2.052$. Transparent to translucent; vitreous. Colourless. Soluble without effervescence in n. acid. Chem. com. 28.1 oxalic acid, 21.8 lime, and 50.1 water. Coniston in Cumberland.

Though properly not a simple mineral, the characters of water in its two conditions may be noted here.

*523. WATER.—HO.

Fluid and amorphous. $G.=1.000$ when pure, but seawater 1.027 and 1.0285 at 62° Fahr. When pure it is without taste or smell, and colourless in small quantities, but in larger masses green or blue. Chem. com. hydrogen-oxygen, with 88.9 oxygen and 11.1 hydrogen. Attains its greatest density at $39^\circ.1$, boils at 212° , and at 32° Fahr. freezes and changes to

ICE.

Rhombohedral; $R 117^\circ 23'$ (120°); usually six-sided tables of OR. ∞R ; also acicular crystals, macled in delicate groups or stars with six rays. Cleavage, probably basal. $H.=1.5$; $G.=0.9268$ (*Ossann*), 0.918 (*Brunner* at 32° Fahr., and quite pure). Transparent; vitreous. Colourless, but in large masses greenish or bluish. Refracts double.

The water found on the earth is never pure, but contains more or less of various substances,—atmospheric air, carbonic acid, nitrogen gas; silica, alumina, and salts (carbonates, sulphates, nitrates, phosphates) of lime, magnesia, soda, potash, protoxides of iron and manganese; or chlorides, and fluorides of the metallic bases; and in the sea and some saline springs also iodine and bromine. (J. N.—L.)

II. GEOLOGY.

Geology.

INTRODUCTION.

It is not easy to give an accurate and comprehensive definition of the science of geology; for its nature is so complex and various, that it is difficult, in a few words, either to specify its object or to assign its limits.

It is, indeed, not so much one science, as the application of all the physical sciences to the examination and description of the structure of the earth, the investigation of the processes concerned in the production of that structure, and the history of their action.

We might, perhaps, without impropriety, classify all the physical sciences under two great heads, namely, Astronomy and Geology. The one would comprehend all those sciences which teach us the nature, the constitution, the motions, the relative places, and the mutual action of the Astra, or heavenly bodies; while the other singled out for study the one Astrum on which we live, namely, the earth.

Giving this wide meaning to geology, it would include all the sciences which treat of the constitution and the distribution of the inorganic matter of our globe, as well as those which describe to us the living beings that inhabit it. These sciences are—first, that of chemistry and mineralogy (which may be called one), which teaches us what are the elements of which terrestrial matter is composed, and what are the laws which govern the combinations of those elements into all the variety of known substances, solid, fluid, or gaseous, and the forms, properties, and qualities of those substances; secondly, the science of natural history or (biology, the science of life), including botany and zoology in their widest acceptance; and thirdly, that of meteorology and physical geography (which may also be looked on as one), which describes to us the form and disposition of land and water, and air, and the distribution of the temperatures and motions that affect them.

The sciences commonly included under the head of physics, those which teach us the nature and laws of magnetism, electricity, light, heat, force, and motion, would be common ground to geology and astronomy, serving to bind together all human knowledge of matter and its laws into one great whole.

Let it not be supposed that the giving this high place to geology, arises from a wish unduly to exalt it at the expense of the other sciences. Our object is to show that this large view of geology is not only a true, but a necessary one, and that if we do not sometimes look at it from this aspect, we cannot fully describe, nor can the reader rightly understand and appreciate what geology is.

That it is true, is shown by the very fact of the late appearance of geology in the world of science. It was not till some very considerable advances had been made in all the physical sciences which relate directly to the earth, that geology could begin to exist in any worthy form. It was not till the chemist was able to explain to us the true nature of the mineral substances of which rocks are composed; not till the geographer and the meteorologist had explored the surface of the earth, and taught us the extent and the form of land and water, and the powers of winds, currents, rains, glaciers, earthquakes, and volcanoes; not till the biologist (naturalist) had classified, and named, and accurately described the greater part of existing animals and plants, and explained to us their physiological and anatomical structure, and the laws of their distribution in space;—that the geologist could, with any chance of ar-

iving at sure and definite results, commence his researches into the structure and composition of rocks, and the causes that produced them, or utilise his discoveries of the remains of animals and plants that are inclosed in them. He could not till then discriminate with certainty between igneous and aqueous rocks, or between living and extinct animals, and was therefore unable to lay down any one of the foundations on which his own science was to rest.

Neither would it be a satisfactory classification if we were to limit the range of geology to any period of the earth's history; to assign to it, for instance, all time previous to the existence of the human race, and, uniting all the natural sciences under it up to that time, consider it then to be brought to an end, or to split up and diverge into the many independent sciences that concern our contemporary existences, whether organic or inorganic. For not only is there no trace of any hard boundary line between the human and the pre-human period of the earth's natural history; but there appears in each one of the separate natural sciences a perfect blending and continuity from the remotest geological era to the present time. The present is but a part of the past. The inorganic objects we see around us are the result of processes going on in past time, such as are still at work producing the same results; the living beings around us are either the direct descendents of those that lived formerly, or their substitutes and representatives, the living and the extinct forming parts of one great connected series and chain of species, genera, and orders, each of which parts would be incomplete without the other. There is therefore no possibility of making any division in geology such as we are now considering it, or assigning any limit to its range from the earliest period of the earth's ascertainable history to the present moment.

Moreover, as there is no natural science to which the geologist has not to appeal for information upon some point or other in his researches, so there is none which can be fully and completely studied without the help of the geologist, or without including facts or theories which are commonly and rightly reckoned parts of his peculiar intellectual domain. If he has to call upon the professors of each one of the physical sciences in turn, for assistance in his own investigations, he is sure, sooner or later, to repay the obligation by the discovery of a number of facts that enlarge the boundaries of the science he has applied to, or the statement of many problems whose solution throws light upon parts of it that have been hitherto imperfect and obscure.

It is not intended that the reader should infer from what has been said, that in order to be a geologist, he must be thoroughly acquainted with the whole circle of the physical and natural sciences. Such universal acquirement few men have the power to attain to, and of these still fewer retain the ability and the will to make original advances in any particular branch.

No man, however, can be a thorough geologist without being acquainted, to some extent, with the general results of the other sciences, and being able both to understand them when stated in plain untechnical language, and to appreciate their application to his own researches. Such a general acquaintance involves neither profound study, nor requires any great power of mind above the average of hu-

Geology.

Geology. man intellect. It is, indeed, what every well-educated man ought to possess.

The necessary preliminary to the science of geology is not the possession of great and accurate knowledge of the whole circle of the natural sciences by any individual persons, but that this knowledge must exist somewhere. Some man or men must have this knowledge, and must be able to combine it, either piecemeal or at once, with the special knowledge of the geologist, before the latter can hope to solve the many difficult and profound problems that arise in the course of his researches.

It may be said with perfect truth, that the geologist is less able than any other student of science to pursue his investigations alone, and independently of the assistance of others; but this is, in fact, only saying in other words that which we are insisting on, namely, that geology in its highest and widest sense embraces all the physical and natural sciences, and is, as it were, made up of them.

If, however, this wide scope be properly given to the term geology, and it be made to include every physical science that treats of anything belonging to the earth, what, it may be asked, is the special business to which the geologist devotes himself as distinct from the follower of other sciences? What is that which he does, and the others do not? Above all, what is that which he teaches to the rest in return for the knowledge communicated to him?

The answer to these questions will show us that there is another and a more restricted sense of the word geology than the wide and general one in which we have been using it. This sense is rather the one formerly attached to the word *geognosy*, by which we may understand the knowledge of the nature and position of the different masses of earthy or mineral matter of which different districts and countries are composed without reference to the history of their production. This was the early and simple meaning of the word geology, when considered as synonymous with *geognosy*, namely, the examination and description of the different varieties of rocks and the minerals they contained. Geology was looked upon in the light of a geographical mineralogy, and even yet it is regarded more or less under this aspect by many persons. No one, indeed, could have anticipated, from the mere study of masses of stone and rock, where, to a partial and local view, all seems confusion and irregularity, the wonderful order and harmony which arise from more extended observation and the almost romantic and seemingly fabulous history which becomes at length unfolded to our perusal. To discover the records on which this history is founded, and to understand their meaning aright, frequent, long-continued, and wide-spread observation and research in the field, and patient and conscientious registration and comparison of the observed facts in the closet, are absolutely necessary.

This collection and co-ordination of facts it is which is the proper and peculiar business of the *geognost*. The ditch, the "cutting," the quarry, and the mine; the cliff, the gully, the mountain-side, and the river-bank; these are his "*subjects*,"—that which he has to study, to examine, to dissect, to describe the minutiae of the structures they expose, and to classify and arrange the facts they may afford, depicting their lineaments on maps and sections, and recording them in written descriptions. The business of the *geognost*, then, is to make out, from indications observed at the surface and in natural and artificial excavations, the internal structure, the *solid geometry*, of district after district, and country after country, until the whole earth has been explored and described. If, while so doing, he notes all those facts which may enable him or others to understand and explain how that structure has been produced, he then becomes a geologist.

It might at first be thought that in order to make out

the solid structure of lands and countries it would only be necessary to understand the nature of the mineral matters of which they were composed, and that for this purpose no knowledge of organic or living beings would be required. It is, however, one of the most remarkable results of geological science that an acquaintance with organic, and especially with animal forms, is at least as necessary for a geologist as a knowledge of minerals, and that a correct knowledge of organic remains (portions of fossil plants and animals) is a more certain and unerring guide in unravelling the structure of complicated districts than the most wide and general acquaintance with inorganic substances.

The cause of this necessity, puzzling and paradoxical enough, perhaps, at first sight, may be briefly stated as follows. When we come to examine the structure of the crust of the globe, we find that its several parts have been produced in succession, that it consists of a regular series of earthy deposits (all called by geologists rocks) formed one after another during successive periods of time, each of great but unknown duration. Now, the mineral substances produced at any one period of this vast succession of ages do not appear to have had any essential difference from those formed at another. We cannot, therefore, with any certainty, discover the order of time in which the series of rocks was formed, or the order of superposition which they consequently preserve with regard to each other, from an examination of their mineral character or contents only. The animals and plants, however, living at one period of the earth's history were different from those living now, and different from those living at other periods. There has been a continuous succession of different races of living beings on the earth following each other in a certain regular and ascertainable order, and when that order has been ascertained, it is obvious that we can at once assign to its proper period of production, and therefore to its proper place in the series of rocks, any portion of earthy matter we may meet with containing any one, or even any recognisable fragment of one, of these once living beings.

Just as when we find under the foundation-stone of any ancient building a parcel of coins of any particular sovereign, we know that the erection of that building took place during his reign; so when we find a fragment of a known "fossil" in any piece of rock, we feel sure that that rock must have been formed during the period when the animal or plant of which that fossil is a part was living on the globe, and could not have been formed either before that species came into existence or after it became extinct.¹ In cases, therefore, where the original order of the rocks has been confused by the action of disturbing forces, or where the rocks themselves are only at rare and wide intervals exposed to view, their order of deposition and consequent succession of place may be more easily and certainly ascertained by the examination and determination of their fossil contents than by any other method.

Practically, it has been found that while a very slight acquaintance with the most ordinary forms of some ten or a dozen of the most frequently occurring minerals is all that a geologist must *inevitably* learn of mineralogy, the number of fossil animals and plants, with the forms and the names of which he will have to make himself familiar, will often have to be reckoned by hundreds.

This branch of geological knowledge is now known under the name of *Palæontology*.

Perhaps, however, the tendency of late years has been to neglect to too great an extent the bearing of mineralogical

¹ The very rare and exceptional cases in which ancient coins *may* have been deposited in the foundation of a recent building, or fossils originally in one rock may have been washed out and buried in another, need not more than a passing notice.

Geology. knowledge on geology. There are many subjects on which we have still to ask the chemist and mineralogist to enlighten us.

One deficiency which is particularly obvious in Britain is the want of a good and precise nomenclature of rocks, and especially of igneous rocks. Since the publications of Jameson and Macculloch no attempt has been made in English to supply this deficiency, and to bring up our lithological nomenclature to the present state of chemical and mineralogical knowledge. Neither was the want succinctly supplied in any other language till the appearance of the *Gesteinslehre* of Bernhard Cotta. By the assistance of this and other works we hope, to some slight extent, to supply the deficiency in this treatise.

DISTRIBUTION OF THE SUBJECT.

In order to reduce the great subject of geology to something like order, it appears advisable to divide it into three heads, for which we may use the terms—1. Geognosy; 2. Palæontology; and, 3. The History of the Formation of the Series of Stratified Rocks.¹

PART I.—GEOGNOSY.

SECT. I.—LITHOLOGY.

CHAP. I.—ON THE ORIGIN AND CLASSIFICATION OF ROCKS.

Lithology, or the study of the mineral structure of rocks, is based on mineralogy. The number of minerals, however, which enter so essentially into the composition of rocks, as to be called their constituents, is very few when compared with the whole number of minerals known to the mineralogist.

The principal rock constituents are the following.—One simple substance, namely, carbon; one primary compound, silica or quartz, to which, perhaps, rock-salt may be added; and the following secondary compounds, made up of two or more primary compounds, namely, carbonate of lime (calcite or calc spar), sulphate of lime (gypsum), and a number of silicates, which may be grouped under four heads, as the Felspars, the Hornblendes or Augites, the Micas, and the Zeolites.

Crystallization.—One of the most obvious properties of minerals is their crystallization. All crystals are, as it were, built up of minute crystalline particles of like forms, and have been produced by the successive external additions of these minute particles.

It is clear, then, that these particles must have been free to move and arrange themselves; in other words, they must have been in a *fluid*, or *nearly fluid* state. But this fluidity may have been the result either of *solution* in water or other liquids, or of *fusion* by heat. Whenever, then, we find a crystal or a mineral particle that has an internal crystalline structure, we may feel assured that it has once been either *dissolved* or *melted*.

But if this be true as regards individual crystals or crystalline particles, it must be true also of rocks that are made up of such crystals or such particles.

Now some minerals, as, for instance, carbonate of lime, are readily soluble in water containing carbonic acid gas, or in liquid acids; if, therefore, we meet with a rock composed of crystalline particles of carbonate of lime, we could easily believe that it had once been dissolved in water and deposited from that solution.

As regards the solid acid silica, it is also soluble in water

By Geognosy may be understood the study of the structure of rocks independently of their arrangement into a chronological series, and it might be divided into two parts—Lithology and Petrology. By Lithology is meant the study of the internal structure, the mineralogical composition, the texture, and other characters of rocks, such as could be determined in the closet by the aid of hand specimens.

Under Petrology we may arrange the larger characteristics of rocks, the study of rock-masses, their planes of division, their forms, their positions and mutual relations, and other characters that can only be studied in "the field," but without entering on the question of the geological time of their production.

The subject of Palæontology will be left for a separate article, but under the head of "History of the Formation of the Series of Stratified Rocks," a condensed abstract of that history will be given, in the form of a chronological classification, mentioning some of the principal and typical groups of rocks known to have been produced at different parts of the earth during each of the known great periods of its existence.

containing carbonic acid gas or some other substances, and also when in certain chemical states, and in water at a high temperature. We can therefore easily understand the deposition of crystals of silica or quartz from aqueous solutions.

For the production of many silicates, however (as, for instance, the artificial silicates, porcelain, slag, and glass), great heat is necessary, and the consequent fusion that takes place. We know, also, with regard to many, if not most of the natural silicates, that they are practically insoluble in water, or in any other fluids which are found abundantly in nature.

When, then, we meet with rocks composed altogether of crystals, or crystalline particles, of such silicates, we are compelled to conclude that those rocks were once in a state of fusion from heat.

But in each of these cases we should find gradations from some rocks in which the crystalline particles were large and distinct, through others where they became less and less, and were eventually only discernible with a lens, into some at last which appeared quite *compact* and homogeneous. The very fact of the gradation, however, would teach us that what was true of the crystalline rocks might also be true of *compact* rocks of the same mineral composition, and that therefore crystalline and compact limestone, quartz crystals and compact flints, might equally have been dissolved in water, and crystalline and compact silicates equally been melted by heat. In the latter case the artificial silicate glass again assists us, since we know that the very same mass which, if cooled under given circumstances, will form a perfectly homogeneous glass, will, if allowed to cool more slowly, become opaque and stony, and that ultimately it will begin to granulate, that is, its constituents will begin to separate from each other and form distinct crystals in the mass.

Chemical Rocks.—These considerations at once prepare us for the belief that many rocks have been chemically formed, that is, have consolidated from fusion or solution in obedience to chemical laws. Those that have become consolidated from fusion we may call Igneous rocks; those that have consolidated from solution Aqueous rocks.

¹ Stromatology (from *στρωμα*, stratum) might perhaps be used to express this portion of geology.

Geology.

Chemically-formed aqueous rocks may be either crystalline or compact.

Chemically-formed igneous rocks may be either crystalline, compact, or glassy.

Both kinds may have occasionally concretionary, nodular, sparry, fibrous, or other textures, according to local modifying circumstances.

In chemical crystalline rocks, whether aqueous or igneous, the external forms of some of the crystals are often very imperfect and sometimes even irregular. Crystals of one mineral having been first formed, prevented the regular formation of the crystals of the other minerals; or the whole mass having crystallized together, the crystals were mutually hindered from attaining their full development by the growth of their neighbours, and all became thus locked and interlaced together in a congeries of mutually imbedded and intertangled crystalline particles.¹

These crystalline particles, although not perfect crystals, have yet some faces and angles of perfect crystals, being evidently formed in the position where we now find them. They are *innate* or *ingrown* crystalline granules.

Loaf-sugar, sugar-candy, crystallized alum, are familiar examples of this structure, and will serve to explain what is meant by the *innate* crystalline structure of marble or of granite.

Mechanical Rocks.—When, however, we began to study rocks with a view to examine into their mineral constitution, we should soon become aware of another essential difference in them. We should find some rocks the particles of which were large and distinct, but not at all crystalline; or if crystalline internally, we should see that their external form was not regular like a crystal, but exhibited evident marks of mechanical fracture and attrition, of wearing away, or rounding.

The particles of the rocks which are now alluded to, whether internally crystalline or internally compact, are not mutually imbedded and interlaced, like those of chemical rocks, and have no such appearance of having *grown* where we now find them, but have evidently been brought together from different places, and adhere to each other either in consequence of having been squeezed together by mechanical pressure, or because they are cemented by some other substance which serves to bind and unite them to each other.

In these rocks the particles are generally more or less rounded and smoothed externally, as if water-worn.

This water-worn form and derivative origin is very obvious with respect to some of these rocks, which consist of *pebbles* or rounded fragments of other rocks, compacted together in *sand*, which is clearly the result of the rounding process.

In many cases the very rock from which the pebbles were derived can be pointed out, and the distance, therefore, which they have been carried is known. In other cases the fact of mechanical transport is equally obvious, though the original site may be unknown.

From those cases where the particles are large and their form distinctly visible, there is every gradation through those where they become less and less, till at length they are not discernible by the lens. We have, then, compact derivative rocks just as we have compact chemical ones.

To all such derivative rocks we may with great propriety assign the term *Mechanical*, as showing that their

materials have been mechanically transported to their present sites.

The machinery employed in this transportation must clearly be either currents of water or currents of air, and the mechanical rocks, therefore, must be all either Aqueous or Aerial rocks, the latter being very few and unimportant compared with the former.

Even with regard to igneous rocks, which must in themselves be purely chemical compounds, they still may have their mechanical accompaniments whether they were formed in the air or in the water, as we see in the case of the ashes, cinders, and fragments blown from the mouths of volcanoes.

Organic Rocks.—There is yet another source from which some rocks are derived, inasmuch as some are found to be wholly, or almost wholly, composed of fragments of animals or plants. These rocks may be termed *Organic*, in the sense of organically-derived rocks.

The portions of the plants or animals may be either little altered from their original condition, or very much altered and altogether mineralized. In the first case, they belong perhaps more particularly to the mechanically, in the latter, to the chemically, formed rocks.

Mixtures.—As, moreover, chemical precipitates are liable from many causes to be adulterated with mechanical impurities, and mechanical deposits to be impregnated with chemically acting gases or liquids, and as both mechanical admixtures and chemical actions and reactions may play a part in the formation of rocks made of organic materials, we can easily see how all three classes of rocks may occasionally be mingled together and pass into each other, and how many aqueous rocks may have been formed by the union of two or of the three agencies, and appear to belong to one or the other class according to the point of view from which we observe them.

We have now arrived, then, at the conclusion that different rocks had an aqueous, an igneous, or an organic origin, solely from the consideration of the nature of the mineral particles composing them. This conclusion, however, by no means depends entirely on such considerations. The aqueous rocks are known to be so, not only from their being composed of soluble minerals, or of minerals that have been water-worn, or parts of plants and animals that have either lived in water or been carried down into it, but also because their materials are arranged in regular layers and beds or *strata*, obviously the result of their having been regularly *strewed* out over the bottom of the seas and lakes in which they have been deposited. They are hence often called *Sedimentary* and *Stratified* rocks.

The igneous rocks, on the other hand, are many of them such as we see now to be poured forth from the mouths of volcanoes in the state of molten lava; others again are closely allied to these, and there is a regular chain of gradation from these through their whole series.

Those which least resemble actual lava are found sometimes to have been injected, in the form of veins and tortuous strings, into the cracks and crevices of other rocks, or to have cut through them in great wall-like masses called “*dykes*” just as lava does. In many of these cases they have exerted just such an influence on the rock they came in contact with as great heat would have exercised. The neighbouring rocks have in fact been burnt, and are sometimes greatly altered from their original state as seen at a distance from the igneous rocks.

Metamorphic Rocks.—This fact, together with the consideration of the chemical actions and reactions that may be set up in the mass of rocks by the percolation of various fluids or gases, and the mechanical or chemical forces that may be brought into play by the action of pressure and other agencies, naturally disposes us to ask the question,—Whether many rocks as we now see them may not be in a

¹ The paragenesis of minerals in chemically-formed rocks is a subject that has not yet received the attention it deserves. The peculiar association of minerals, and the relative order of their crystallization, as shown by their mutual indentation and envelopment, would, if accurately observed and described, doubtless explain much that is still obscure as regards the formation of such rocks, as also that of the contents of mineral veins.

Geology.

Geology. very different state from that in which they were originally formed? We should ultimately find reason to answer this question in the affirmative, and introduce another class under the head of Metamorphic (or transformed) rocks, to include those which had, by means of subsequent alteration, acquired any essentially different characters from their original ones.

Guided by these considerations, we may class all rocks whatever under the four great heads of *Igneous*, *Aqueous*, *Aerial*, and *Metamorphic*.

The *Igneous* are almost entirely chemically-formed rocks, but some of their varieties have their mechanical accompaniments.

The *Aqueous* rocks are either chemical, mechanical, or organic, those of mechanical origin being far the most abundant, although not the most important kinds.

The *Aerial* are all mechanical.

The *Metamorphic* are either those in which the original structure and composition are still obvious, or those in which those characters are altogether obscured and replaced by others produced either by heat, or pressure, or both conjoined.

We shall commence with the description of the igneous rocks, because these may be looked upon as those most essentially original and self-subsisting, or most independent of the others.

Before entering on the technical description of rocks, however, it will be as well, perhaps, to define exactly, what we mean by the term rock.

A *mineral* is an inorganic substance that has a definite chemical composition, and a regular and symmetrical form; each of the particles of which it is made up exactly resembling all the other particles.

A *rock* is a mass of mineral matter consisting of many individual particles, either of one species of mineral, or of two or more species of minerals, or of fragments of such particles. These particles need not at all resemble each other either in size, form, or composition; while neither in its minute particles, nor in the external shape of the mass, need a rock have any regular symmetry of form.

Geologists are accustomed also to include under the term rock, all considerable accumulations of mineral matter, whether they be hard or soft, compacted or incoherent. In this sense soft clay, loam, or loose sand, may be called "a rock."

CHAP. II.—IGNEOUS ROCKS.

The igneous rocks are divided by Sir C. Lyell and others into two classes—the Volcanic and the Plutonic. Such a classification is theoretically correct, as separating those formed at the surface, in air or water, from those formed deep in the earth; but practically we often meet with rocks that it is difficult to place with certainty in either class. It is, moreover, often advisable to avoid terms that involve theoretical or foregone conclusions. For these reasons we should prefer, with Sir R. I. Murchison and others, to arrange the igneous rocks under three heads—Volcanic, Trappean, and Granitic; taking the middle term, Trappean, as one of convenience only, to include some that are possibly volcanic, some that are more essentially granitic, with many intermediate or undetermined rocks between the two.

Igneous rocks differ among each other—

1st, As being made up of different minerals.

2d, As having different textures.

The three principal varieties of textures are the crystalline (or granular), compact, and glassy.

When a rock is distinctly granular, so that the crystals of its mineral constituents are clearly discernible, they may be determined by simple inspection. In the compact and vitreous textures, however, the determination of the mineral constituents of a rock can only be arrived at by chemical

Geology: analysis. This will enable us to find out of what substances the rock consists, and what are their proportions; and the consideration of these proportions, and the comparison of them with those forming different minerals, will enable us to determine with greater or less certainty of what minerals the rock is composed, or, at all events, what minerals it would probably form if they were allowed to develop themselves.

It has been shown from the processes of the manufacture of glass, that the very same molten mass of silicates would form transparent glass, opaque slag, or crystalline stone, according to circumstances. As these different conditions of texture receive different names, so may the different textures of natural substances receive different names, notwithstanding that in some cases they consist of essentially the same ingredients.

As some slags become porous, or vesicular, and thus pass into cinders, so some igneous rocks likewise assume a vesicular or cindery texture.

When the pores or vesicles become filled with a crystalline nucleus or kernel of any mineral, either by subsequent infiltration, or during the process of consolidation, so that the dispersed crystalline patches look like almonds stuck into the mass, the rock is said to be amygdaloidal.

When single detached crystals are disseminated through a compact base, or large crystals through a fine-grained base, the rock is said to be porphyritic. The term Porphyry, then, which has been often used as a designation for a particular class of rocks, will here be used chiefly, or solely, to distinguish this variety of texture, which is one that may occur in every kind of igneous rock.

From what has been said before, it may be inferred that all igneous rocks without exception are composed of minerals which are silicates.

These minerals may be said to belong to two great classes,—silicates of magnesia and silicates of alumina,—the species or varieties of each resulting from their various mixtures with silicates of potash, soda, lime, iron, manganese, &c. The silicates of magnesia, &c., constitute the hornblende, or pyroxenic, or augitic minerals; the silicates of alumina, &c., forming the feldspathic ones. The micaceous minerals, which we may look on as resulting from mixtures of the two, or as holding an intermediate place between them, are in reality of minor importance so far as unaltered rocks are concerned.

The feldspars are the basis of all igneous rocks, those in which no feldspar of any kind is present being very few and unimportant, even if they exist at all. The hornblende and augitic minerals hold the next most important place; and the volcanic and trappean rocks may be divided into two great series depending on the amount of those minerals which are mingled with the feldspars. Those rocks in which feldspar alone occurs, or in which it greatly predominates, may be called the feldspathic rocks; those in which the hornblende or augitic minerals play a considerable part may be called hornblende or pyroxenic rocks. It must, however, be clearly borne in mind that feldspar in some form or other is always the basis of the latter, while hornblende and augite in any form are often entirely absent from the former.

I.—THE VOLCANIC ROCKS.

These are often spoken of under the general term of Lava. They include, however, some that would be more commonly described as trap rather than lava, and others, such as tuff and ashes, which could not strictly be called by either name.

The volcanic rocks have been classified by Abich under three heads,—*Trachyte*, *Dolerite*, and *Trachydolerite*. Bunsen, also, in his Memoir on the Volcanic Rocks of Iceland, gives a similar classification, describing his *normal*

Geology. *trachytic* rocks as one end of the series, and his *normal pyroxenic* rocks as the other end, with many intermediate varieties between the two.

Bunsen gives us the following as the mean value of the composition of his two normal rocks:—

	Normal Trachytic. Trachyte.	Normal Pyroxenic. Dolerite.
Silica.....	76·67	48·47
Alumina and protoxide of iron...	14·23	30·16
Lime.....	1·44	11·87
Magnesia.....	0·28	6·89
Potash	3·20	0·65
Soda.....	4·18	1·96
	100·00	100·00

He then shows that, by analyzing any intermediate variety of rock, and determining the proportion of any one of these ingredients (taking the silica as the easiest and best), the proportion of the other ingredients may be calculated, and thus may be determined the quantities of these two normal substances which have been mixed together to form the rock in question.

In the following descriptions of the volcanic rocks we are largely indebted to Cotta's *Gesteinslehre*, to the Introduction to Daubeny's *Volcanoes*, and to the last chapter of the third volume of D'Archiac's *Histoire des Progrès de la Géologie*.

The Trachytes are so called from the Greek word *τραχύς*, rough, as they commonly have a rough prickly feel to the finger. They are usually light-coloured, pale gray, or white, but sometimes dark gray and nearly black. They are composed principally of feldspar,—the feldspar being one of the varieties that is rich in silica, such as orthoclase, adularia, or albite, and not any of those in which the bases are more abundant, such as labradorite or anorthite.

As Trachyte is made into a class as well as a species of rock, we may similarly elevate Dolerite.

The Dolerites, so called from the Greek *δολερός*, deceptive, are usually of a dark green or black colour, weathering brown externally. They are commonly heavier than the Trachytes, as containing a less proportion of silica and a greater one of the heavier bases.

They are composed partly of a feldspathic and partly of an augitic or pyroxenic mineral, the feldspar being commonly, though not perhaps invariably, one of the more basic silicates, such as anorthite or labradorite.

The Trachytes, or Feldspathic Lavas.

1. *Trachyte*, properly so called, has either a fine-grained or quite compact texture, a harsh feel, and sometimes a cellular and scorified appearance. It varies in colour from a pale gray to dark iron gray, and is sometimes reddish, from the presence of iron. It is composed of a confused aggregation of crystals of feldspar, often minute and needle-shaped, but with others larger and more distinct.

This feldspar is said to be commonly potash albite (or pericline), and glassy feldspar (or adularia), in which some of the potash is replaced by soda. Crystals of mica and hornblende are often present, and sometimes even of augite, the whole either confusedly united without cement, or embedded in a feldspathic paste, either cellular or compact.

2. *Trachytic porphyry* has seldom a scorified aspect, looking often more like a plutonic than a volcanic rock, as that of the Pic de Sancy, and the Roc de Cacadoigne, of Mont Dor, which at first sight resembles granite in external appearance.

Crystals of glassy feldspar, sometimes small, but sometimes as much as half an inch long, white or flesh-coloured, are set in a compact light-coloured feldspathic paste, with brown mica, and sometimes also with crystals of quartz.

"Many varieties of trachytic porphyry contain a number of very small globules, which seem to consist of melted feldspar, having often in their centre a little crystal either of quartz or mica. The

assemblage of these globules leaving minute cells between them, sometimes gives to the rock a scorified aspect." (Daubeny.) Chalcedony occurs in small geodes,¹ and sometimes intimately mixed with the paste in which the crystals are imbedded.

Trachytic porphyry passes sometimes by insensible gradations into—

3. *Pearlstone*, which is composed of a number of globules from the size of a nut to that of a grain of sand, of a vitreous or enamelled aspect, and pearly lustre, adhering together without any paste.

These sometimes lose their lustre and size, and pass into a compact stony mass, or change into globules of feldspar, compact, or radiated—the whole rock being composed of them. Many variations occur; the whole sometimes becoming fibrous, cellular, spongy, and passing gradually into pumice.

4. *Domite* is a grayish white, fine-grained, compact, earthy, and often friable variety of trachyte. It frequently contains flakes of brown mica.

It appears to be a decomposed trachyte, in which the feldspar is affected, but the mica not. The passage of muriatic (hydrochloric) acid is, by some, supposed to have affected this transformation. It is a remarkable rock, but not one of general occurrence beyond the district of the Puy de Dôme, in France.

5. *Andesite*, a trachytic rock, found at Chimborazo and other parts of the Andes; has white crystals resembling albite in a crystalline base of a dark colour. It has various degrees of compactness and consistency, and has a coarse conchoidal fracture.

Small crystals of glassy feldspar occur, though rarely, but those of hornblende are common; and augite is also present sometimes. From the predominance of hornblende it sometimes passes into a diorite or greenstone.

6. *Clinkstone* or *Phonolite* is a compact homogeneous rock, with a scaly or splintery fracture, sometimes conchoidal, of a grayish green, or ashy gray colour, both weathering white externally. It is often rendered porphyritic by scattered crystals of glassy feldspar, but these are commonly not very distinctly separable from it, appearing only as brilliant surfaces here and there in the mass. Hornblende, augite, and magnetic iron are rare in it. According to Gmelin it consists of a mixture of glassy feldspar, with a zeolite in variable proportions. It may, therefore, be formed from trachyte by the addition of sea-water; the soda of which, combining with some of the orthoclase, would make glassy feldspar, while the water, combining with the other constituents, would form a zeolite. (*Abich, in D'Archiac, vol. iii., p. 604.*)

Clinkstone commonly splints into thin slabs, and is often so finely laminated as to be used for roofing slate. The slabs give a metallic sound when struck with the hammer, whence its name. It is sometimes perfectly columnar; the columns splitting across into slabs, which are also used as slates. It may, however, perhaps be doubted, whether many of the so-called volcanic clinkstones really contain water according to the definition, and whether they are not a flaggy, or laminated variety of compact trachyte.

7. *Obsidian*, or *Volcanic glass*, is the vitreous condition of a trachytic rock. It is said to be necessary for its natural production that the rock should be composed of minerals rich in silica, or "trisilicates;" the simple "silicates" or "bisilicates" of alumina, being incapable of forming obsidian.² (*Daubeny, p. 16, 2d edition.*)

8. *Pumice* is the cellular and filamentous form of obsidian, and the same remarks as to origin will apply to it.

¹ Geodes are rounded concretions, generally hollow, and containing crystals. They are sometimes called "potato stones" from their size and shape.

² Without disputing the truth of the origin here assigned to all naturally formed obsidian, it is yet equally true, that basalt can be artificially converted into obsidian, by simple melting and rapid cooling. Messrs Chance of Birmingham now melt the basalt of the Rowley Hills by simple heat without the addition of any foreign ingredient, and cast it into blocks and ornamental mouldings for architectural purposes. Portions which are allowed to cool rapidly,

Geology. Abich divides pumice into two groups; the cellular, being dark green, poorer in silica and richer in alumina, derived from clinkstone, trachyte, or andesite; and the filamentous, white, containing more silica, and derived from trachytic porphyry.

The Dolerites, or Augitic Lavas.

9. *Dolerite*.—A crystalline, granular, distinct mixture of labradorite and augite with some titaniferous magnetic iron ore, and also often with some carbonate of iron and carbonate of lime. General colour dark gray.

The labradorite forms white or light gray tabular crystals, and the augite black columnar ones. Both can easily be distinguished by the naked eye, especially in the coarser varieties. The magnetic iron forms small octohedral scarcely visible grains, which can be recognised only by the magnet. (*Cotta*.)

Cotta mentions a variety from Augasse near Liegfried, which contains 28 per cent of the carbonates, three-fourths of that being carbonate of iron.

10. *Anamesite* is properly only a fine-grained dolerite, so fine-grained that we can only distinguish the fact of the granular texture, and no longer recognise the individual minerals. Its colour is dark gray or greenish or brownish black. It forms the intermediate step between dolerite and

11. *Basalt*, which is a compact, apparently homogeneous, nearly or altogether black rock, with a dull conchoidal fracture. It often contains crystals or grains of augite, olivine, or magnetic iron, and is sometimes vesicular or amygdaloidal.¹

The knowledge of the composition of basalt dates from 1836, when Gmelin showed that it was, like phonolite, an intimate mixture of one part that was decomposable in acid and another not decomposable. The decomposable portion is partly of the nature of a zeolite, partly of that of labradorite; the undecomposable portion is augite. (*Cotta*.)

Basalt, therefore, as it contains water in its zeolitic portion, bears the same relation to dolerite that clinkstone does to trachyte.

The three rocks above mentioned differ rather in texture than in mineral composition. In the two following rocks another feldspathic mineral is substituted for the labradorite.

12. *Nepheline Dolerite* is a crystalline granular mixture of nepheline, augite, and some magnetic iron. (*Cotta*.)

13. *Leucite Rock* is a crystalline granular, porphyritic-like, or even a compact, aggregate of leucite, augite, and some magnetic iron; generally gray. (*Cotta*.)

Trachy-dolerite, or Intermediate Lavas.

These rocks, from their very nature, do not admit of any precise definition or nomenclature. The rocks already named and described are mixtures of various minerals. When those mixtures are in anything like definite proportions, and the minerals are well characterized, the rocks assume a particular character, and are capable of definition. When, however, the mixtures become indefinite, and the minerals begin to pass one into another, or are so intimately blended that they cannot be distinguished, attempts at definition only lead to confusion instead of order, and encumber the memory rather than assist it.

Instead of separating these blending rocks, then, and distinguishing them by different names, it is better to follow the example of Abich, and unite them under

one term, such as that proposed by him of—14. *Trachy-dolerite*.

Neither is this a mere evasion of a difficulty, since the things themselves are so similar, both in substance and in origin, that the creation of distinct names would be merely making distinctions where no real or essential difference exists.

It may be useful, here, perhaps, to give Abich's table of the specific gravity, and the per centage of silica of some of the above rocks, arranging them according to the latter character.

	Specific Gravity.	Per centage of Silica.
1. Porphyritic trachyte.....	2.5783	69.46
2. Trachyte	2.6821	65.85
3. Glassy andesite.....	2.5851	65.55
4. Domite.....	2.6334	65.50
5. Andesite	3.7032	64.45
6. Phonolite.....	2.5770	57.66
7. Trachy-dolerite	2.7812	57.66
8. Dolerite.....	2.8613	53.09

From this it appears that the per centage of silica in porphyritic trachyte is equal to that of albite; in trachyte and andesite, equal to that of orthoclase; and in dolerite, equal to that of labradorite. Trachy-dolerite, intercalated among the rocks, as andesite and oligoclase are between potash albite, and labradorite among the feldspars, shows the passage from one to the other. Lastly, with only two exceptions, the above table shows us that the specific gravity increases as the per centage of silica diminishes; and Abich, therefore, says that the determination of these two characters, joined to the observation of the mineralogical constituents, will suffice to determine with precision to which kind any volcanic rock belongs.

There is yet another variety of volcanic rocks to be considered, that, namely, called Tuff or Peperino.

15. *Tuff* (ash) is ordinarily the ashes, dust, and powder, mixed with little lapilli and coarser fragments, blown from a volcanic focus, and falling either on to the land or into the sea. If it fall on the land it may become compacted into a rock, either by the simple pressure of its own weight, or in consequence of the percolation of water containing mineral matter in solution. This water may either be rain falling with the ashes, or rain or other water subsequently gaining access to them. If the ashes fall into the sea they become subject to the conditions under which all other mechanically-formed aqueous rocks are produced. In this case tuffs often contain fossil shells.

Abich describes the trachytic tuffs of the neighbourhood of Naples as of two sorts,—one inferior, of a clear straw-colour, characterized by fragments of glassy feldspar, augite, and hornblende; the other, or upper tuff, being white, in thinner beds, and with much pumice.

Bunsen, in his description of the volcanic rocks of Iceland, seems inclined to attribute a metamorphic origin to tuffs, and to derive them from the decomposition or alteration of the pyroxenic rocks of that island. He calls them palagonitic tuffs, the mineral palagonite (a hydrated silicate of alumina and lime) being an essential constituent of these tuffs both in Iceland and in Etna, as shown by Walterhausen.

He refers to Darwin's observations on a basaltic lava which has flowed over limestone at Port Praya (C. de Verde Islands), and says that the lava, when in contact with the limestone, possesses all the characters of palagonite.

Without denying that some tuffs may have been formed from the decomposition *in situ* of actual lava, we are still inclined to look upon that as the exception rather than the rule, and to believe that tuff in general is a mass of volcanic "ash," deposited mechanically, however it may have been subsequently modified either by igneous or aqueous agencies.

Some geologists confine the term tuff to trachytic masses, and use the word "peperino," to designate those derived from pyroxenic (or augitic) rocks.

Tuff and peperino, from the nature of their origin, must have a great variety of character, from a fine-grained compact stone to a coarse breccia or conglomerate, and from a loose incoherent accumulation to a hard tough stone.

Immense piles of volcanic sand and gravel, and great breccias composed of large semi-angular fragments, also not unfrequently occur, which would hardly be called tuff, but

form obsidian, undistinguishable by any external character from that of volcanic districts. Specimens may be seen in the Museums of Jermyn Street, London, and Stephen's Green, Dublin.

¹ According to Cotta, the rock of the Giant's Causeway, &c., in the north of Ireland, ought to be called anamesite rather than basalt.

Geology. which must not be altogether omitted in our enumeration of volcanic rocks.

II.—TRAPPEAN ROCKS.

We have before said that we adopt this designation as a convenient one only, and for the same reason we would extend it. The word "trap" has hitherto been considered to be strictly applicable only to hornblendic or augitic rocks. It is derived from the Swedish *trappa*, a stair,—those rocks being supposed usually to assume a step-like form. The term, as thus derived, is, however, no more exclusively applicable (except from custom) to the hornblendic than to the feldspathic igneous rocks, and has been often used vaguely to designate any igneous rocks which could not be said to be distinctly granitic on the one hand, or absolutely volcanic on the other. In this vague and general sense we shall here use it, its very vagueness being its recommendation as best adapted to receive a class of rocks that do not admit of any strict definition or circumscription.

As the volcanic rocks are divisible into three heads,—Feldspathic, Augitic, and Intermediate,—so we may conveniently divide trappean rocks into three similar heads,—*Feldspathic*, *Hornblendic*, and *Intermediate*. For the two first of these the general designations, Felstone and Greenstone, may be used,—felstone corresponding to trachyte, and greenstone to dolerite. It is not easy to make a combination of words answering to Abich's trachy-dolerite, but the intermediate rocks exist in abundance which would be comprised under such a designation.

Felstone is a name taken from the German *Feldstein*, and proposed by Professor Sedgwick to designate a class of igneous rocks to which many titles have been given, but which have never, we believe, been yet properly examined and described. Compact feldspar, petrosilex, and cornean, are among these names, as well as the hornstone of some geologists, though that name has also been applied to chert.

Feldstone or Feldspathic Traps.

16. *Felstone* is a compact, smooth, hard, flinty-looking rock.

It has two principal varieties,—the pale green, passing into a greenish or yellowish white; and the blue or gray, varying from pale to dark gray. The gray or blue variety weathers white, its external margin being white sometimes to the depth of a line, sometimes to that of an inch or two. Some blocks that appear wholly white have a small blue patch in the centre. The green or greenish white variety is often very translucent at the edges; the gray is commonly opaque. The fracture is generally smooth and straight, seldom conchoidal; but in some of the blue or gray varieties it is rough and splintery. It often splits into small slabs, and sometimes, especially the green kinds, into laminae.

The fragments sometimes ring with a metallic sound like clinkstone, and many so called clinkstones (such as those of the Roche Sanadoire and Tuilliere in the Mont Dor district, and those of the Velay) are almost undistinguishable by any external characters from many of the felstones of Wales and Ireland.

In many felstones, both in North Wales and South Ireland, lines and striae, resembling lines of lamination or deposition, of slightly different colours, can be traced through the mass of the rock, sometimes straight, sometimes more or less wavy and tortuous, like the variously hued lines and bands in a slag from an iron furnace, and resulting, probably, like them, from the motion of the mass when in a pasty and semi-fluid condition.

In the most smooth and compact varieties, the lens will often disclose small shining facets of crystals of feldspar, and these become larger and more numerous till we reach the completely granular

and crystalline felstones. Small crystals or crystalline portions of quartz also are occasionally present in most varieties.¹

Sometimes the rock becomes nodular and concretionary, the nodules varying in size from that of a pea to that of a man's fist, either scattered in a compact or powdery base, or touching each other and making up almost the whole mass of the rock. The substance of these nodules is sometimes the same as that of the base, but in some instances they are hollow, and contain crystals of quartz and other minerals, and also a soft, dark green earth. In this respect it seems to resemble the rock previously described as pearlstone, though it never has any pearly or other lustre.

Felstone as thus described is probably a mixture of a feldspar with silica in a state of paste. We may look on it as a compact form of trachyte, more or less altered by pressure, or other agencies, and containing a larger proportion of silica.² It passes from that state to one in which the minerals are crystallized out more or less completely, becoming first a granular and crystalline felstone, and then a granular aggregate of crystals of feldspar and quartz, passing into a quartziferous porphyry.

This latter is the rock known in Cornwall as elvan, and we think, as a convenient designation, "elvanite" might be adopted as a name for it and its varieties.

17. *Pitchstone* appears to be a variety of felstone, having a more vitreous character, and a resinous lustre; whence it derives its name. It is of many colours, varying from black to green, gray, and yellow. The black varieties look, however, more like hornblendic or augitic mixtures than purely feldspathic rocks.

Clinkstone is frequently spoken of as a trappean as well as a volcanic rock, but it is probable that many of the rocks so described would not come within the definition of clinkstone given before, and are only platy, flaggy, and laminated (perhaps even "cleaved") varieties of felstone. There may, however, be other true trappean clinkstones, the hydrated varieties of felstone, just as volcanic clinkstone is a hydrated trachyte.

18. *Felstone porphyry*, or *Feldspar porphyry*, is a rock consisting of a base of compact felstone, with distinct scattered crystals of feldspar embedded in it. The base is commonly either of a dull green, gray, or red colour, and

¹ Felstone, as here described, is a very abundant rock among some of the older formations in the British Islands, making up whole mountain masses; but it appears to be little known or remarked on the Continent, as Cotta speaks of it as only rarely seen and in small quantity, and but two specimens of it occurred in a collection of 660 igneous and altered rocks purchased from Krantz of Bonn.

² Professor Haughton has recently analyzed some specimens of Irish felstone, and has found in them such an amount of silica as confirms the view commonly entertained of this rock, that it is a mixture of feldspar and quartz. His results, as given to the Geological Society, Dublin, in a recent paper, are—

Felstone of Ballymurtagh, county Wicklow.

Quartz	45.54
Feldspar	54.16
					99.70

Felstone of Knockmahon, county Waterford.

Quartz	40.81
Feldspar	57.19
					98.00

Felstone of Benaunmore, near Killarney.

Quartz	20.51
Feldspar	77.85
					98.36

This superabundance of silica in these old igneous rocks, so far beyond that which is found in any trachyte, is certainly a very curious subject for speculation.

Could they ever have flowed at the surface with their present constitution? Has their composition been changed, by aqueous metamorphism or otherwise, since their formation?

Geology. the imbedded crystals are commonly white or flesh colour, or some other shade generally contrasted with the base by being of a paler hue.

19. *Quartziferous Porphyry (Elvanite)* has the same base, or a granular one of the same materials, with disseminated crystals or crystalline grains of quartz.

Greenstone, or Hornblende Trap.

Greenstone is an old and well-known name for a numerous and important class of trappean rocks. It is a translation of the German *Grünstein*, and synonymous with the French *Diorite*.

20. *Greenstone, or Diorite*, consists of a mixture of feldspar (orthoclase) and hornblende, varying in texture from a fine-grained compact rock, in which the crystalline state of the minerals is barely discernible with a lens, to a coarsely crystalline aggregate. Its colour is generally a dull green, varying from light to dark green, sometimes almost black. In some varieties, on the other hand, where the feldspar is very white and in great quantity, the rock might almost be described as white, speckled with dark green spots. It weathers to a dull dark-coloured brown, the weathered blocks being generally massive and well rounded, and covered with patches of white lichen. On breaking open the weathered part of a greenstone and testing the rock with acid, we almost invariably find that it will effervesce along the inner border of the weathered portion. Many Greenstones, also, even when apparently unweathered, effervesce with acids along the minute cracks and pores in the mass.

The feldspar of greenstones is commonly presumed to be orthoclase, but is, perhaps, often albite; and in some of the rocks which come under this head augite or hypersthene is substituted for hornblende. Mica, of a dark brown colour, sometimes occurs (as in some of the Wicklow greenstones), either in distinct plates, or as coating the surfaces of small crevices or those of the other crystals.

M. Delesse says that many rocks hitherto classed as greenstone contain no hornblende, their green colour being the result of the greenness of some of the feldspar composing them. These, then, would probably come under the head of one of our crystalline felstones.

Greenstone, like felstone, becomes sometimes porphyritic, in consequence of one or other of its constituents forming distinct crystals in a compact mixture of the rest, or larger disseminated crystals in a granular crystalline base. When the greenstone is quite compact and dark coloured, it is not, perhaps, very easy to distinguish it from basalt by any external characters.

21. *Melaphyre* is a name for a black porphyritic rock, containing crystals of augite or oligoclase, in a base of augite and labradorite or oligoclase.

Under the general head of Greenstones and Melaphyres, Cotta describes the following rocks:—

22. *Diabase*.—A crystalline granular, sometimes porphyritic, or even a slaty, mixture of augite and labradorite or oligoclase, mostly with some chlorite.

23. *Calc-diabase*.—A finer-grained, or entirely compact diabase, with round grains of calcspar.

24. *Gabbro, Euphotide, Diallage rock*.—A crystalline granular mixture of labradorite or saussurite, and diallage or smaragdite.

25. *Hypersthene, and Hypersthene rock*.—A crystalline granular mixture of labradorite and hypersthene.¹

26. *Augite rock, Lherzolite*.—A coarse-grained to compact rock, consisting essentially of augite alone. Rare. Lherz in the Pyrenees.

27. *Norite* is a name of Esmark's for a rock yet undetermined; some of its characters seem to belong to diorite and some to gabbro.

28. *Diorite*.—A crystalline granular mixture of hornblende and albite; sometimes even slaty or porphyritic.

29. *Globular Diorite, Orbicular Greenstone, Corsican Granite*.—A crystalline granular mixture of grayish white feldspar (anorthite), dark gray hornblende, and some quartz, in which alternating concentric layers of hornblende and feldspar form globular concretions from one to three inches in diameter.

30. *Micaceous Diorite*.—A crystalline granular mixture of hornblende and oligoclase, orthoclase, quartz, and mica. Mostly dark, or quite black.

31. *Hornblende rock, Amphibolite*, consists essentially of hornblende alone, which forms sometimes a crystalline granular, sometimes a quite compact aggregate.

32. *Kersanton*.—A crystalline mixture composed essentially of hornblende and mica, in which, however, some feldspar is often mingled. In the latter case it effervesces slightly with acids.

33. *Eclogite*.—A crystalline mixture of green smaragdite and red garnet. The garnet occurs as porphyritic crystals in the fine-grained base of smaragdite.

34. *Disthene rock*.—Principally composed of disthene, with which, however, some garnet, mica, or smaragdite is mingled.

35. *Aphanite, Melaphyr*.—A compact or fine-grained, dark gray, brown, or black rock, which apparently consists principally of a feldspathic mineral intimately mixed with augite, hornblende, magnetic iron, and the like. Its exact mineralogical composition is not yet determined. It is sometimes vesicular, amygdaloidal, or porphyritic, and is even said to be sometimes slaty.

36. *Serpentine*.¹—A compact, mostly green or brown rock, consisting essentially of the mineral serpentine only. Fracture splintery and dull, easily workable and unctuous to the touch. A variety of serpentine is Schiller rock, which contains crystals of Schiller spar.

37. *Garnet rock*.—A crystalline granular, but very unequal mixture of garnet, hornblende, and magnetic iron.

38. *Eulite*.—A mixture of olivine-like oxide of iron, green augite, and brownish-red garnet.

39. *Epidote rock*.—A granular compact, or variolitic mixture of pistacite (green epidote) and quartz.

40. *Labradore rock*.—A crystalline aggregate of labradorite, with interspersed crystals or crystalline particles of dark hornblende. As a rule, it also contains small crystals of iron pyrites.

Basalt, like clinkstone, must also be enumerated among the traps as well as among the lavas, since it may be very difficult to say, with respect to some masses of basalt, that they were ejected from what might be truly described as a volcano.

Claystone, or Wacke, is sometimes spoken of as a trappean rock. It is probably either a compact basalt or greenstone, in a decomposed and earthy state, or an ash partially hardened and consolidated.

The traps, both felstone and greenstone, are accompanied, like the volcanic rocks, by their respective ashes or tuffs.

41. *Feldspathic ash*² is usually a rather coarse-grained flaky-looking rock, of a pale green, pale gray, or white colour. It has often a soapy feel to the touch, and would be then called chlorite-schist by many persons. It is commonly to be easily detached in flakes, which are quite translucent, and can be as easily ground down into powder. Other varieties are much harder and more compact; and there is, in fact, every gradation from a soft ash into a compact felstone, undistinguishable from solid trap.

Some of these solid-looking traps, however, show casts

¹ We have included serpentine among the trappean rocks, as there may doubtless be injected masses entitled to the name. Many serpentines, however, are only metamorphosed magnesian limestones, a fact which was confirmed to us by Sir W. Logan in 1854, from his observations in Canada.

² Professor Sedgwick uses the term "schaalstein" to designate these ashes, translating it by "trap shales" instead of ash. If, however, we use the term "ash" in a technical sense as the translation of tuff, there does not appear any valid objection to it. The specimens of German "schaalstein" which we have seen are not the same as any of the British "ashes" we are acquainted with.

¹ A magnificent mass of this rock, with crystals two or three inches wide, forms a hill at the head of St George's Bay, Newfoundland.

Geology. of fossils, and contain angular fragments of slate and other rocks, clearly betraying their mechanical origin. Some even contain crystals of feldspar, making the rock look like a porphyry, until closely examined, when the crystals are found to have their angles worn, and to have been more or less weathered and rounded before they were included in the base.

Along with these also, there generally occur angular or rounded fragments of felstone, slate, or other rocks, of every size up to blocks of 6 or 8 inches in diameter; the rock then becoming a trappean breccia or conglomerate, with either a hard and compact or a loose and flaky base.

Sand is sometimes mingled with this base; and there is then a passage from ash, through sandy ash and ashy sandstone, into pure sandstone.

It is rare to find a genuine ash that will not effervesce slightly with acids. The nodular concretionary structure, which we have previously mentioned as occasionally to be seen in some felstones, likewise occur in felstone ash. At least, the base in which the nodules lie is often of that flaky slightly coherent character which is characteristic of ash.

42. *Greenstone ash* is perhaps still more various in composition than that of felstone.

One well-marked variety is a quiet compact rock, of a pale greenish brown hue, speckled with small black spots.

Another is a flaky coarse-grained ash, like that of felstone, but of a darker green or olive colour. This sometimes contains embedded crystals of hornblende¹ that have had their edges rounded and worn, together with angular or rounded fragments of other rocks.

Another variety of greenstone ash is a dark hornblende slate, passing into hornblende schist; and it is very possible that many hornblende schists, actinolite schists, &c. are metamorphosed ash-beds.

It is obvious that rocks thus made chiefly or entirely of igneous materials would more easily be metamorphosed than purely siliceous, argillaceous, or calcareous rocks, and would then be converted into rocks having all the appearance of trap. If they contained crystals of feldspar or hornblende, such altered rocks could not be separated from porphyries.

Greenstone ash often effervesces with acids as well as felstone ash.

III.—THE GRANITIC ROCKS.

We have before said that all igneous rocks were composed of silicates, and pointed out that the varieties of the volcanic and trappean rocks were characterized by the relative amounts of hornblendic or augitic minerals (silicates of magnesia, &c.) which were mingled with their feldspathic constituents (silicates of alumina, &c.) These silicates are, in the volcanic and trappean rocks, generally one of the more basic varieties. The bases, then, in the compound, just previous to consolidation, must have been in comparatively great proportion to the acid (silica), so that none of the latter was left unused or uncombined, and consequently none was allowed to crystallize out separately as quartz. The granitic rocks, on the other hand, are distinguished by the relative abundance of silica which they contain. Not only are all the minerals composing them as highly silicated as possible, but there was moreover a superabundance of silicic acid (or silica) beyond that which could be taken up by the basic substances present in the mass. This silica, therefore, has been left uncombined, and on the cooling and consolidation of the rock was compelled to crystallize out by itself as quartz.

¹ Near Black Ball Head, county Cork, is a cliff of such a greenstone ash, in which crystals of hornblende, 3 inches wide, have been seen. They are dull and worn externally, but internally quite bright and glistening.

Geology. So long as granite was looked upon as necessarily the most ancient of rocks, this superabundance of silica and occurrence of quartz was considered to indicate a difference in the proportion or distribution of the constituents of the globe, in the more ancient geological periods, from that which exists at present. The mineral character of rocks was supposed to depend upon age. We shall touch upon this subject presently.

In the meantime we would observe that we have already seen that some felstones contain distinct crystals of quartz, and pass into quartziferous porphyry. Now, if a rock consisting of granular crystals of quartz and feldspar, in anything like equal proportion, began to contain flakes of chlorite, talc, or mica, it would then pass into a granite; if, instead of a micaceous mineral, it were to acquire any hornblendic one, it would then become a syenite.

Again, if a greenstone containing granular crystals of feldspar and hornblende were likewise to exhibit crystals of quartz, it would pass into a syenite; and should the hornblende give way to a mica, this also becomes a granite.

These transitions are not merely hypothetical, but have been observed and described; and we have, therefore, existing in nature, every kind of gradation, from a trachytic or doleritic lava, through a feldspathic or hornblendic trap, into genuine granite.

43. *Granite*.—True granite in its most ordinary form is one of the most easily described and certainly recognized of all rocks. It is a granular, crystalline aggregate of the three minerals feldspar, mica, and quartz. Its name is sometimes said to be derived from its granular structure, but Jameson derives it from "*geranites*," a term used by Pliny to designate a particular kind of stone.

Ordinary granite varies according to the composition of the feldspar and mica composing it,—according to the relative proportions of those minerals to each other and to the quartz—and according to the size of the crystals and the state of aggregation of the several constituents.

The feldspar of granite may be either orthoclase or potash feldspar, frequently flesh-coloured, but sometimes white; albite or soda feldspar, generally dead white; an intermixture of those two minerals; or lastly, a feldspar containing both potash and soda, which may be called soda-orthoclase or potash-albite, as the case may be. Other varieties of feldspar, except, perhaps in some instances, oligoclase, are seldom found in granite as constituents of the mass.

The mica of granite varies greatly in colour and lustre, being sometimes dark coppery-brown, passing into black, sometimes green, sometimes golden yellow, and sometimes a pure silvery white. Whether its chemical constitution be equally various is perhaps hardly yet sufficiently ascertained. The quartz is commonly colourless or white, but sometimes dark gray or brown.

The proportions of the three constituents vary indefinitely, with this limitation, that the feldspar is always an essential ingredient, and never forms less than a third, rarely less than half of the mass, and generally a still larger proportion.¹ Sometimes the mica, sometimes the quartz, becomes so minute as to be barely perceptible.

¹ Professor Haughton, in his paper on the Granites of Ireland (*Geological Journal*, London, vol. xii., p. 180), gives the following as the proportions of the Dublin and Wicklow granite:—

Mica	13.37
Feldspar	61.18
Quartz	24.98
						99.53

A detached granite boss, near Enniscorthy, had

Mica	3.60
Feldspar	89.69
Quartz	6.44
						99.73

Geology.

The state of aggregation of the mass varies also greatly, some granites being very close and fine grained, others largely and coarsely crystalline. The colours of the rock are generally either red, gray, or white; the first when the feldspar is flesh-coloured, the latter when it is pure white, the intermediate gray tints depending chiefly on the abundance and colour of the mica, but sometimes on that of the quartz.

Large and distinct crystals of feldspar sometimes occur, disseminated at intervals through the mass, giving the rock a porphyritic texture. It is then called porphyritic granite.

Other minerals besides the three mentioned above, sometimes occur in granite. Among these are hornblende, actinolite, tourmaline, schorl, chlorite, and steatite.

When hornblende is abundant in rock, and the mica becomes scarce, or altogether disappears, it becomes a syenite.

44. *Syenite*, in its true form, is a granitic rock. It is named from the city of Syene, in Egypt, where it is formed of a crystalline aggregate of the four minerals feldspar, hornblende, mica, and quartz; the mica being in small and uncertain quantity. We have already, however, had occasion to remark, that syenite may be formed from either felstone or greenstone, and we may look upon it therefore either as a local variety of granite, or as a passage or transition rock between granite and the traps.

45. *Protogine*.—When talc occurs instead of mica, the granite has been called Protogine, from an erroneous supposition of its being always more ancient than granite.

The name, however, may be retained for the mineralogical variety, independently of any foregone conclusion to be drawn from it.

Instead of talc, chlorite sometimes occurs, as at Camaross, county Wexford, either in regular flakes or as a greenish coating to the surface of other crystals, but I am not aware of any name having been proposed for this variety. The granites of Cornwall and Devon sometimes contain so much schorl as to merit the name of schorl rock, and would doubtless have been christened with two or three different designations by continental geologists.

46. *Eurite* is a term applied to a fine-grained crystalline aggregate of quartz and feldspar, where the mica is either absent or occurs in such minute flakes as to be invisible.

It generally occurs as veins or as local masses in other granites, and rarely as veins traversing other rocks at a distance from granite. These, therefore, are probably veins of segregation or of injection during consolidation, and not of subsequent formation.

47. *Minette* is a name for a fine-grained rock, consisting principally of mica, but not having a schistose texture like mica schist.

48. *Pegmatite* is a crystalline aggregate of quartz and feldspar, in which the crystals are arranged as if with a design to produce a certain pattern, more or less resembling letters or characters (from *πηγμα*, a coagulation).

49. *Granulite* is a similar composition, in which the quartz occurs in thin flakes, so as to give almost a schistose texture to the mass.

50. *Elvan* or *Elvanite*.—Elvan is a Cornish term for a crystalline granular mixture of quartz and feldspar, forming veins that are either seen to proceed from granite, or occur in its neighbourhood, and may thus be readily supposed to proceed from it.

In the Newry and Mourne mountain district he found three granites having the following proportions:—

1. Wellington Inn.	2. S. of Newry.	3. Carlingford.
Mica14.59	13.67	22.86
Feldspar.....61.98	64.17	50.76
Quartz23.23	21.96	26.08
99.80	99.80	99.70

VOL. XV.

It has three varieties:—

(a.) An equally crystalline mixture of quartz and feldspar; generally fine-grained. This may either be considered as a granite destitute of mica, or as a granular felstone.

(b.) A compact felstone base with dispersed crystals, or crystalline particles of quartz, sometimes angular, sometimes rounded, and amygdaloidal. This may be considered as a quartziferous felstone porphyry.

(c.) A crystalline granular base of quartz and feldspar, with dispersed crystals of either quartz or feldspar.

The feldspathic portion of these rocks is often earthy, probably from decomposition.

We would propose *Elvanite* as a good euphonious term, and as being less cumbersome than the term of Quartziferous porphyry, for these rocks which differ in texture from Eurite, or Pegmatite, or Granulite.

Professor Haughton, in his paper in the Geological Journal before quoted, gives the following as the composition of some rocks, which we should consider *Elvanites*.

Croghan Kinshela, Wicklow.		Mourne Mountains.	
Albite	62	Albite.....	27.8
Quartz.....	38	Orthoclase.....	44.2
	100	Quartz.....	28.0
			100.0

The composition of the Carnsore granite is similar, being—

Felspar.....	78.5
Quartz.....	21.5
	100.0

But this, by its texture and coarsely crystalline grain, deserves to be considered as a true granite; and it moreover does contain occasionally a small proportion of mica.

As the granite rocks are all hypogenous or nether-formed, that is, have all been consolidated before reaching the surface of the earth, they are necessarily devoid of "ash," or of any mechanically-derived accompaniments whatever.

We have remarked above, that the relative quantity of silica had a marked effect upon the nature of the rock; that among the lavas, quartz only appeared in these trachyte porphyries which were beginning to resemble granite; and that among the traps it only appeared among those feldspar porphyries which were closely allied to, and passing into, granite, while from the true granites it is never absent. It has been attempted from this to prove that the more siliceous an igneous rock was, the more ancient it must be. Even Abich says that we may, perhaps, thus deduce a scale for the history of the formation of the earth;—those rocks which contain, as essential constituents, "trisilicates" of both their protoxide and peroxide bases, being "primitive;" while those which contain quartz are called "primitive Plutonic;" and those without quartz, "primitive volcanic."

M. Riviere also supposes orthoclase to be confined to the older, labradorite to the more recent rocks. The other bases, too, as magnesia and lime, have been supposed to characterise newer rocks than those of soda and potash, and soda itself to be newer than potash.

We would venture to suggest that these mineralogical differences depend upon space or locality rather than upon time; that the proportionate quantity of silica is referable to the depth at which an igneous rock has been cooled or consolidated, or to the nature of those it penetrated, rather than to the time at which it was formed. At great depths in the earth, pure silica itself may possibly be fused by the intense heat there to be met with; and the most refractory silicates may be equally molten at a somewhat less depth, and consolidate or crystallize on becoming cooler a little higher; while those portions of molten matter containing a greater quantity or variety of bases which act as more perfect fluxes may be kept fluid till they reach the surface, and thus consolidate only in the air or in the water.

Whether the whole quantity and variety of the more fusible bases formed part of the original deepest-seated molten mass, and were separated from it on the first cooling and crystallization of the simpler minerals, or whether a

Geology.

Geology. larger proportion of those bases was acquired during the passage of the molten rock through the higher part of the earth's crust, and thus the quantity of "flux" increased in proportion as the heat and pressure diminished, may be matter for speculation. We will not now stop to consider it farther than to warn the student not to take it for granted that the mineralogical and lithological composition or structure of any rock whatever has any necessary and determinate relation to its geological age. Granite might become solid at a temperature that would keep felstone or trachyte still fluid; and these might solidify at temperatures which would keep molten all greenstones, basalts, and dolerites, so that from the very same stream of igneous matter proceeding from the interior to the surface of the earth, the more readily fusible portions might be successively squeezed out, as it were, as the infusible ones solidified, and contracted in consequence of that solidification.¹ This action might take place in spite of the greater specific gravity of the more fusible minerals, since the difference in the specific gravities would probably be small compared with the power of the eruptive force.

It is true, indeed, that actual subaerial volcanoes, with cones and craters and *coulées*, or *streams* of lava, are only known as recent geological phenomena—as either now active or as having been so during a recent geological period. But we shall see hereafter reason to believe that the preservation of any volcanic cones belonging to the more ancient periods was not to be expected. The parts preserved from destruction and denudation are the more deeply-seated portions only, the *roots*, as it were, of the volcano, the very parts which we do not see while the volcano is active or entire, but which we do see in some (such as those of the Mont Dor) that are half ruined, and we then find these old lava roots to be essentially the same as the traps; and we have already seen that deeply-formed trap is not to be separated by any hard line from granite. If, therefore, we could follow any actual lava-stream to its source in the bowels of the earth, we should in all probability be able to mark in its course every gradation, from cinder or pumice to actual granite.

That this change of state from a granite into a trappean rock does actually occur is well known, and has been proved in a most interesting manner in Professor Haughton's paper before quoted. Near Carlingford (Ireland), a syenite, having the following composition:—

Hornblende.....	15.40
Orthoclase.....	67.18
Quartz	17.16
	99.74

comes in contact with, and sends veins into, a large district of limestone. The dykes proceeding from this syenite are converted into a kind of greenstone or dolerite by taking up a large quantity of lime from the adjacent limestone, which enters into combination with the silica, and lets the potash go free, so that their mineral composition becomes,—

Hornblende	14.16
Anorthite	85.84
	100.00

Anorthite, or a lime felspar, is thus formed by the combination of lime with the silica existing in the mass, which in parts not reached by the lime can only form orthoclase and quartz. Anorthite had not been previously mentioned as a constituent of any other rock than a lava, and yet we see it here occurring in a mass proceeding from a granitic syenite, and therefore we may well suppose lava in many cases to have similarly proceeded from a granitic compound.

M. Delesse, in the *Annales des Mines*, 1849, has some

Geology. interesting observations on the magnetic power of the igneous rocks, and some of their constituent minerals, as also of some of the glasses formed from melting rocks. No practical results, however, being yet arrived at, we shall confine ourselves to this mention of the subject. (D'Archiac, vol. iii., p. 595.)

Bischof has some very important observations on the contraction of igneous rocks, as they pass from a fluid to a solid or crystalline state. (D'Archiac, p. 598.)

He experimented on basalt, trachyte, and granite, and found the following results:—

	Volume in the state of Glass.	In Crystalline state.
Basalt.....	1	0.9298
Trachyte	1	0.9214
Granite.....	1	0.8420
	In the Fluid state.	In Crystalline state.
Basalt	1	0.896
Trachyte	1	0.8187
Granite	1	0.7481

From this we see that granite contracts 25 per cent., or a quarter of its volume, in passing from a fluid to a crystalline state, and 16 per cent. in passing from a glassy to a crystalline state. These effects must have had a great importance "when the primary granites were first cooling," says M. D'Archiac; but their importance seems to us still greater to geologists who are examining the broken and contorted rocks on the flanks of existing granite chains,¹ and the phenomena of intrusion which we shall hereafter meet with in such situations. M. Deville and M. Delesse arrive at results rather different from Bischof's, and the latter gives the following table as comprising the limits within which the several rocks mentioned contract on passing from a fluid to a solid state.

Granite, leptynites, quartziferous porphyries, &c. 9 to 10 per cent.	
Syenitic granite, and syenite	8 to 9 ...
Porphyry, red, brown, or green, with or without quartz, having a base of orthose, oligoclase, or andesite	8 to 10 ...
Diorites and porphyritic diorites (greenstones)...	6 to 8 ...
Melaphyres.....	5 to 7 ...
Basalts and trachytes (old volcanic rocks)	3 to 5 ...
Lavas (volcanic and vitreous rocks).....	0 to 4 ...

M. Delesse sums up his results as follows:—

"When rocks pass from a crystalline to a glassy state, they suffer a diminution of density which, all things being equal, appears to be greater in proportion to the quantity of silica and alkali, and, on the contrary, less in proportion to that of iron, lime, and alumina which they contain. In arranging the rocks in the order of their diminution of density, those which we regard as the more *ancient* are generally among the *first*, while the more *modern* are the *latter*; and in each case their order of diminution of density is almost exactly the inverse of their order of fusibility."

On this we would remark as before, that for "ancient" and "modern" might be substituted "deeply formed" and "superficially formed;" the most infusible and the most contractible rocks being those produced at the greatest depth and under the greatest pressure, while the highly fusible compounds escape to the surface, and suffer little contraction or solidification.

M. D'Archiac remarks, that if granite contracts on cooling only ten per cent., and that there be a thickness of 40,000 metres of it in the crust of the globe, crystallization alone would diminish the terrestrial radius at least 1430 metres, and consequently alter the form and rapidity of ro-

¹ The chemist is reminded of the fact, that if a mixture of metals, as for instance tin, bismuth, and lead, be melted, they will, as the mixture cools, have a tendency to solidify and crystallize separately as the temperature of the mass reaches their respective melting-points. This constitutes a great difficulty in large bronze castings.

¹ We would just warn the student here, that, without altogether denying that there may have been such a rock as a primitive granite, none of the granites now known at the surface can be shown to have an antiquity greater than that of some of the aqueous rocks with which they are associated.

Geology. tation of the earth. Such speculations are practically useful only in a negative sense, as showing the great improbability of anything like a shell of 40,000 metres having cooled and consolidated at once in the crust of the earth during any of the known geological epochs.

Geology. steep slopes or precipices, sometimes exerts a more wholesale destructive power, by gradually loosening and undermining very considerable masses of ground, and thus causing them to be *launched* forward, down the slope, producing what are called "landslips."

CHAP. III.—AQUEOUS ROCKS.

We are compelled to look upon the purely igneous rocks as original productions. We can only speculate, and that very vaguely, on what was the condition of the materials which compose them, previously to their being placed, in a molten state, in the positions where they subsequently consolidated.

In our examination of the aqueous rocks, however, we can go a step farther back, and learn, either accurately or approximately, whence the materials composing them were derived, and what was their previous condition. This is true of all aqueous rocks, whether chemically, organically, or mechanically formed.

We will examine the mechanically-formed rocks first.

I.—MECHANICALLY-FORMED ROCKS.

Preliminary Remarks on their Origin.

The instruments used by nature in the production of these rocks are,—moving water, whether fluid or solid (ice), and moving air.

The Sea.—The sea is probably never and nowhere stagnant. Currents, moving with greater or less rapidity, keep the whole mass in circulation; so that we may look upon the ocean, through all its depths, and in all its gulfs, bays, and recesses, as one great slowly moving whirlpool.¹

It is probable, however, that no currents produce any marked or appreciable effects upon solid rock at great depths of water. The mechanical powers of the sea are principally brought into action by the motion of its surface along the shores of all lands, and in its narrower and shallower channels. Sea-breakers along beaches, and at the foot of cliffs, act like ever-moving jaws constantly gnawing at the land. The currents caused by the ebb and flow of the tides along shallow shores remove some of the eroded materials; the great oceanic currents of circulation, where they strike upon coasts, carry off others, and transport all, either mediately or immediately, to greater distances.

In looking at the destructive action of water, however, we must never forget that by *destruction* we do not mean *annihilation*, but only *re-arrangement*. Rock forming "land," that is, rock above the level of the sea, is destroyed; but its materials are carried off and deposited, either in similar or in different combinations, to form rock below the level of the sea.

For instances of the erosive and destructive action of the breakers, and the abrading and transporting power of currents, during historic times, we must refer the student to Sir C. Lyell's *Principles of Geology*, chapters 20, 21.

Rain.—The sea, however, is not the sole agent of the destruction of that portion of rock at or above its level, which we call land. All rain falling upon land, and either running over its surface or draining through its interior, is constantly abrading and carrying off particles of pre-existing rock in the shape of mud, silt, and sand. From the gutters and the ditches, from the rills, the streams, and the brooks, these materials for the building of mechanically-formed rocks are almost unceasingly being carried into the rivers, and by them transported to the beds of lakes and seas. Rain soaking into ground, and issuing as springs on

Ice and Snow.—When rain falls as snow, on the other hand, it exerts a conservative and protective effect as long as it retains its solid form, but, on melting, acts like rain, and even with greater intensity, inasmuch as a greater amount of water is often set loose and in motion over the land by the rapid melting of snow than would fall in the same space of time in the shape of rain directly from the clouds. The most extensive and powerful floods are those of the spring in mountainous districts, when the snows melt rapidly on the hills. If rain or other water soaks into rocks and fills up their interstices, either the small pores, or the crevices, joints, and fissures by which all rocks are traversed, and this water then freezes, this conversion into ice is accompanied by an expansion which exercises an almost irresistible mechanical force, the effect of which will be either the disintegration of the particles in the one case, or the breaking and rending asunder, and the displacement of the larger masses in the other. On mountain summits and sides subject to great vicissitudes of temperature, this agency exerts no mean effect. The hardest rocks will be broken up by it, and enormous blocks ultimately displaced and toppled over precipices, or set rolling down slopes to suffer still further fracture, and produce still greater ruin in their fall.

Glaciers.—When mountains are covered by perpetual snow, all the part so covered is protected by this envelope from all change. In such situations, however, the moving power of water takes another form, that of the glacier, or "river of ice." The lower border of the perpetual snow-mass passes into ice, from the alternation of melting and freezing temperatures, just as snow on the roof of a house forms icicles at its lower edge, when partly melted and re-frozen. This ice accumulates in the valleys, and is frozen into a solid or nearly solid mass, called a glacier. Glaciers sometimes fill up a valley 20 miles long, by 3 or 4 wide, to the depth of 600 feet. Although apparently solid and stationary, they really move slowly down the valley, and carry with them, either on the surface, frozen into their mass, or grinding and rubbing along the bottom, all the fragments, large and small, from blocks many tons in weight, down to the finest sand and mud, that rain, and ice, and the friction of the moving glacier itself, detach from the adjacent rocks. The cause of this motion is now generally believed to be that attributed to it by Professor J. Forbes, namely, a slight degree of plasticity, a *demi-semifluidity*, in the ice mass, by which it is enabled to actually flow down the valley, just as a viscous substance, such as partially melted pitch, would flow.¹

The glaciers of the Alps, and probably those of other parts of the world, descend to a vertical depth of nearly 4000 feet below the line of perpetual snow, before they finally melt away, and leap forth as rivers of running water. The confused pile of materials, of all sorts and sizes, which they there deposit, is called the "moraine." This word is also applied to the lines of blocks that are being carried along on the surface of the glacier.² The river of water that proceeds from the end of a glacier is of course quite unable to move the large blocks which had been carried with ease by

¹ Professors Tyndal and Huxley have recently disputed this idea of Professor J. Forbes's, and shown the motion of glaciers to be the result of the minute, almost molecular, *fracture* and *regelation* of the ice particles, which move as if they were sand continually thawing and re-freezing. (*Philosophical Magazine*, 1856.)

² See Professor J. Forbes's work on the *Glaciers of the Alps*, and also Johnstone's *Physical Atlas*; also the works of Agassiz, Charpentier, &c.

¹ See Maury's *Physical Geography of the Sea*, and Johnstone's *Physical Atlas*, &c.

Geology. that of ice, and only transports the finer particles, as mud and sand.

Icebergs.—If, however, it so happen that a glacier come down into a lake, or into the sea, before it melt away, large fragments of it (icebergs) will be frequently floated off, with all their freight of rock-fragments of all kinds; and these loaded icebergs may then be carried great distances before they entirely dissolve. In this manner, large unworn angular blocks of rock may sometimes be dropped on the bed of the sea even hundreds of miles from their original site. The terminal moraine, instead of a pile at the foot of the glacier, is disseminated far and wide over the bottom of the surrounding seas.

River Valleys.—Rivers are not the producers of their own valleys; they are the results of those valleys, but they are their immediate results. The river could not be formed till after the valley, with all its tributary branches, had been marked out; but the valley could not even be marked out without the river, in most cases, instantly springing into existence, and commencing to modify, and deepen, and complete the valley.

Action of Rivers.—The re-direction of draining water into old channels will be more certain and frequent in proportion to the steepness of the ground and consequent rapidity of the flow of water; and channels once selected will there be more rapidly deepened, and more completely and permanently formed. Such deep valleys (ravines, as we should then call them) are scarcely to be obliterated, or otherwise altered than from deepening and enlargement, by any number or amount of changes, short of the removal of the mass of high ground which they traverse. As long as the mountains remain undestroyed, the valleys and ravines must obviously be continually enlarged, either vertically or laterally, by the action of the waters which traverse them.

The temporary damming up of rivers, and subsequent breaking down of the barrier and escape of the lake formed above it, produces sometimes the most remarkable instances of the power of moving water. Rocks as big as houses are thus set in motion, and carried sometimes for very considerable distances down the valleys. (See *Lyell* as above; also *Jameson's Mineralogy*, vol. iii., where all these causes of mechanical destruction, including that of ice and icebergs, are distinctly pointed out.)

We shall be able better to understand how rapidly the size of water-borne fragments increases in proportion to the velocity of the moving water, when we learn from Mr W. Hopkins, that the power of water to move bodies that are in it increases as the sixth power of the velocity of the current. Thus, if we double the velocity of a current, its motive power is increased sixty-four times; if its velocity be multiplied by 3, its motive power will be increased 729 times; if by 4, 2048 times; and so on.

In studying the mechanical force of water upon rock, also, it is necessary to bear in mind that all earths and stones lose fully a third of their weight when suspended in water. These considerations enable us to understand more readily the fact of blocks of rock many tons in weight having been removed from breakwaters and jetties, and carried sometimes many yards during great storms, as also of still larger blocks hurried along by floods, &c.

The rolling power of water upon stones lying in its bed depends greatly on their shape also, the same current being easily able to roll along pieces of rock in the form of rounded pebbles that it would be quite unable to move if they were in the shape of flat slabs; while, reversely, flat slabs or flakes would float more easily, or sink more slowly, than rounded or square-shaped fragments of the same weight and cubic contents. Flakes of mica, therefore, might be floated and transported onwards where grains of quartz, even though lighter than the mica, would sink; and, on the other hand, rounded quartz pebbles might be rolled forward where

Geology. smaller and flatter pieces, in the shape of shingle, would be brought to rest.

Mr Babbage has lately treated of this subject, in a paper of which an abstract appeared in the *Journal of the Geological Society*, November 1856.

He there supposes the case of a river, the mouth of which is 100 feet deep, delivering four varieties of fine detritus into a sea which has a uniform depth of 1000 feet over a great extent, which sea is traversed by one of the great ocean currents, moving with a certain given velocity.¹

He takes for granted that the four varieties of detritus are such as, from their size, shape, and specific gravity, would fall through still water, the first 10 feet per hour, the second 8 feet, the third 5 feet, and the fourth 4 feet. The combined effect of the downward motion of the detritus, and the onward motion of the water, would then bring the first variety to the bottom of the sea, at a distance of 180 miles from the river's mouth, and strew it over a space 20 miles long; the second variety would only begin to reach the bottom 225 miles from the river's mouth, and would be spread over 25 miles, and so on, as in the following table:—

No.	Velocity of fall per hour.	Nearest distance of deposit to river mouth.	Length of deposit.	Greatest distance of deposit from river mouth.
	Feet.	Miles.	Miles.	Miles.
1	10	180	20	200
2	8	225	25	250
3	5	360	40	400
4	4	450	50	500

We should thus have, proceeding from the same river, and poured into the sea, either simultaneously or at different times, four different and widely separated patches of mud or clay formed on the sea bottom.

Mr Babbage says, that this subject was suggested to him from his observing the *extreme slowness* with which a very fine powder, even of a very heavy substance, such as emery, subsides in water, and speaks of mud clouds being suspended in the depths of the ocean, where the density of the water increases, for vast periods of time.

The amount of mechanical work done by rivers can be estimated by examining their waters at different periods, and determining their solid contents. If this be done by simply evaporating the water, the result will be not only the mechanically suspended mineral matter, but also that which was chemically dissolved in the water. As the separation of these two, however, is rather troublesome, and not very important, it is not often attempted; neither, as a measure of the work done, would it be often necessary, since the chemical solution of mineral matter is perhaps more frequently than not the consequence of the mechanical erosion of it by the water.

Sir C. Lyell, in his *Principles*, gives the following as the results of various observations:—

The total mineral matter carried down by the Ganges into the sea, according to Everest, is 6,368,077,440 cubic feet per annum, part of which has been deposited at its mouth, forming a gentle submarine inclined plane of 100 miles long, and sloping from 4 fathoms to 60 fathoms in depth. Lyell says, that for the transport of this quantity, it would require a fleet of 2000 Indiamen, each of 1400 tons, to start every day throughout the year. This mass of matter would cover a square space 15 miles in the side every year with mud a foot deep, or would raise the whole surface of Ireland 1 foot in the space of 144 years. The Brahmapootra probably carries an equal quantity.

Mr Barrow calculated that the Yellow River (Hoang Ho) in China, carried down into the Yellow Sea 48,000,000 of cubic feet of earth daily; so that, assuming the Yellow Sea to be 120 feet deep, an English square mile might be converted into dry land every seventy days, and supposing its area to be 125,000 square miles, the whole would be made into terra firma in 24,000 years.

Herodotus remarked that "Egypt was the gift of the Nile," and that the sea probably once flowed up to Memphis, the old gulf having been filled up by the Nile mud, as the Red Sea would be filled up if the Nile were turned into it. The edge of the present delta is, however, now swept by a powerful current, which carries off all detritus delivered into it, and thus future increase is

¹ The supposed velocity of the river and ocean current is not stated in the abstract.

Geology. prevented. Otherwise the Nile would by this time have formed a long tongue of land projecting into the Mediterranean, just as the Mississippi has projected a tongue of land 50 or 60 miles long, into the Gulf of Mexico, having previously filled up the inlet which formerly penetrated from that sea deeply into North America, and received the rivers more than 100 miles inland from the present coast. According to Dr Riddell, the solid matter contained in the Mississippi is about 80 parts in the 100,000 of water by weight, or about 33 by volume; and Sir C. Lyell calculates, that it brings down 3,702,758,400 cubic feet annually, and that the present delta has required 67,000 years for its formation.

If we turn to the European rivers, Bischof states that Chandelon, by daily experiments during December 1849, found in the Maes, at Leige, a maximum of 47.4 parts of suspended matter alone, a minimum of 1.4, and a mean of 10 parts, in the 100,000 of water.

In the Rhine, at Bonn, Mr Leonard Horner found, August 1833, when it was unusually low and turbid, 31.02 of suspended and dissolved matter; and in November, when swollen, 51.45. Bischof found in March 1851, 20.5 of suspended matter alone; and at another time, when it was clear, only 1.73 of such parts; while Stiefensand, near Uerdingen, after a flood, found 78 parts of suspended matter in the 100,000 of water.

In the Danube, August 5, 1852, there were found 9.23 of suspended, and 14.14 of dissolved matter—total solids, 23.37 in the 100,000; while in the Elbe at Hamburg, there were in June 1852 only found 0.9 of suspended, and 12.7 of dissolved matter.

In these experiments much depends on the state of the river, and also on the part of the river where the water is taken from, whether far from the bank, at the surface, or near the bottom; and so on.

Whether the matter thus carried down by rivers is deposited at their mouths, and forms a delta, or is carried off to a greater or less distance, depends on the tidal or oceanic currents which are to be met with at the mouth of the river. In lakes, deltas or flats are almost invariably met with at the mouths of rivers. In sheltered bays and gulfs, where there is no great rise and fall of tide, and consequently no great scour of the river's mouth, deltas are also formed; witness the Po, the Rhone, Nile, Mississippi, Orinoco, Indus, Ganges, Brahmapootra, &c. Where, however, there are strong ebb tides, or where the river mouth is swept by a strong oceanic current, the detritus is carried off directly into the sea, as in the case of the Amazon, the Rio de la Plata, the St Lawrence, and of most of the rivers of Britain and Western Europe.

It results from even such a hasty and rapid glance as we have just thrown over the principal mechanical powers of moving water that are daily and hourly at work around us, that we begin to acquire the notion that we are living in a vast workshop, and that all the earthy matters we see about us, the mud, the clay, the soil, the dust, the sand, the gravel, and the boulders, are only so much raw material in process of manipulation. They may be likened to the refuse and the chips of some vast manufactory. They are the building materials of stratified rocks, which are being carried from the quarry to the place of construction, much being dropped and scattered by the way. Every pebble, every grain of sand, every atom of mud, is a fragment of pre-existing rock, removed at some period of past time, and destined ultimately to enter into the structure of some other rock in the future.

This building metaphor might be carried still farther when we come to speak of the chemically-formed rocks, since many of the mechanical deposits are bound together by cements and mortars which are more or less identical in composition with those used in architecture.

Description of Mechanically-Formed Rocks.

51. *Conglomerate, Puddingstone, Breccia.*—In the preceding paragraphs, we have mentioned the method of formation of pebbles, gravel, and shingle, in rivers and along the sea-coasts. When those materials are compacted together into stone, they are called *conglomerate* or *puddingstone* if the pebbles are round, *breccia* if the fragments are sharp and angular

Geology. The degree of induration or consolidation in conglomerates varies greatly. Some seem to have been consolidated by simple pressure; and from these the pebbles may often be removed by a slight blow with the hammer, or even by the knife, the form or mould of the pebble remaining in the little film of sand which fills up all the interstices between the larger fragments. Sometimes the conglomerate has been bound or cemented together by calcareous, ferruginous, or siliceous infiltrations, the matrix in which the pebbles lie being as hard and indestructible as the pebbles themselves, a blow with a hammer breaking the pebbles as easily as the mass of the rock in which they are embedded. The size of the fragments in conglomerates and breccias varies greatly. In some rarer cases, blocks of as much as two feet in diameter occur; but the more ordinary sizes are from that of a man's head to that of walnuts. Below that size, the rock begins to pass into the coarser varieties of sandstone.

52. *Sandstone and Gritstone.*—The very process by which fragments of rock are rounded produces sand, as the waste resulting from their attrition. Pebbles themselves also are gradually broken or diminished into grains of sand. Sandstone is nothing else but sand, formerly loose and incoherent, subsequently compacted into solid stone. The grains both of sand and sandstone generally consist of quartz, sometimes clear and colourless, sometimes dull white, sometimes yellow, brown, red, or green. The red colours are usually the result of the covering of each little grain with peroxide of iron, which sometimes acts as a sort of cement to the stone, serving to bind the particles together. The green colours are commonly derived from silicate of iron; and the green and red are often intermingled, in consequence of the change of the iron from the condition of a silicate to that of an oxide or peroxide.

The size of the grains varies from that of a pea to the minutest particle visible to the naked eye; many sandstones and gritstones even requiring a lens in order to distinguish the particles of which they are composed.

The materials are equally various, as, along with grains of quartz, may occur grains and particles of any mineral substance whatever. Grains of feldspar, distinguishable by their dull white colour and peculiar appearance, occur abundantly in some sandstones, which may then be called feldspathic sandstones. Flakes and spangles of mica are rarely altogether absent; and in many sandstones they occur so abundantly, and in such regular seams, as to cause the rock surfaces to glitter, and the rock itself often to split into thin plates and slabs. These are called *micaceous sandstones*. When grains of limestone occur in any remarkable proportion, the rock may be called a *calcareous sandstone*, though this designation is often applied to sandstones the quartzose or other grains of which are bound together by a cement of carbonate of lime, either invisible to the eye or occurring as a network of little veins and strings of crystalline carbonate of lime running throughout the stone. Other varieties of sandstone are similarly named from the prominent character of some part of their contents.

Argillaceous sandstone is a term not often used, nor is it very often applicable, though many rocks contain various mixtures of sand and clay. In many sandstones, too, little flat rounded patches of clay, more or less indurated, often occur. Similar little patches of clay may be seen on sandy shores, either originally deposited there in little hollows, or rolled as clay pebbles from some bed of clay. In quarrying sandstone, these clay patches are commonly called "galls" by the workmen. In highly indurated grits, they sometimes assume the form of pebbles of *slate*, though the slaty structure may often have been assumed in consequence of the subsequent induration, and not before they were embedded in the sandstone.

Geology.

There are many local terms used by quarrymen and miners for different varieties of sandstones, such as—

Rock, used generally in South Staffordshire to denote any hard sandstone.

Rotch, or *roche*, is generally used for a softer and more friable stone.

Rubble, means either loose angular gravel, or a slightly compacted brecciated sandstone.

Hazel is a North of England term for a hard grit.

Post is a similar term for any bed of firm rock, and is generally applied to sandstone.

Peldon is a South Staffordshire term for a hard, smooth, flinty grit.

Calliard, or *galliard*, is a northern term for a similar rock.

Fresstone is a term in general use, which is often applied to sandstone, but sometimes to limestones, and even to granite, as in the counties of Dublin and Wicklow. It means any stone which works equally *freely* in every direction, or has no tendency to split in one direction more than another.

Flagstone, on the contrary, means a stone which splits more freely in one direction than any other, that direction being along the original lines of deposition of the rock. These stones are ordinarily sandstones, though often very argillaceous, and some flagstones are perhaps rather indurated clay in thin beds than sandstone. Thin-bedded limestones may likewise often be called flagstone.

Sandstones, like *conglomerates*, may have been consolidated either by simple pressure continued for a long period of time, by pressure combined with an elevation of temperature, by the infiltration of mineral matter in solution, or by the aqueous or igneous solution and subsequent reconsolidation of some of the particles composing it, or lastly, by a combination of two or more of these actions. Some of the loose tertiary sands of the North of France, such as the *Sable de Fontainebleau*, and the *Sable de Beauchamp*, exhibit these actions in a very remarkable way. The *Sable de Fontainebleau* is a pure white siliceous sand. It is covered in some places by beds of a freshwater limestone called the *Calcaire de Beaue*. Water containing carbonate of lime in solution, derived either from this limestone, or from other sources, percolates through the sand, and deposits the lime, binding the sand either into globular concretions, or even into rhombohedral crystals, such as carbonate of lime ordinarily forms.

Besides these smaller concretions, other large parts of the sand have been compacted together, either at the time of deposition, or subsequently, into a very hard white gritstone, which is extensively used as a paving-stone in the district where it occurs. This *grès de Fontainebleau* forms picturesque crags and precipices, all the more striking perhaps, from the loose and easily removed sand in which the beds and other irregularly formed masses of the consolidated rock occur. The cementing substance of the sandstone may in some cases be carbonate of lime, equally diffused through the mass. In other cases, however, the quartzose grains appear to be bound together by a siliceous cement, as if the percolating water had contained dissolved silica. This is obviously the case in one variety, a glittering rock being produced, greatly resembling ordinary quartzite, only more white and lustrous; this variety is called "*grès lustrée*," or lustrous grit.

The *grès de Beauchamp* consists of similar locally consolidated and semi-concretionary lumps of sandstone, occurring here and there in loose sand. On the plains north of Meulan, these lumps of gritstone are discovered by "sounding" or piercing the loose sands with an iron rod, and they are then extracted and broken into square blocks, and used for forming the roads of the country.

These tertiary grits are often as hard and intractable, and break with as splintery a fracture under the hammer of the geologist, as the grits he is accustomed to meet with among the oldest rocks of the British mountains.

When among the materials of a sandstone there occur any containing a notable proportion of alumina, which may be known by the earthy odour given out when the rock is breathed upon, we have the constituents for the formation of clay, and it only remains for those materials to be ground down into fine powder and mixed with water, either naturally or artificially, for clay to be produced.

53. *Clay*.—Perfectly pure clay is a hydrated silicate of alumina. This is the substance known as "*kaolin*," or "*porcelain clay*," derived from the decomposition of orthoclase, albite, or other feldspars, from which the silicates of potash, soda, &c., have been washed out. In some granitic districts, the granite being decomposed yields this substance, which is carried down by water, and deposited in hollows,

the quartz and mica being often left behind in the state of loose sand.

Common clay, however, is often largely coloured with oxide of iron, and mingled with many impurities, besides being mixed in variable proportions with sand. Any very finely divided mineral matter, which contains from ten to thirty per cent. of alumina, and is consequently "plastic," or capable of retaining its shape on being moulded and pressed, would commonly be called clay.

These clays have a number of varieties, of which the following are the principal:—

Pipe-clay, free from iron, white, nearly pure.

Fire clay, nearly free from iron, and from all alkalies, often containing carbon, but this does not prevent its forming bricks that will stand the heat of a furnace.

Shale, regularly laminated clay, more or less indurated, and splitting into thin layers along the original laminæ or planes of deposition of the rock. The colliers' and quarrymen's terms for shale are *Bind*, or *Bluebind*, *Metal*, *Plate*, &c. When very fine, and containing a large proportion of carbonaceous matter, the collier calls it *Batt*¹ or *Bass*, the geologist carbonaceous or (bituminous) shale, and the coal merchant often "*slate*." In Scotland the collier's term for shale appears to be "*blaes*," or "*blues*," the shales being often bluish gray. When lumpy, they are called "*lipey blaes*." Black, argillaceous shales (or batts) are called "*dauks*;" "*fekes*," or "*gray fekes*," seem to be sandy shales such as would be called "*rock binds*" in South Staffordshire. (See William's *Mineral Kingdom*.) In the South of Ireland carbonaceous shale is called "*kelve*," and indurated slaty shale is termed "*pinsill*," or "*pencil*," as it is used often for slate pencils.

Clunch is a common name for a tough, more or less indurated clay, often very sandy.

Loam is a soft and friable mixture of clay and sand, enough of the latter being present for the mass to be permeable by water, and to have no plasticity.

Marl is properly calcareous clay, which, when dry, naturally breaks into small cubical or dice-like fragments. Many clays, however, are commonly but erroneously called marls, which do not contain lime.

Argillaceous flagstone is an indurated sandy clay or clayey sandstone, which splits naturally into thick slabs or flags.

Clay slate is a metamorphosed clay, differing from shale in having a superinduced tendency to split into thin plates, which may or may not coincide with the original lamination of the rock. It will be more particularly described among the metamorphic rocks.

II.—CHEMICAL AND ORGANIC ROCKS.

Preliminary Observations on their Origin.

Before entering on the description of these rocks, it will be useful briefly to consider the nature and action of the forces concerned in their production. We shall take as our principal guide in this examination Bischof's *Chemical and Physical Geology*, as translated for and published by the Cavendish Society.

Carbonate of Lime.—Carbonate of lime is nearly insoluble in pure water, but if the water contain carbonic acid gas, the mineral is easily dissolved by it, either in consequence of some special solvent power in water so impregnated, or in consequence of the carbonate being converted into a soluble salt (never yet seen in a solid state) in the form of a bicarbonate of lime.

Rain water and snow contain small quantities of carbonic acid derived from the atmosphere, and acquire more in sinking through the soil.

If water, in sinking into the earth, meets with carbonic acid gas rising from the interior, it becomes saturated with it, and

¹ This term of "*batt*"—commonly applied in South Staffordshire to a lump of shaly coal which will not continue to burn in the fire, and therefore soon becomes ash, and is consequently of little worth—has gone out of general use in the English language except in composition, where it is retained in the word "*brick-bat*" for the broken end of a brick.

Geology. carbonated springs are produced. The waters of springs, rivers, and lakes, therefore, always contain some, and probably a very variable amount of carbonic acid gas. The waters of the European seas, according to Vogel and Bischof, contain from 7 to 23 parts by weight of carbonic acid gas in the 100,000 of water. But from experiments made in the French ship "Bonité," in the Indian Ocean, only from 0.4 to 3.0 parts by weight in the 100,000. (*Bischof*, vol. i., p. 113, &c.)

The quantity of carbonate of lime thus held in solution by water containing carbonic acid gas is likewise very variable. In springs it may occasionally reach the point of saturation, which is about 105 parts in the 100,000.

In the rivers of Great Britain and Western Europe, the quantity of mineral matter held in solution varies from 4 to 55 parts in 100,000 parts of water, the mean quantity being 22. Of this mineral matter one half is commonly carbonate of lime, the least proportion, or 35 per cent., being found in the Loire; the greatest, 82 to 94 per cent., in the Rhone at Lyons. The quantity of mineral matter in the Thames, near London, is 33 in the 100,000 parts of water, 15 of which, or 46 per cent., are carbonate of lime. Bischof calculates that if the mean quantity of carbonate of lime in the Rhine be assumed as 9.46 in the 100,000 of water, which it is at Bonn, then, according to the quantity of water estimated by Hagen to flow at Emmerich, enough carbonate of lime is carried into the sea by the Rhine, for the yearly formation of three hundred and thirty-two thousand millions of oyster shells of the usual size.

Notwithstanding the vast quantity of carbonate of lime thus carried down into the sea, observation shows that the quantity to be found in sea-water is commonly very small. In most analyses of sea-water it is not mentioned at all. Sea-water from Carlisle Bay, Barbadoes, contained 10 parts in 100,000; sea-water from between England and Belgium, only 5.7 parts in 100,000. In the open sea, at a distance from any land, it is said to be rarely if ever discoverable by analysis.

The smallness of the quantity to be found in sea-water, compared with that in almost all rivers, is doubtless owing to the quantity of carbonate of lime constantly abstracted from sea-water by marine animals, in order to form their shells and other hard parts.

Bischof states that the quantity of free carbonic acid gas contained in the sea, is five times as much as is necessary to keep in a fluid state the quantity of carbonate of lime to be found in it. He argues, therefore, that it is impossible for any carbonate of lime to be *precipitated in a solid form at the bottom of the sea by chemical action alone*.

Carbonate of lime is deposited on land by springs and rivers, in consequence of the evaporation of the water, and the consequent extrication of a portion of the carbonic acid gas that previously held the carbonate of lime in solution.

But it is clearly impossible for any evaporation of water and gas to occur to a sufficient extent in the sea for this precipitation to take place. We are almost compelled, therefore, to conclude with Bischof, that all our marine limestones have been formed by the intervention of the powers of organic life, separating the little particles of carbonate of lime from the water and solidifying them, in order to enable them to form part of a solid rock.

There is of course the possibility that the sea once contained a much greater proportion of carbonate of lime than it does now, though this does not appear likely when we recollect that in the earliest and least fossiliferous of our formations there is a much smaller proportion of limestone than in later and more fossiliferous rocks; and that even in the oldest¹ limestones organic remains are to be found.

¹ In the highly altered limestones associated with gneiss and mica slate, we could hardly expect to find traces of fossils, even if they

Geology. The purely chemical processes now open to our observation, in which limestone is being formed, are the following:—

54. *Stalactites* and *Stalagmites*, *Travertine* and *Calc Sinter*, are formed in places where water containing carbonate of lime in solution suffers from evaporation, and deposits the carbonate in a solid form. Each drop of water loses by evaporation both water and carbonic acid gas, thus becoming more saturated with the carbonate of lime, at the same time that it loses some of its solvent power. It is therefore forced to part with some of this carbonate of lime, which adheres in a solid form to the nearest part of the solid substance over which the water passes. In the case of *stalactite* and *stalagmite*, a coating of solid matter is thus formed, with long icicle-like pendants hanging from the roof of caverns or arches, and columns rising from the floor wherever the water continues to drop long enough in one particular spot. Vertical sheets of it may even be formed when the water oozes from a long joint or crevice in the roof. The part hanging from the roof is called *stalactite*; that on the floor *stalagmite*. The limestone thus formed is commonly white or pale yellow, subcrystalline, often fibrous, and when thin, semitransparent or translucent.

Stalactites may often be seen under the arches of bridges, vaults, or aqueducts, especially if the stone of which they are built be limestone. Sometimes they are even derived from the carbonate of lime contained in the mortar or cement used in their construction.

Travertine, or *Calcareous Tufa*, is deposited by exactly the same process on the margins of springs or on the banks of rivers and the sides of waterfalls, or wherever water containing carbonate of lime in solution is brought into circumstances where rapid evaporation can take place. Sticks and twigs hanging over brooks often become coated with it; and the incrustation of bird's nests, wigs, medallions, and other matters, by the action of what are called petrifying wells, is commonly known. In Italy large masses of solid and beautiful travertine are deposited by some of the springs, so that it is used as a building stone. The Colosseum at Rome is built of stone thus formed. The name *travertine* is derived from the Tiber, meaning simply Tiber-stone.

Pipes to convey water, especially water from boilers, frequently become choked up by the deposition of limestone. Bischof says that there are fifty springs near Carlisle giving out 800,000 cubic feet of water in twenty-four hours, from which, according to Walchner's calculation, a mass of stone weighing 200,000 pounds could be deposited in that time.

Marine Limestones.—The marine depositions of carbonate of lime now taking place are best studied in coral reefs. In almost all tropical seas, incrusting patches or small banks of living coral are to be found along the shores, wherever they consist of hard rock, and the water is quite clear. In the Indian and Pacific Oceans, however, far away from any land, huge masses of coral rock rise up from vast and often unknown depths just to the level of low water. These masses are often unbroken for many miles in length and breadth; and groups of such masses, separated by small intervals, occur over spaces sometimes of 400 or 500 miles long, by 50 or 60 in width. The barrier-reef along the N.E. coast of Australia is composed of a chain of such masses, and is more than 1000 miles long, from 10 to 90 miles in width, and rises at its seaward edge from depths which in some places certainly exceed 1800 feet. These reef masses consist of living corals only at their upper and outer surface; all the interior is composed of dead corals and shells, either whole or in fragments, and the calcareous portions of other marine animals. The interstices of the mass are filled up and compacted together by calcareous

once contained them. Organic forms have, however, lately been discovered in altered limestone from the gneiss of Scotland.

Geology.

sand and mud, derived from the waste and debris, the wear and tear of the corals and shells, and by countless myriads of minute organisms, mostly calcareous also. The surface of a reef, where exposed at low water, is composed of solid-looking stone, which is often capable of being split up and lifted in slabs, bearing no small resemblance to some of our oldest limestones. These slabs and blocks, when broken open, are frequently found to have a semicrystalline structure internally, by which the forms and the organic structure of the corals and shells are more or less disguised and obliterated. The "bottom" in and among the reefs composing the great Australian barrier, at a depth of some twenty fathoms, often looked, when brought up in the dredge, very like the unconsolidated mass of some of the coarse shelly limestones to be found among the oolites of Gloucestershire. At other times the dredge came up completely filled with the small round foraminiferous shells called orbitolites, and these organisms seemed in some places to make up the whole sand of the beach either of the coral islets or of the neighbouring shores. In the deep sea around, and in all the neighbouring seas, from Torres Straits to the Straits of Malacca, wherever "bottom" was brought up by the lead, it was found to be a very fine-grained impalpable pale olive-green mud, which was wholly soluble in dilute hydrochloric acid. This substance, when dried, would therefore be scarcely different from chalk, though it commonly was of a greener tinge. Raised coral reefs, in the islands of Timor and Java, were often internally as white and friable as chalk, though they had frequently a rougher and grittier texture, and weathered black outside. The weathered surfaces of these limestones, often at a height of 200 or 300 feet above the sea, with their embedded shells of all descriptions, including a tridacna of one or two feet in diameter, differed in no respect from some of the surfaces of the Great Barrier Reef, where exposed at low water. (*Voyage of H.M.S. Fly.*)

On the upper surfaces of some of the existing coral reefs small islands are formed; the coral sand being drifted by the winds and waves till it forms a bank reaching above high-water mark. In some of these islands the rounded calcareous grains are bound together into a solid stone by the action of rain-water, which, containing a small quantity of carbonic acid, dissolves some of the carbonate of lime as it falls, but being shortly evaporated, redeposits it again in the form of a calcareous cement. Some of this stone presented very distinct examples of the oolitic structure presently to be mentioned, little minute grains and particles being enveloped in one or two concentric coats, like the coats of an onion. That this stone was not consolidated under water was proved by nests of turtles' eggs being found embedded in it, evidently deposited by the animal when the sand was above water, and was loose and incoherent.

Guided by these facts and observations, we may form tolerably accurate notions of the mode of origin of all our marine limestones, and attribute to them an organic-chemical origin, taking into account, at the same time, how easily they may have been subsequently altered in texture by the metamorphic action either of water or of heat.

We must also bear in mind that, although the carbonate of lime may have been secreted and brought into a solid form from its aqueous solution by the action of animal life, yet that the original form it thus received has been retained in only a small part of it; the great mass having been subjected to the mechanical actions of erosion, trituration, and transport, to a greater or lesser extent, in the process of its conversion into calcareous sand and mud, and deposition as beds of limestone.

¹ See Dr Carpenter's papers on these creatures in the *Philosophical Transactions*.

Geology.

Fresh-water Limestones.—Those limestones which have been formed in fresh-water lakes, and are called fresh-water limestones, may more nearly resemble travertine in their mode of origin, since there is nothing to forbid the supposition of the waters of lakes becoming so highly impregnated with dissolved carbonate of lime as actually to deposit it as a chemical precipitate. At the same time, most fresh-water limestones look more like the result of the deposition of a highly calcareous, rather clayey mud, than of a precipitate of pure carbonate of lime. They become then the extreme term of marl or calcareous clay, and may be the result of either the disintegration of shells, &c., or of the mechanical action of rivers on previously existing calcareous rocks, the calcareous mud thence derived being perhaps mingled with the detritus of other rocks in greater or less quantity.

Silica.—The aqueous deposition of silica is sometimes a purely chemical one, as in the case of the *siliceous sinter* deposited round the Geysers, or hot springs, of Iceland; and round the hot springs of St Miguel and Terceira, in the Azores; and the chalcedony round those of New Zealand. Cold-water springs also, in some instances, deposit siliceous matter; but in these the silica is generally combined with alumina, oxide of iron, and other bases. In all these cases, evaporation of the water takes place; and Bischof attributes the formation of quartz crystals in cavities, and of compact quartz in veins, to the total evaporation of water containing silica in solution, and trickling down the sides of such cavities. He shows the impossibility of ascending springs depositing the quartz, inasmuch as those must be full of water, and therefore total evaporation of successive films of water could not take place. He attributes the formation of quartz crystals in drusy cavities to a similar evaporation of water containing silica, that has filtered through the adjoining rock. Agates, chalcedony, &c., show very distinctly the successive deposition of films of silica.

Marine Flints.—To account for the deposition of silica on the bed of the sea, where evaporation is not possible, we are compelled, as in the case of limestone, to call in the aid of the powers of animal life. The minute shells of many of the infusoria are almost entirely composed of silica, which they have extracted from the water of the sea. Some kinds of rock, such as the tripoli, or polishing slate, are entirely made up of these microscopic substances, some beds thus formed being many fathoms in thickness and many miles in extent.

All seas, from the equator to the poles, abound with these minute organisms. They have been found living even in ice. The phosphorescence of the sea, also, is due to the presence of organic beings, a large proportion of which are siliceous-cased animalcules. The bottom of the mid-Atlantic, at a depth of 2000 fathoms, was found, in some of the late hydrographic surveys of the United States, to be covered by what appeared to be a fine clay; but this, on examination, was discovered to be entirely composed of the siliceous shells of infusoria.¹ According to Ehrenberg, there are formed annually in the mud deposited in the harbour of Wismar, in the Baltic, 17,946 cubic feet of siliceous organisms. Although it takes a hundred millions of these animalcules to weigh a grain, Ehrenberg collected a pound-weight of them in an hour. So prolific are they, moreover, that "a single one of these animalcules can increase to such an extent during one month, that its entire descendants can form a bed of silica 25 square miles in extent, and 1½ foot thick. As a parallel to Archimedes, who declared he could move the earth if he had a lever long enough, we may say,—Give us a mailed animalcule, and with it we will in a short

¹ Maury's *Physical Geography of the Sea*, p. 210. The student is reminded that this fine clay is not formed of the debris of these shells, but of the unbroken shells themselves. This will give him an idea of their minuteness.

Geology. time separate all the carbonate of lime and silica from the ocean."¹ The silica thus rendered solid, may either be deposited alone, or may be associated, as will most probably be the case, with the debris of calcareous matter forming marine limestones, and having an equally organic derivation. When thus diffused in the finest particles, pretty equally perhaps through the mass of calcareous mud, it may either be consolidated in this equally diffused state, producing a more or less siliceous limestone, or it may, in obedience to certain chemical laws, segregate itself from the calcareous matter, and form either distinct layers and veins, or concretionary balls and nodules. The presence of any body itself consisting largely of silica, such as many sponges, will facilitate and determine this process, affording a centre of attraction for the siliceous particles to collect around it from the adjacent matter.²

These views of the organic origin of most marine limestones and flints are corroborated by the fact, which we shall presently describe, of almost all great masses of limestone being accompanied by siliceous portions of a peculiar character, such as are not found in any other rocks except limestone.

Carbonate of Magnesia.—Magnesia occurs in sea-water in the form of chloride of magnesium and sulphate of magnesia. Of the solid salts dissolved in sea-water, 8 to 15 per cent. consists of chloride of magnesium, and 6 to 16 per cent. of sulphate of magnesia. (*Bischof*, vol. i., p. 99–105.) From the quantity of free carbonic acid in the sea, it is plain that these might be converted into carbonate of magnesia, but that if so, it would be kept in solution as a bicarbonate (sesqui-carbonate), as in the case of carbonate of lime. All that has been said, therefore, as to the necessity for calling in the aid of organic life to solidify carbonate of lime from the waters of the sea, "holds good in regard to carbonate of magnesia, and the more so since this salt always separates later than carbonate of lime, even from fluids which have undergone a very high degree of evaporation." (*Bischof*, vol. i., p. 117.)

There is, however, this difficulty in this view,—the carbonate of lime is largely separated from the sea-water by being made to enter into the composition of the hard parts of marine animals in overwhelming proportion, whereas the per centage of carbonate of magnesia to be found in the hard parts of corals and mollusca does not exceed 1 or 2 per cent.³ Neither do we know any class of animals that secrete any much greater quantity of magnesia as some of the infusorial animals secrete silica. Yet in many widely-spread magnesian limestones the quantity of magnesia is almost equal to that of lime, and the proportion is frequently as much as 20 to 30 per cent. According to Forchhammer, the fucoid marine plants contain more than 1 per cent. of magnesia; but the remains of such plants are rarely if ever found in magnesian limestones. Magnesian limestones are, moreover, generally poor in organic remains, though this may be the result of their more perfect crystallization and mineralization in various ways, by which the organic structure has been obliterated, rather than of the absence of organic beings from the original deposit.

In whatever way effected, it is true that magnesian limestones, containing various proportions of lime and magnesia, have been deposited originally as magnesian limestone at the bottom of the sea, sometimes in large quantities, and over considerable areas.

It is equally true that pure carbonate of lime has in many

cases been subsequently converted into dolomite or magnesian limestone by chemical metamorphic action.

The resemblance which magnesian limestones, even where the carbonate of magnesia is in comparatively small proportion, bear to true dolomites, and their likeness to a chemical precipitate rather than to a mere sedimentary deposit, induce us to pause before denying altogether that such precipitation of carbonates, whether of lime or magnesia, have taken place on the bed of the sea without the intervention of organic life.

Sulphate of Lime and Rock-salt (chloride of sodium) are undoubtedly chemical precipitates, and we are here again met by the same difficulty as before, in assigning a proximate cause for that precipitation in the open sea. If we could imagine a portion of sea-water separated from the ocean, and left as a shallow lagoon to gradually dry up, there would be no difficulty in the case.

Bischof gives the following as the average composition of the salts of the sea-water (vol. i., p. 379):—

	Per cent.
Saline contents of sea water	3·527
Consisting of—	
Chloride of Sodium (common salt)	75·786
Chloride of Magnesium	9·159
Chloride of Potassium	3·627
Bromide of Sodium	1·184
Sulphate of Lime (gypsum)	4·617
Sulphate of Magnesia (Epsom salts)	5·597
	100·000

He tells us too, that when sea-water is evaporated, the point of saturation for sulphate of lime is much sooner reached than that for rock-salt; 37 per cent. of the water being required to be removed in the one case, and 93 per cent. in the other. Gypsum, therefore, must always be deposited before rock-salt, and it is possible for the point of saturation to be reached for gypsum in many cases without that for rock-salt being attained. This may be the reason why, although the sea contains sixteen times as much salt as it does gypsum, that the latter more frequently occurs as a mineral deposit than the former, though not often in such great masses.

In isolated seas, such as the Dead Sea, where the water is entirely saturated with salt, evaporation doubtless causes a precipitation on its bed (*Bischof*, p. 400). Here, and in shallow lagoons, such as the limans of Bessarabia, south of Odessa, that dry up in summer, we have the formation of rock-salt going on before our eyes.

In fresh-water lakes, sulphate of lime may be deposited, either directly, the water becoming saturated with that substance, or in consequence of springs or rivers containing sulphuric acid, which convert into sulphates the carbonates of the marls and calcareous muds already deposited. In some instances chemical reactions, such as the oxidation of iron pyrites (bisulphuret of iron), and that of sulphuretted hydrogen, may be supposed to take place, producing sulphuric acid, which immediately acts on any carbonate of lime that it can reach.

Carbon may be looked upon as essentially an organic element. Wherever we find carbonaceous matter in rocks, therefore, we may suspect it to have been derived from organic substances. Even the diamond is now believed to be a crystallized gum, or other vegetable product; and graphite may in like manner be looked upon as a possible, if not a probable, result of the metamorphosis of either animal or vegetable substance into a mineral. Even the purest graphite contains traces of earthy matter, diminishing its claims to be considered an original independent substance.

Carbon enters into the composition of animal matter, but its most abundant source is the vegetable kingdom.

Again taking Bischof as a guide in the explanation of the conversion of the organic substance wood into the rock

¹ *Bischof*, p. 188.

² Mr Bowerbank has proved the presence of sponge particles in many flints and cherts, and refers them all to that origin.

³ It was stated by Professor Rogers, at the meeting of the British Association at Cheltenham, that Silliman junior had recently found a very large per centage of magnesia in the composition of corals.

Geology. which we call coal, we abstract some of his results in the following remarks:—

Table of the Composition of Carbonaceous Substances.¹

Substances.	Carbon.	Hydrogen.	Oxygen and Nitrogen.
Wood	49.1	6.3	44.6
Peat	54.1	5.6	40.1
Lignite.....	69.3	6.6	25.3
Coal	82.1	5.5	12.4
Anthracite	94.0	3.0	3.0

In addition to these elements, however, the four latter substances given above contain variable quantities of earthy impurities, which are given, as in

Peat.....	from 4.6 to 10.0 per cent.
Lignite	0.8 to 47.2 ...
Coal.....	0.24 to 35.5 ...
Anthracite	0.94 to 7.07 ...

Looking on these earthy matters as accidental and unessential, we learn from the examination of the above table, that the rocks anthracite, coal, and lignite, and the intermediate substance peat, consist of the same constituents as the organic substance wood, the differences between them being in the proportions in which these constituents occur.

No other rocks except the coals have a composition at all similar to this.

If we abstract from wood some 30 per cent. of its oxygen and nitrogen, and compress the remainder till it becomes more dense and compact, it must form coal.

If, therefore, we suppose wood (or vegetable matter) buried under accumulations of more or less porous rock, such as sandstone and shale, so that it might rot and decompose, and some of its elements enter into new combinations, either gaseous or liquid, those combinations always using up a greater quantity of oxygen and nitrogen than of carbon and hydrogen, or of oxygen and hydrogen than of carbon, we should have the exact conditions for the transformation of vegetable matter into coal.

This process might naturally take place in four ways:—

- 1st. By the separation of carbonic acid gas (consisting of two equivalents of oxygen and one of carbon= CO_2) and carburetted hydrogen (consisting of four equivalents of hydrogen to two of carbon= C_2H_4) from the elements of the wood.
- 2d. By the separation of carbonic acid from the elements of the wood, and the oxidation of some of the hydrogen (i.e., its conversion into water= H_2O) by combination with external oxygen.
- 3d. By the separation of both the carbonic acid and the water from the elements of the wood.
- 4th. By the separation of all three substances, carbonic acid, carburetted hydrogen, and water, from the elements of the wood.

The loss of carbon is greatest in the first case, and least in the third, being always greater in proportion to the quantity of carburetted hydrogen which is disengaged.

The great quantities of carbonic acid gas (choke damp) and carburetted hydrogen (fire damp) met with in coal mines, shows the fact of the large extrication of these substances, and corroborates, if need were, this explanation. Reservoirs of these gases in a highly compressed state are often found to be pent up in the crevices and cavities of coal beds, and are the cause, when tapped, of many of the accidents which take place. Some beds of coal are so saturated with gas, that, when cut into, it may be heard oozing from every pore of the rock, and the coal is called "singing coal" by the colliers.

Bischof shows, that "under circumstances otherwise similar, the conversion of vegetable substances into coal takes

¹ See also a very clear explanation of this subject in Ronald's and Richardson's *Chemical Technology*, vol. i., p. 31.

place in the same way, whether they are mixed with much or little earthy matter." He also believes, from Kremer's and Taylor's investigations into the nature of the ash of coal, that there was an *intimate mixture* of vegetable and earthy substances, and that coal containing earthy matter could not be formed from compact wood without previous decay having taken place (vol. i., p. 269). He seems to suppose that, in many instances, this decay has gone so far as to convert the vegetables into "mould," which has been drifted as a kind of vegetable mud, and when mixed with earthy matter, deposited under water in the place where we now find it as coal.

From these preliminary considerations, we learn that plants living in the air extract from it the invisible carbonic acid and other gases, and by the hidden processes of life, compel them to enter as solid and visible substances into the composition of their own bodies; and that animals¹ living in the sea, in like manner extract from it the invisible solutions of lime and other substances, and similarly compel them to become solid and visible parts of their own bodies. In each case the substances thus rendered visible and solid by the action of organic laws, become, after the death of the organism, subject to the ordinary laws governing inorganic matter, and after undergoing more or less alteration, are used as materials for assisting in the construction of the external crust of our earth.

Description of the Chemically and Organically formed Aqueous Rocks.

55. *Limestone* may be hard or soft, compact, concretionary, or crystalline, consisting of pure carbonate of lime, or containing silica, alumina, iron, &c., either as mechanical admixtures, or as chemical deposits along with it.

Different varieties of limestone occur in different localities, both geographical and geological, peculiar forms of it being often confined to particular geological formations over wide areas, so that it is much more frequently possible to say what geological formation a specimen was derived from, by the examination of its lithological characters, than in the case of limestone, than in that of any other rock².

Compact limestone is a hard, smooth, fine-grained rock, generally bluish gray, but sometimes yellow, black, red, white, or mottled. It has either a dull earthy fracture, or a sharp, splintery, and conchoidal one. It will frequently take a polish, and when the colour is a pleasing one, is used as an ornamental marble.

Crystalline limestone may be either coarse or fine-grained, varying from a rough granular rock of various colours, to a pure white, fine-grained one, resembling loaf sugar in texture. This latter variety is sometimes called *saccharine*, sometimes *statuary marble*. The crystalline structure of limestone is either original, when it is often found that each crystal is a fragment of a fossil; or it has been superinduced by metamorphic action on a limestone formerly compact.

Chalk is a white, fine-grained limestone, sometimes quite earthy and pulverent, sometimes rather harder and more compact, as the chalk of the north of Ireland, and some of that of the north of France.

Oolite is a limestone in which the mineral has taken the form of little spheroidal concretions, and the rock looks like the roe of a fish, from which its name, signifying *egg*, or *roe-stone*, is derived. These little concretions have several concentric coats, sometimes hollow at the centre, some-

¹ Although coral-reefs were dwelt on as the most obvious and abundant source of limestone at the present day, it was not intended to infer that they had always been so. The older limestones have none of the huge reef-making corals in them; the small corals they contain merely contributed to their formation, together with other animals that secreted carbonate of lime.

² No experienced British geologist would be likely to confound characteristic specimens of the limestones of the Silurian, Carboniferous, Oolitic, and Cretaceous formations of Britain and Western Europe; while any one might easily mistake the argillaceous or arenaceous rocks of those different formations.

Geology.

Geology. times enclosing a minute little grain of siliceous, or calcareous, or some other mineral substance. It is commonly of a dull yellow colour, but gray oolitic limestone is not unfrequent. Its peculiar structure gives it the character of a freestone, working easily in any direction; whence its value as a building stone.

Bath stone, Portland stone, Caen stone, are well-known examples of oolitic limestone.¹

Pisolite is a variety of oolite, in which the concretions become as large as *peas*. It is a structure not confined to limestone, however, as other rocks or minerals occasionally assume it.

Many limestones are named from their containing some peculiar variety of fossil, as *nummulite*, *clymenia*, *crinoidal* limestone, and *shell limestone*, or *muschelkalk*.

Others have local names given them, as the *calcaire grossier* of Paris, a coarse limestone, some beds of which are used for building, while others are a mass of broken shells.

Cipolino, a granular limestone containing mica; *majolica*, a white, compact limestone; *scaglia*, a red limestone in the Alps. (Murchison and Nicol, in *Johnston's Physical Atlas*.)

Ireland especially abounds in a great variety of limestones used for ornamental marbles, such as the green serpentine-marble of Ballynahinch in Galway; the black marble of Kilkenny; the brown, red, and dove-coloured marble of Cork and Armagh; and many others less known, and some of them unworked, but equally beautiful with those that are. In Derbyshire and North Staffordshire, we have a similar abundance of ornamental marbles.

Fresh-water limestones have commonly a peculiarity of aspect, from which their origin may sometimes be suspected, even before examining their palæontological contents, or petrological relations. They are generally of a very smooth texture, and either dull white or pale gray, their fracture only slightly conchoidal, rarely splintery, but often soft and earthy.

Flint and Chert.—The association of flints with chalk is well known. Chalk flints occur as rounded nodular masses, of very irregular, and sometimes fantastic shape, and of all sizes, up to a foot in diameter. They are commonly white outside, but internally are of various shades of black or brown, sometimes passing into white. They have sometimes concentric bands of black and white colours internally, and exhibit markings derived from organic bodies round which they have often been formed. Flint occurs in chalk not only in nodules, but also in seams or layers, sometimes

Geology. short and irregular, sometimes regular, over a distance of several yards. These seams vary from half an inch to two inches in thickness, and are commonly black in colour.

Almost all large masses of limestone have their flints or siliceous concretions. These are frequently called *chert*, as in the carboniferous limestone, where the nodules and layers of chert exactly resemble the flints in chalk.

Fig. 2.

Sketch of part of a seam of black chert in the limestone near Dublin. These seams, like those in chalk, are sometimes quite regular for some distance, and then either suddenly terminate, split up, or are subject to other irregularities like those in the figure.

Even the tertiary limestones around Paris have their flints, the melanite of that locality being nothing but a siliceous concretion, found in the Calcaire St Ouen, and possibly other places.

Pure siliceous concretions occur even in the freshwater limestones and gypsum beds of Montmartre.

This invariable, or nearly invariable accompaniment of limestone and siliceous deposits,—those siliceous parts having a chemical, and not a mechanical formation,—strengthen the hypothesis of the organic origin of both, as previously described.

The silica diffused through the calcareous mud, of which the limestone was composed, has sometimes remained so diffused, instead of separating as nodules or layers, producing a *cherty* or *siliceous limestone*.

Clay, or argillaceous matter, has frequently been deposited with the calcareous, producing *argillaceous limestone*, which may be known by the earthy odour given out by it when breathed upon.

Carbonaceous matter, derived either from decaying vegetables, or perhaps more frequently from the decomposing animals of whose hard parts the rock is composed, produces in like manner the *black limestones*, which are in some instances called *bituminous limestones*. Little nests of pure anthracite, or other variety of carbonaceous matter, are sometimes found in the hollows of shells buried in limestone. The fetid smell, like that of sulphuretted hydrogen gas, given off by many limestones when struck with a hammer, is probably another result of the decomposition of animal matter, producing what is called "*fetid limestone*," or, by the Germans, "*stinkstein*."

When the argillaceous has been mingled with the calcareous matter in very large proportion, a subsequent separation of the two has often taken place, the lime having segregated itself from the mass in this case, as the siliceous separated from the calcareous matter in the case of flints and chert. Nodular lumps of limestone are then produced, divided from each other by little, often irregular, seams and layers of shale or clay. These concretionary lumps of limestone are sometimes merely scattered through the clay, but they often form regular seams or beds, the upper, or under, or both surfaces being uneven and nodular. It is sometimes difficult to say whether the little parting films and small seams of clay which occur between the beds have been deposited at different times from the calcareous matter, or having fallen together with it as an argillo-calcareous mud, have had their calcareous particles sucked out of them, as it were, by the segregating influence of chemical affinity.

It is by no means intended to infer that alternate deposits of thin layers of calcareous matter and purely argillaceous or arenaceous matter have not frequently occurred; we only wish to put the student on his guard against taking particular structures as proofs of original deposit, which, especially in so active and unstable a substance as carbonate of lime, may in many instances be the result of subsequent agency.

Fig. 1.

Sketch of some beds of limestone containing nodules of white chert, at Middleton Moor, in Derbyshire, in which the irregular and fantastic shapes assumed by these nodules are well exhibited, as also their likeness to flints in chalk.

¹ This oolitic structure is by no means confined to what is known as the Oolitic formation. We have already mentioned its occurrence in coral limestone. It occurs also largely in the carboniferous limestone of Ireland, and may recur in the limestones of any formation.

Geology.

It is comparatively rare to find such a mingling of quartzose sand and lime as could be called *arenaceous limestone*, though we have already seen that *calcareous sandstones* are not uncommon. Scattered pebbles, however, are sometimes found in chalk and other limestones; and a curious instance, first noticed by Professor Haughton, occurred at Crumlin, near Dublin, of angular fragments of granite, several inches in diameter, accompanied by granitic sand, being found embedded in limestone, four or five miles from any known granitic mass *in situ*. Such fragments may perhaps have been floated in the roots of trees and other vegetables, just as in the present day pebbles of hard stone, highly valued by the natives, are found in the roots of trees cast up upon the shore of archipelagoes of coral islands in the Pacific, as mentioned by Chamisso and Darwin.

Magnesian limestone.—Carbonate of magnesia is often found in marine limestones, mingled in various proportions with the carbonate of lime. Its occurrence in small quantity frequently gives a sandy appearance and gritty feel to an otherwise smooth and compact limestone. When examined with a lens, this apparent sand is found to be made up of minute dolomitic crystals, commonly of a yellowish brown colour, and with a pearly lustre.

In a true magnesian limestone the crystallization and the pearly lustre is generally very distinct, though sometimes the crystals are minute. Its colour is commonly some shade of brown or yellow, occasionally tinged with red; gray and black varieties, however, occur sometimes over very large areas.

Magnesian limestone is very variable in lithological character. It is sometimes of a powdery, earthy, and friable texture; sometimes splits into thin slabs, some of which are flexible; sometimes forms singular concretionary masses, a number of balls touching each other, either like bunches of grapes, when it is called botryoidal, or like musket balls, or great piles of cannon shot. Many of these balls, on being broken open, are found to have a radiated structure. That all these curious forms have been produced subsequently to the deposition of the mass is shown by the fact of the lines of deposition or stratification proceeding through them regularly, without regard to the spherical outlines or radiated structure of the balls.

Magnesian limestone occurs in two forms, original and metamorphic. In some limestones the carbonate of magnesia has clearly been deposited together with the carbonate of lime, the whole having been originally formed as a magnesian limestone.

In other instances, it can be shown, from the geological conditions, that whether the rock originally contained magnesia or not, its present distribution and mode of occurrence, and its highly crystalline structure, are the result of agencies operating subsequently to the original formation of the rock, and affecting a number of different beds simultaneously, along certain narrow lines of fissure, to the neighbourhood of which the *dolomatized* condition of the rock is confined.

57. *Gypsum* occurs as a rock in various ways. It sometimes forms regular beds, sometimes irregular concretionary masses, sometimes veins and strings in the mass of other rocks.

Compact Gypsum or *Alabaster*¹ is one variety; granular, finely crystalline gypsum another. The thin beds and the veins and strings of gypsum are commonly fibrous, the fibres being at right angles to the beds. The gypsum of Montmartre, from which plaster of Paris is derived, is chiefly granular gypsum, each bed being composed of many layers of little crystals, slightly differing in colour and texture, and thus assuming a regularly laminated appearance. This would lead us to suppose that this rock, which is associated with fresh-water limestones and marls, was formed by the

periodical deposition of layers of small crystals of sulphate of lime at the bottom of the water.

Geology.

In August 1855 we observed in the quarries north of Montmartre one or two beds, six or eight inches in thickness, of beautifully crystallized sulphate of lime, in large perpendicular plates, interstratified with these little layers of crystals. All the beds were horizontal; and the layers of small crystalline grains were quite parallel to the stratification; but in the beds above mentioned, large tabular crystals and broad flakes of selenite, of rather irregular form, had struck directly across the bed, more or less nearly at right angles to it, the original horizontal lamination not being obliterated, but being in some places waved, as if slightly disturbed by the formation of the crystalline plates, the angles of these waves having evident relation to the faces and angles of the superinduced crystalline plates.

Fig. 3.

a. Layers of small crystalline granules of gypsum.
b. Crystalline plates of gypsum, traversed by the faintly seen and displaced original layers of granules. These lines are not sufficiently oblique in the woodcut; on the faces of some of the crystals they form angles of 35° with the plane of the beds.

This formed a good case, like that before-mentioned as occurring in the spheroidal concretions of magnesian limestone and other rocks, of a molecular change of structure having taken place in the mass of the rock subsequently to its formation. It yet remains for the chemist to explain to us the exact method of operation by which these changes are produced.

58. *Rock-salt* commonly occurs in Britain as a rudely crystalline, irregularly bedded mass, commonly stained of a dirty red by the mixture of feruginous clay and other impurities. Perfect cubical and transparent crystals occasionally occur, and curious spheroidal bands, of a white colour, are sometimes observable in the roof of a salt-mine. Bed-like masses of rock-salt are often 60 or 90 feet thick, thinning out probably in all directions, and thus taking the form of large cakes. In other countries, more numerous beds occur, but not making up larger masses. In some of these the salt is perfectly pure and white; but in all countries, and in all geological formations, the association of salt with gypsum, and with green, red, and variegated marls, is a frequent if not invariable occurrence. We have already seen how natural and almost inevitable is the occurrence of gypsum with rock-salt; but the accompaniment of red and variegated clays has not yet been explained. When it is, it will probably throw great light on the circumstances under which the rock-salt itself has been deposited. Dolomite is also often found in connection with rock-salt.

59. *Coal* is a rock the general aspect and nature of which is familiar to everybody. Its chemical composition has been spoken of above, and the resemblance of that composition to that of wood, and the way in which, by a slight alteration in the proportion of its component parts, and an accompanying physical consolidation, the one may be converted into the other. Coal is very commonly divided into bituminous and non-bituminous. Now bitumen is rather a vague term, including several combustible substances, such as asphalt or mineral pitch, elastic bitumen or mineral caoutchouc, naphtha, petroleum, &c. These bituminous substances are all either fluids, or are readily soluble in naphtha. It is, however, impossible to dissolve any appreciable portion of coal in naphtha, which shows that it does not contain any actual bitumen, though it may contain the

¹ Alabaster is derived from Alabastron, a town of Egypt, where it was manufactured into boxes for ointment. The term "alabaster" was then applied to carbonate of lime, as well as sulphate of lime.

Geology. constituents of it. The natural and artificial bitumens are the result of the decomposition of vegetable matter, and may be extracted also from coal by subjecting it to distillation. They always contain from 7 to 9½ per cent. of hydrogen, combined with carbon and oxygen. The so-called bituminous coals, then, are those in which the mineralizing process has only proceeded to a certain extent, leaving a considerable proportionate amount of hydrogen and oxygen in their composition; while those called non-bituminous are those from which a greater quantity of the latter substances have been extracted, and a larger proportion of carbon left behind. If the decomposition of wood results in the formation of carbonic acid gas, which takes away both carbon and oxygen, or of carburetted hydrogen, which takes away a large proportion of carbon, the carbon in the remainder will not be in such excessive proportion, and the constituents of the resulting coal will more nearly resemble those of bitumen. In this sense they may be called bituminous coals. If, however, a large portion of the oxygen and hydrogen be extracted, either as water or in any other form, the proportion of carbon in the remainder becomes excessive compared with that in the composition of bitumen; and hence the coals may be called *non-bituminous*.

Coals vary greatly, not only in the proportions of their essential constituents, carbon, hydrogen, and oxygen, but also in the amount of earthy matter (forming ash) which has been accidentally and mechanically mingled with those constituents. We have seen that the per centage of ash is sometimes as much as 35 per cent. in coals that have been regularly analysed. In poorer varieties of coal, however, such as are never brought to market, but which are occasionally used in particular localities, this per centage is doubtless still greater; and we have in nature every gradation, from pure coal into a mere carbonaceous (commonly called bituminous) shale or "batt," which often contains enough inflammable matter to give out flame and support combustion for a time when burnt with better coals, but soon passes into a lump of ash, unaltered in form, and not retaining heat longer than a brickbat would under similar circumstances. These *batts*, shales, or slates, often accompany coal, being found not only either just above or just below it, but in it, in the form of thin seams, layers, or cakes, which are often not to be separated from it without some trouble.

Just as limestone is often mingled with clay, and passes through argillaceous limestone and calcareous clay (or marl) into clay itself, so coal passes through earthy or ashy coal, and carbonaceous shale, into common shale or clay, no very hard boundary-line being to be drawn between the many minor graduating varieties of the different substances.

Discarding the impure or imperfect coals, the recognisable varieties of true coal are sufficiently numerous. They may be grouped under three heads:—Anthracite, ordinary or pit-coal, and brown coal or lignite.

Brown coal or lignite sometimes shows the structure of the plants from which it is derived but little altered from their original condition; stems with woody fibre "crossing each other in all directions. It is of a more or less dark colour, soft and mellow in consistence when freshly quarried, but becoming brittle by exposure, the fracture following the direction of the fibre of the wood." (*Chemical Technology*, Ronalds and Richardson, vol. i., p. 32.)

"Other kinds present only occasional distinct indications of vegetable structure, and appear throughout as a stratified mass of a dark, nearly black colour, with an earthy fracture; while in some varieties the structure is still more dense, and the fracture is conchoidal."—*Ib.*

The latter varieties, as in the case of the Bovéy coal of Devonshire, are often scarcely distinguishable by any external characters from some varieties of ordinary coal.

Ordinary or pit-coal has many varieties; indeed these

are often as numerous as the different seams of a coal-field, and even the different beds of a compound seam are readily distinguished from each other by the colliers, who give particular names to them; and even small blocks of these varieties can be recognised by them, and identified with the seam, or part of a seam, from which they are derived. Neither are these distinctions, which are only to be perceived after long practice, unimportant, since these varieties have distinct qualities, some of them being better adapted to smelting, and said to be "good furnace coal;" some of them to blacksmith's work, or "good shop coal;" others to various uses; while only a few, comparatively, are best fitted for domestic purposes, and are brought to market by the coal-merchant.

Some idea of the immense varieties of coal may be gained from an inspection of the report of the Admiralty coal investigation (*Mems. Geolog. Survey*, vol. i.), as well as from the varying qualities of those which we are in the habit of using daily in our houses. "As many as seventy denominations of coal are said to be imported into London alone." (*Chem. Tech.*)

All these minute varieties are commonly included under four principal heads:—1. Caking coal; 2. Splint, or hard coal; 3. Cherry, or soft coal; and 4. Cannel, or parrot coal.

Caking coal is so named from its fusing or running together on the fire, so as to form clinkers, requiring frequent stirring to prevent the whole mass being welded together. It breaks commonly into small fragments with a short uneven fracture. The Newcastle coal, and many others from different localities are caking coals. They leave many cinders and a dark dirty ash.

Splint or hard coal is well known in the Glasgow coal-field. It is not easily broken, nor is it easily kindled, though, when lighted, it affords a clear, lasting fire. It can be got in much larger blocks than the caking coals.

"*Cherry or soft coal* is an abundant and beautiful variety, velvet black in colour, with a slight intermixture of gray. It has a splendent or shining resinous lustre, does not cake when heated, has a clear shaly fracture, is easily frangible, and readily catches fire." (*Chem. Tech.*) It leaves comparatively few cinders, and its ash is white and light. It requires little stirring, and gives out a cheerful flame and heat. The Staffordshire coals principally belong to this variety.

Cannel or parrot coal is called cannel from its burning with a clear flame like a candle, and parrot in Scotland from its crackling or chattering when burnt. Cannel coal varies much in appearance, from a dull earthy to a brilliant shiny and waxy lustre. It is always compact, and does not soil the fingers. Its fracture is sometimes shaly, sometimes conchoidal. The bright shining varieties often burn away like wood, leaving scarcely any cinders and only a little white ash. The duller and more earthy kinds leave a white ash, retaining nearly the same size and shape as the original lumps of coal. Cannel coal often takes a good polish, and can be worked into boxes and other articles. *Jet* is an extreme variety of cannel coal in one direction, as *batt* or carbonaceous shale is in another.

Anthracite is heavier than common coal, with a glossy, often iridescent lustre, and a more completely mineralized appearance. It rarely soils the fingers, has a distinctly sharp-edged conchoidal fracture, or else breaks readily into small cubical lumps. It is not easily ignited, but when burning gives out an intense heat, so as to sometimes melt the bars of the grate or furnace in which it is used. It does not flame, and gives off but little smoke, being in this respect similar to coke or charcoal.

In many ordinary coals, little flakes of mineral charcoal occur, retaining that part of the vegetable structure called the vascular tissue. They are called "mother of coal" by the colliers in some places. "It is frequently seen in the form of a thin silky coating, covering some of the surfaces of the coal." (Professor Harkness on Coal, *Edinburgh New Philosophical Journal*, July 1854. Microscopical examination exhibits not only the vascular but the cellular tissue of plants in the substance of many coals, as was shown by Mr Witham in his work on the structure of fossil plants, and by many observers since.)

All coals have a peculiar structure, which bears a slight analogy to crystallization. They break or split not only along the bedding, but across it, along two set of planes

Geology.

Geology.

at right angles to the bedding and to each other. The smooth, clean faces produced by one of these division planes are more marked and regular than that produced by the other, as may be seen by examining any lump of coal. The principal of these division planes are called by the colliers the *face* of the coal, the other being called the *back* or *end* of the coal. They preserve their parallelism sometimes over very wide areas; and the mode of working or getting the coal, and the direction of the galleries, is governed by the direction of the *face*. In some places these division planes are called "cleat," in others "slines."

It is a structure which is probably the result of the mineralizing process undergone in passing from an organic to an inorganic state, and may be likened perhaps to the "cleavage" of a mineral rather than to either the true "slaty cleavage of rocks, or to their "foliation" or "jointing"—structures that will be hereafter described.

III.—AERIAL ROCKS.

Although the amount of rocks, or accumulations of earthy matter, formed of materials which were brought into their present situation by the action of the wind, is comparatively of small importance, it is not expedient wholly to overlook this action. Along all low sandy coasts hills are formed of drift sand, which sometimes attain a considerable altitude, as much, for instance, as 200 or 300 feet. These hills are commonly called "dunes." They have been described as advancing on the low shores of France, in the Bay of Biscay, at the rate of 60 and 70 feet per annum, overwhelming houses and farms in their progress. Similar accumulations take place on the coast of Cornwall, where the sand, composed largely of fragments of shells and corals, becomes converted sometimes into a hard stone by carbonate of lime or oxide of iron. (De la Beche's *Manual*.)

Lieutenant Nelson has described similar aerial accumulations in the Bermuda Islands, giving them the name of *Æolian* rocks.

Along the south coast of Wexford, as also in Smerwick harbour (county Kerry), and other parts of the British Islands, similar accumulations are in progress.

On the eastern coast of Australia, about Sandy Cape, this process is going on on a still larger scale. In Port Bowen, in the same neighbourhood, we once saw a very good instance of it. The rise and fall of the tide there is as much as 16 feet; and at low water great sand-banks are exposed, derived from the shallow sea outside and the waste of the porphyritic rocks on the coast. These sand-banks rapidly dry under the hot sun; and the trade-wind, which blows home-upon the shore, then drifts the sand up upon the beach, and piles it into hills 50 or 40 feet high. Behind these hills is a large mangrove swamp, which is being gradually buried under the advancing sand, some of the mangrove trees only just peering above it, others half covered, and so on. The drift of sand through the gaps of these dunes was exactly like a snow-drift in a heavy storm whenever the wind blew freshly.

Large districts, with hills of 200 or 300 feet in height, are found also on the coasts of Western Australia, stretching sometimes 10 miles inland, formed of loose incoherent sand, once apparently drifted by the wind, though now brought to rest by the growth of a wide-spread forest of gum-trees. Parts of these sands, which consist greatly of grains of shells and corals, are compacted together into a stone, hard enough to be used for building, by the action of the rain-water dissolving some of the carbonate of lime, and redepositing it on evaporation. Curious cylindrical stems, from 1 inch to 18 inches in diameter, are there seen projecting from the soil, and have been taken for petrified trees, which they greatly resemble; but we observed, in

1842, a number of these supposed trees exposed in a little cove, south of the entrance of Swan River, ending downwards in tapering forms like stalactites; and we believe them, therefore, to have a stalactitic origin, due to the percolation of water down particular pipes and channels in the sand.

Nor is it along the coast only that such accumulations are taking place. In the interior of great dry continents, there are vast spaces covered with sand and sand-hills, which are shifted and carried about by the wind, just as some sand-banks are deposited now here, and now there, carried about by the water. We have but to recal to the mind of the reader the well-known stories of caravans crossing the desert being met and sometimes overwhelmed by moving columns of sand, and the way in which many of the temples of Egypt have been buried under such accumulations, for him to see that this action cannot be altogether overlooked. Egypt would probably have been long ago obliterated by drift-sand if it had not been for the Nile, and the strip of vegetation that accompanies and defends it. In the interior of Australia, Captain Sturt reports the existence of vast deserts of sand, with long lines of great sand-hills, 200 feet high, the base of one touching that of its neighbours, and all stretching in straight lines each way to the horizon.

It would be quite proper also to class among aerial rocks such accumulations of tuff as were derived from volcanic ashes falling on the land, and also the masses of pebbles, cinders, and fragments so derived, were it not more convenient to describe them in connection with the volcanic rocks, so as not to separate in our account those falling on the land from those deposited in water.

Soil.—The accumulation of decayed vegetable matter, mingled sometimes with animal, always with earthy mineral matter, which is called "soil" or "mould," is also an aerial process, deserving of more attention than it has yet received. Soils sometimes occur as distinct rocks, interstratified with other rocks.

CHAP. IV.—THE METAMORPHIC ROCKS.

Preliminary Observations.

In the course of the foregoing descriptions we have mentioned the segregation into concretionary lumps and nodules, of siliceous from calcareous matter, and of calcareous from argillaceous; and we have described the radiated and concretionary forms assumed sometimes by magnesian limestone and the re-arranged crystallized beds of gypsum. These, however, are not the only instances of such separation of parts, and assumption of new forms and combinations, by the particles of rock after their deposition, and after their more or less complete consolidation. Any mineral diffused in a state of minute division through a mass of different nature from itself, seems to have tendency to segregate itself from the mass, and collect together upon certain points or centres. Iron, either in the form of iron pyrites (bisulphide of iron), or ironstone (clayey carbonate of iron), or hæmatite (oxide of iron), frequently forms such concretionary lumps. Iron pyrites, either in cubical crystals, or in balls with an internal radiated structure, is frequent in all argillaceous and calcareous rocks, and in many trap rocks. Ironstone forms regular layers of round nodules, sometimes as much as a foot or 18 inches in diameter, in many argillaceous rocks. These nodules, when broken open, are often found to be traversed by cracks in all directions, more or less filled up with crystalline spars (carbonate of lime, &c.), together with crystals of galena, blende, iron pyrites, and other minerals.

In other clays, carbonate of lime, mingled perhaps with iron, produces similar stones, called septaria or cement

Geology.

Geology. stones in some places. They often take a polish, and the sparry veins produce a variously ornamented appearance.

In these septaria and ironstone balls the external crust is generally smooth and compact, the internal cracks becoming larger and more numerous as they proceed towards the centre. As the cracks are obviously the result of desiccation and consequent contraction, and as the external crust would naturally be the first part to consolidate, it does not at first seem obvious why the cracks should not occur outside rather than in.

Professor Hennessy, however, remarked to us, that in the case of volcanic bombs, which have a similar structure, the fact of the preliminary consolidation of the external crust was the cause of the internal fissuring, since, when that was formed, no farther shrinking or contraction of the whole body could take place; and the internal parts being thus relieved from external pressure, would shrink and contract among themselves, being rather attracted towards the dense external crust than towards the centre. If consolidation commenced at the centre, the whole nodule would have contracted towards the centre, and thus have shrunk into a less size and a denser state, without the occurrence probably of either external or internal cracks.

Hæmatite, whether red or brown, affects a kidney-shaped concretionary form, often hollow, with a minutely radiated structure at right angles to the surface of the mass.

Other minerals, such as galena and blende (the sulphides of lead and zinc), occur in small balls or nests in some rocks, evidently formed as concretions, and not rolled fragments or pebbles.

This separation of one matter from another, and subsequent assumption of a condition more or less different from that possessed by rocks at the time of their original formation, leads us naturally to consider the next great division of our subject, the metamorphic or transformed rocks.

The mere physical force of pressure, as aqueous rocks after their formation become gradually covered by subsequent accumulations, must produce change in them in the way of consolidation and induration. The pressure may of itself be sufficient in some cases to cause the hitherto incoherent particles of sand or clay to cohere and be compacted into a solid stone. It will, however, be greatly assisted, either by the infiltration of water containing mineral matter in solution, or of pure water dissolving and rearranging the soluble materials which it may find in the rocks.

Heat may, in like manner, modify the effects of pressure, either by its mechanical power of expansion producing pressure in every direction, and subjecting rocks to alternate expansions and contractions according to its own variations, or by setting in action chemical forces of decomposition and recomposition, and thus altering the chemical combinations in the materials of rocks.

Heat may also be joined with water, either raising it to various temperatures or actually converting it into steam, and we may thus get changes produced which neither cold water nor dry heat would be able or likely to effect of themselves. It has been stated that it is impossible to maintain the bulb of a thermometer in the boiler of a steamer at very high temperatures, since the glass is dissolved by the chemical action of water heated under pressure. (Sedgwick's *Introduction to Synopsis of Classification*, &c., 3d Fasciculus, p. 29, note.) Now, it may not unfrequently happen that we may have all the forces of pressure, heat, and the dissolving power of water combined in the interior of the earth.

The presence of water in rocks is known by experience, since no stone is ever quarried which will not part with some water on being dried, either naturally in the air or artificially. Bischof says, that he has observed, on breaking blocks of basalt, "wet patches, like rain drops, upon the fractures, and sometimes quite in the centre of the mass,

Geology. affording positive evidence of the permeability even of so compact a rock as basalt." He says also, that almost all water contains both carbonic acid, and often a slight proportion of silica (silicic acid) in solution, that the silicates in which the silica is in its soluble modification are decomposed by weak acids, and that those also in which it is in its insoluble modifications are unable to resist the long-continued action of acids.

This gives us the explanation of the brown spots and patches found in many rocks containing silicate of lime, such as basalt and greenstone, and also their brown and weathered surfaces. Along the internal margin of the brown part of basalt and greenstone a mineral acid will almost always cause effervescence, as also along the minute cracks and crevices and pores by which the water gains access to the interior. It is plain that the silicate of lime is converted into carbonate in the first place, and this being removed by subsequent solution from more carbonic acid and washed out, the protoxide of iron left behind is converted into peroxide, and the brown colour produced.

Limestone containing much silica or silicate of alumina, and some protoxide of iron diffused through its mass, is, in a similar way, converted into *rotten stone*, while pure limestone is wholly dissolved and washed away.

The decomposition of those rocks which do not contain any lime proceeds in the same way, though it is not so easy to detect it by the occurrence of effervescence with acids along the margin of the decomposed part. Feldspar rocks have their silicates of potash, soda, &c., converted first into carbonates and then into bi-carbonates, which are dissolved and washed away. Their decomposed portions are generally white rather than brown, from the absence of iron, though shades or streaks of red and brown occasionally occur, showing its presence in small quantities.

In the examination of these changes, the study of pseudomorphic crystals of minerals is of great importance. A pseudomorph is one mineral occurring in the crystalline form of another. These are either "alteration pseudomorphs," in which the first mineral has been gradually changed into the other, or "displacement pseudomorphs," in which the first mineral having been gradually removed particle by particle, another has gradually, and particle by particle, taken its place. This action is a very important one; for it is precisely that of "petrification," as it is called—that by which organic remains are mineralized, and their external form, and more or less of their internal structure, preserved.

Animals and plants, by means of their fluids, take up and convert into their own substance certain minerals, such as silica, lime, magnesia, soda, potash, phosphorus, carbon, iron, &c. Thus they do in obedience to the organic forces, those chemico-biological actions, the assemblage of which we call *life*. When life no longer exists, and its forces cease to act, the substances of animals and plants become obedient to inorganic laws, and their mineral portions are acted on just in the same way that other mineral matters are affected. Wood may either, as we have already seen, lose certain proportions of its constituents and become more and more *carbonized*; or it may lose the whole of them particle by particle, and as each little molecule is removed, its place may be taken by a little molecule of another substance, as silica, or iron pyrites, and it may thus become entirely *silicified* or *pyritized*.

Bones and shells, and other hard parts of animals, consisting mainly of phosphate and carbonate of lime, may in like manner have the proportions or the state of aggregation of their constituents altered more or less completely, or may have their substance gradually but entirely replaced by another substance more or less different from the former.

Bischof combats the opinion that this pseudomorphous and petrificative process is ever the result of dry heat or of

Geology. sublimation, and shows, with what appears conclusive reasoning, with regard to many substances at all events, that whether it occur in the mass of rocks, or in veins and fissures, it must be the result of *water* (temperature uncertain) containing some acid, chiefly carbonic acid, in solution in the first place, and afterwards by means of that acid becoming impregnated with the solutions of other minerals.

Some of Bischof's remarks are so very instructive that we do not hesitate to quote several passages at length. "Stein converted a crystal of gypsum into carbonate of lime by leaving it for several weeks in contact with a solution of carbonate of soda, at a temperature of 122° F." The sulphuric acid of the gypsum uniting with the soda to form sulphate of soda, which was dissolved and carried away by the water, and the lime uniting with the carbonic acid. "All the striae upon the curved surfaces of the crystal were perfectly retained, as well as the cleavage in the direction of the T-planes. In these artificial pseudomorphic processes, the form of the original substance is retained only under certain conditions, the most essential being slow action; and the same holds good in nature. If these conditions are not fulfilled, the original form is lost."

"In the analysis of a mineral in which changes have already commenced, especially by the addition of new constituents in very minute quantities, it is not unlikely that they may be considered as accidental and deducted. Since, however, alterations seldom take place merely by addition, but more frequently by loss of constituents, it is likewise requisite that the quantities lost should be added to the analytical results.

"There are sufficient grounds for considering andalusite to be a pure silicate of alumina, although previous analyses have pointed out, besides these two essential constituents, potash, lime, magnesia, oxides of iron, and manganese and water. Andalusite is converted into mica, in which change a part of the alumina is removed; potash, magnesia, and peroxide of iron, being introduced into its place. One of these bases is always found in andalusite, sometimes several of them together; and it may therefore be inferred that this mineral, as usually met with, is already in a state of incipient alteration. No other alteration of andalusite is known besides that into mica, except that into steatite. The latter change presupposes not only a partial but a complete disappearance of the alumina, and its replacement by magnesia. These examples will suffice to show the importance of the minute quantities of substances present in minerals, and generally considered as accidental. These substances, which are troublesome to the chemist, because he cannot introduce them into the chemical formula, acquire significance when compared with the constituents of the pseudomorphs, resulting from the alteration of the mineral in question. They then no longer appear as accidental, but indicate the transition of one mineral into others, and lay before us clearly the greater part of the conversion process.

"It is possible that several changes may frequently have taken place before the last product was formed. In the alterations of complex minerals, especially silicates containing several bases, there are, certainly, transitions in most cases, and sometimes a long series. Thus Cordierite is the starting point of a whole series of alterations, finally ending with Mica; while Fahlnite, Chlorophyllite, Bonsdorffite, Esmarkite, Weissite, Praseolite, Gigantolite, and Pinite, are remains of Cordierite in pseudomorphic conditions. Inasmuch as the minerals between Cordierite and Mica are only transition products, they cannot be regarded as individual species."

"As petrifications are important and in many cases indispensable aids in recognising the sedimentary formations, so likewise pseudomorphs are important, and frequently the only means of tracing the processes of alteration and displacement which have taken place and are still going on in the mineral kingdom.

"Pseudomorphs furnish us with a kind of knowledge which we have no opportunity of deriving from any other source. It will scarcely ever be possible to convert augite, olivine, or hornblende, &c., into serpentine in our laboratories. But when we find serpentine in the forms of these minerals, this fact is a sufficient evidence that such a conversion can take place; and if in any given instance there are geognostic reasons for the opinion that one or other of these minerals, or even several together, have furnished the materials for the formation of serpentine, there is a high degree of probability that such a change has actually taken place.

"If a crystalline mineral can, under certain conditions, be converted into another, whether with or without retention of form, then the same mineral in an amorphous state would certainly suffer the same change when placed in the same circumstances." From this he shows that amorphous masses of serpentine may be formed from amorphous masses of augite, &c., and also that in some in-

stances the original form of a crystalline mineral may be destroyed together with its substance, and the new mineral occur in its own crystalline form. He concludes the subject thus:—

"The importance of the pseudomorphic processes, and the error of those who regard them as having but little connection with the changes of rocks, is sufficiently shown by the total disappearance of previously existing substances in veins. I consider that the entire removal of fluor and calc spar from a whole series of veins, and the introduction of an equal quantity of quartz in their place, is a matter of vast importance. To what enormous spaces of time do we come when we reflect upon the periods during which the fluor and calc spar were introduced into these fissures, and then the periods during which they were again removed by water, and quartz substituted in their place! And yet this happened after the formation of the rocks in which these fissures occur. If we imagine similar processes to have taken place in the rocks themselves, and extending over not only both these periods, but the entire space of time since their formation, we shall be compelled to admit that inconceivably stupendous changes have taken place. After such considerations, the conversion of extensive masses of rock by the action of water alone into steatite, talc, serpentine, kaolin, &c., cannot appear in the slightest degree strange." (*Bischof*, chap. ii.)

If we allow so large an amount of metamorphic action to the infiltration of water, it becomes no longer difficult to understand the conversion of limestone into dolomite, subsequently to the deposition of the original carbonate of lime. Such cases as those described by Von Buch, and more recently by Mr Andrew Wyley, in the journal of the Geological Society of Dublin (vol. vi., part 2), in his paper on the Dolomitic Rocks of Kilkenny, where dolomite is found traversing ordinary limestones in dyke-like masses running through a great number of beds in a straight line across the country, becoming explicable on the supposition of springs of water containing much carbonic acid and magnesia rising up through fissures, and the consequent solution of some of the carbonate of lime and its replacement by carbonate of magnesia.

If, again, such great changes as those just alluded to may be expected to result from the simple action of water, we may reasonably conclude still greater to be the consequence of the action of water combined with a high temperature, or of a still more intense heat, which first converts into steam the water contained in rocks, and effects great changes perhaps, or, at all events, prepares the way for great changes by that agent, and then proceeds to act upon the minerals contained in rocks with its own powers. We have already seen that some sandstones and gritstones may have probably been cemented by silica held in solution, either in the water in which they were deposited, or in that which subsequently gained access to them. We know that hot water can contain at least a tenth more silica in solution than cold water. If, therefore, a sandstone became penetrated by hot water, or still more by steam, a portion of the silica of which each grain was composed might be dissolved, and as the water ultimately evaporated, this silica would be redeposited, and act as a siliceous cement to the mass. We should thus have a quartz rock or quartzite produced.

It would appear, however, that dry heat alone is able, under favourable conditions, to produce this effect, since the sandstones that have been used as the bottoms of iron furnaces are, in some cases, altered into a kind of quartz rock. It is true that bases, calculated to act as a flux to the quartz, may have gained access to the sandstone in the latter instance, but then they may, on the other hand, have been present in sufficient quantity for that purpose in many sandstones that have been naturally altered into quartz rock.

While we give full allowance to the importance and magnitude of the metamorphic effects produced by water at whatever temperature, there are yet still greater and more general changes, which we must believe can only have been effected by the action of heat, too great to allow of the presence of water.

Geology.

When we see whole mountain ranges, and whole districts of country, consisting of rocks that have more or less analogy in structure and constitution to rocks known to be of igneous origin, we cannot help feeling convinced that igneous action must in some way have been concerned in their production.

When we find that these rocks have every gradation, from such as might have been once molten, into rocks which we know to have been mechanically deposited under water, we are compelled to conclude with Lyell that these rocks are altered or metamorphosed by heat from their original aqueous and mechanical formation into a state more or less nearly approaching true igneous rocks.

Our belief in the truth of this metamorphism becomes certainty when we see these rocks always occurring on the flanks of masses of granite, and examine a district (such as Wicklow and Wexford) where both large and small masses of granite appear, and find these metamorphic rocks, not only always accompanying the granite, but occurring *no where else* except in the neighbourhood of granite or granitic rocks, and their extent always proportioned to the size and extent of the particular granite mass they mantle round.

It is by no means intended to assert that the neighbourhood of granite or igneous rock is the only source of heat from which this metamorphosis can arise. Should any mass of rock, capable of alteration, be so deeply buried in the earth as to be brought within the reach of any centre of heat whatever, the same effect would result; and it is quite possible that a far greater intensity and wider range of heat may be thus reached, than could proceed from the mere intrusion of a more or less isolated mass of igneous matter into spaces which were naturally of a lower temperature. But as an intrusive mass of granite must be a source of great heat, and as the metamorphic effects in question are found always to accompany it, we are obliged to look upon heat as the cause of the effect.

This effect of intense heat may doubtless be variously modified by the previous presence or absence of water, and by the various mixtures of mineral matters occurring in the different rocks before alteration.

The very general appearance of mica, either in distinct flakes or crystals, or as a mere glaze upon the surfaces of laminae,¹ may perhaps be explained by the very various composition of the different varieties of mica, and the consequent number of sources and combinations from which micaceous minerals could be derived. Mr Sorby has shown by the help of the microscope that many ordinary clay-slates are in reality made up of minute mica flakes. Dr W. K. Sullivan also has remarked to us the possibility of several different minerals, or at least many chemical combinations, putting on the micaceous form as a consequence of peculiarity in physical structure rather than of identity in chemical composition.

The metamorphic development of mica, then, offers no difficulties; and we may perhaps suppose that in mica schist, where there are alternate layers of mica and quartz, this development took place in such a way that the basic substances segregated themselves into alternate layers, leaving the silica of the intermediate layers free; these layers being determined by the original lamination or sedimentary layers of the mass, except where that mass was very homogeneous, or greatly affected by "transverse cleavage."

In gneiss, where we have the triple alternation of quartz, feldspar, and mica, a similar action, similarly directed, must be supposed to have occurred under the modifying influence of a different composition in the original rock.

We shall have occasion, under the head of Petrology, to

¹ See *postea*, under the head of Petrology, remarks on the production of mica-schist and gneiss on the flanks of the granite of Wicklow, &c.

Geology.

recur to this subject in describing the "cleavage" and "foliation" of the metamorphic rocks. "Cleavage" is, indeed, a purely petrological structure, whatever may have been its origin, since it rarely, and only to a slight extent, produces any lithological change in a rock beyond that of simple induration. A highly indurated *shale* has no lithological difference from a true *clay slate*, it being often impossible, from an inspection of a mere hand specimen, to say whether it be one or the other.

DESCRIPTION OF THE METAMORPHIC ROCKS.

The metamorphic rocks may be divided into two sub-groups, those in which the original mineral structure is still recognisable—the particles, however they may have altered their form and state, not having entered into new combinations—and those where such new combinations have been produced.

The former sub-group will accordingly consist of arenaceous, argillaceous, and calcareous rocks, while the members of the latter have a general similarity of structure and composition which enables us to speak of them under one general term, such as the *schistose rocks*.

Metamorphosed Arenaceous Rocks.

60. *Quartz Rock or Quartzite*¹ is a compact, fine-grained, but distinctly granular rock, very hard, frequently brittle, and often so divided by joints as to split in all directions into small angular but more or less cuboidal fragments. Its colours are generally some shade of yellow, passing occasionally into red, and at other times into green. When examined with a lens it may be seen to be made of grains, which appear sometimes as if they had been slightly fused together at their edges or surfaces, and sometimes as if imbedded in a purely siliceous cement. This cementation or semi-fusion of the grains shows at once that it is a sandstone which has been altered and indurated by the action either of heat alone or of heat and water. It has either been *baked* or *steam-boiled*.

Metamorphosed Argillaceous Rocks.

61. *Clay Slate* is a fine-grained fissile rock, differing from shale in being invariably highly indurated, and splitting into plates that are altogether independent of the original lamination or bedding of the rock, and frequently cross it at all angles. This fissile structure or "cleavage" is a superinduced or metamorphic one. The original bedding or lamination of the rock may frequently be traced, even in hand specimens, by means of parallel lines or bands of different colour and texture traversing the slate. These bands are called by Professor Sedgwick the "stripe" of the slate.

Clay slate is generally of a dull blue, gray, green, or black colour, sometimes "striped," sometimes irregularly mottled.

Metamorphosed Calcareous Rocks.

62. *Altered or Crystalline Limestone*.—This was for-

¹ The student must carefully distinguish between quartz rock or quartzite, as here described, and pure *vein quartz*, which occurs sometimes, as a white compact flint rock, in considerable mass. The "quartz rock," so often spoken of in Australia, is rarely, if ever, true quartz rock, but commonly vein-quartz; not an altered bed of sandstone contemporaneous with the rocks in which it lies, but a deposition in a vein or fissure produced subsequently to the consolidation of the rocks it traverses.

The Continental geologists seem frequently to fall into the same mistake, and confound two things essentially distinct. In a collection of European rocks purchased lately from Krantz of Bonn, among seven specimens of so-called quartzite, at least five were undoubtedly *vein quartz* and not *quartzite*.

merly called *Primitive*, and is even at the present day often called *Primary Limestone*. Since, however, it is known that many crystalline limestones are not primary, that some of the statuary marbles of Italy and Greece, for instance, are even tertiary limestones in a metamorphosed state, it would seem better to disuse the term primary as a mere lithological designation.

It is probable that some limestones were originally formed as crystalline limestones, inasmuch as many parts of a coral reef are even now crystalline internally. Others, however, have certainly been only made to assume the crystalline structure at a period subsequent to their formation. In the well-known experiments of Sir James Hall, it was shown that even chalk could be converted into a hard crystalline marble, by being heated under such a pressure as should prevent the escape of the carbonic acid gas.

Saccharine, or statuary marble, is a white, fine-grained rock resembling loaf-sugar in colour and texture, working freely in any direction, not liable to splinter, slightly translucent, and capable of taking a polish. Concealed flakes of mica or chlorite sometimes exist in it, as may be seen on examining the weathered surfaces of some of the ancient statuary in the British Museum and elsewhere.

Other varieties of altered limestone are variously coloured, and more largely and coarsely crystalline.

63. *Dolomite*.—Some magnesian limestones are clearly altered or metamorphic, forming a true dolomite or highly crystallized aggregate of nearly equal parts of carbonate of lime and carbonate of magnesia. Its metamorphic character, however, can only be certainly ascertained by its geological relations, and not by its lithological structure.

We had long suspected that some serpentines, or verde antique marbles, were nothing but highly altered magnesian limestones. This suspicion has been confirmed by Mr Logan,¹ director of the Geological Survey of Canada, who assures us he has traced in that country serpentines ending gradually in unaltered beds of magnesian limestone.

The Schistose Metamorphic Rocks.

The term "schist" is used here in a restricted sense, as applicable to the fissile structure of "foliated" rocks.

"Foliation" is a term applied by Mr Darwin² to those rocks which have had such a subsequent structure given to them as to split into plates of different mineral matter, either with the bedding or across it. "Cleavage" indefinitely splits a rock, either with the beds or across them, without altering its mineral character, and thus produces "slate."

"Lamination" will then be the remaining term applicable to "shale," and signifying the splitting of a rock into the original layers of deposition.

When, therefore, we wish to be precise, we can speak of the *foliation* of *schist*, the *cleavage* of *slate*, and the *lamination* of *shale*.

64. *Mica schist* consists of alternate layers of mica and quartz, the mica generally consisting of a number of small flakes firmly compacted together, and the quartz more or less nearly resembling *vein* quartz. Many mica schists, however, contain comparatively little quartz, and seem scarcely to differ from clay slate or shale, except in the shining surfaces of their plates or folia.

Many mica schists have a minutely corrugated or crumpled structure, the layers being bent into sharp vandykes of one, two, or more inches in height and width. Others, however, are quite smooth and straight.

¹ Now Sir William Logan.

² The term "foliated," however, as applied to schistose rocks, such as *mica schist*, and distinguished from "cleaved" as applied to *slate*, was first suggested by Professor Sedgwick in his paper on the "Structure of large Mineral Masses." (*Geological Transactions*, vol. iii., pp. 479 and 480.)

The separation into layers, or "foliation" of mica schist, sometimes coincides with the original bedding of the mass, and sometimes is independent of it. In the latter case, it may in some cases have taken the direction of a previously existing "cleavage." (Prof. Ramsay, *Geological Journal*, vol. ix., p. 172.)

Instead of mica, other minerals are sometimes found, such as chlorite or talc, when the rock would be called *chloritic schist*, or *talcose schist*.

Hornblende schist, again occurs, though we believe, in this case, the whole mass consists of flakes of that mineral without any alternation of quartzose layers. The same remark holds good with respect to the rarer rock called *actinolite schist*. As far, indeed, as our own observation goes, we should doubt the existence of these rocks in any other form than as the result of a partial metamorphosis of some hornblendic "ash," or of some other mechanically-formed rock, derived from the wear and tear of a greenstone or a syenite.

65. *Gneiss* is probably of all others the most completely metamorphosed rock that retains any mark of its original mechanical structure.

Some gneiss can only be distinguished from granite by the regular arrangement of its component crystalline particles in a certain parallelism, so as to give it a slightly schistose structure, or "grain," as it is called by Professor Sedgwick. Other varieties of gneiss, again, can only be separated from mica schist by the occasional occurrence of little plates of feldspar in addition to the layers of mica and quartz. In hand specimens, indeed, it is often very difficult to draw any sharp line of separation between mica schist and gneiss, the more fissile specimens being called mica schist, while the firmer ones would be called gneiss. Even in the field they are often so blended together, and alternate with each other so frequently, that their separation is impossible. There is therefore almost every gradation from dull clay-slate through glossy and so called talcose slate into mica schist and gneiss, and thus into actual granite.

Gneiss might, indeed, in its purest and most typical form, be termed schistose granite, consisting, like granite, of feldspar, mica, and quartz, but having those minerals arranged in layers or plates, rather than in a confused aggregation of crystals. In speaking of it as schistose granite, however, we must never forget that true gneiss was never really a granite, with a peculiar laminated structure, but that it was originally a laminated mechanically-formed rock, — a *sandstone* more or less argillaceous, containing, indeed, the elements of quartz, feldspar, and mica, but not exhibiting any more appearance of those minerals at its first deposition than is exhibited by any of the ordinary unaltered sandstones with which we are familiar. We by no means intend, however, to assert that all sandstones could be converted into gneiss, for it is obvious that purely siliceous sandstones could not, but *purely siliceous* sandstones are much more rare than is often supposed. The great mass of sandstones and of clays do contain the elements of feldspar and mica as well as quartz,—that is to say, they contain alumina, iron, potash, soda, magnesia, &c., as well as silica.

We must also never forget that the extreme term of metamorphism by heat is actual fusion and reduction into the state of an igneous rock, and that it is possible therefore that some igneous rocks, nay, even some granites, may be metamorphosed rocks—aqueous rocks that have been completely melted down again. If we look upon *all* aqueous rocks as in some shape or other *derivative* rocks,—and this is a conclusion from which we cannot escape,—we must regard them as either mediately or immediately derived from igneous rocks. With regard to the mechanically-formed aqueous rocks this is obviously true, because if we trace to

Geology. their original source the silica and alumina, the quartz, the feldspar, and the mica of which they are composed, we must eventually arrive at some igneous, most probably some granitic rock as their parent.

But even as regards the lime and the soda and magnesia of all the chemically and organically-formed aqueous rocks (setting aside the carbonaceous rocks), we are compelled to suppose that the water first derived those minerals from the decomposition of such igneous rocks as contained them. The carbonates of lime and magnesia, and the sulphates of lime, must have acquired their bases primarily from the decomposition of the silicates of lime and magnesia, which are to be found in the igneous rocks; carbon itself being the only element which does not seem primarily derivable from igneous rocks. Speaking generally, then, it need not surprise us to find materials that had once been fused reduced again to that condition. It is true, that in our purest sandstones and clays the matters that once acted as a flux to the silica and alumina may have been washed out and removed more or less completely from their former combinations; but these pure deposits of silica or silicate of alumina are, as just now said, comparatively rare and in small quantity, and if the rocks around them and inclosing them were once to be remelted, they would soon become mixed up and mingled with the rest, and reduced to the same condition.

There can therefore be nothing either unphilosophical or improbable in regarding, with Sir C. Lyell, the whole crust of our globe as consisting of materials passing through an endless cycle of mutations—existing at one time as igneous rocks; then gradually decomposed, broken up, separated out, sorted, and deposited as aqueous rocks, whether chemical, mechanical, or organic; at a subsequent period metamorphosed; and ultimately reabsorbed into igneous rocks.

In this view, the most highly metamorphosed rocks would be those most nearly hovering upon the brink of reabsorption; and gneiss accordingly on the point of passing into granite, and in some cases almost undistinguishable from it.

One thing is quite certain, that many rocks which are now undistinguishable from true igneous rocks, may have been formed by a comparatively slight metamorphism of “ashes,” or other mechanical accumulations of materials derived directly from igneous rock, and subsequently brought within the influence of heat. It is probable that many amygdaloids may be altered tuffs or ashes, and possible perhaps that some clinkstones, whether volcanic or trappean, may have a like origin. Some felstones, again, may be but baked and slightly altered feldspathic ash.

Some real and originally-formed igneous rocks may in like manner undergo metamorphoses, more or less complex. Some felstone or greenstone porphyries, for instance, may have acquired their porphyritic structure by long-continued and comparatively gentle heat, acting on previously compact trap rocks. The same comparatively slight action of heat may have caused many once compact or porphyritic igneous rocks to have become completely crystalline, and possibly may in some cases have generated new combinations, and produced mineral forms that did not exist in the original rock. Trappean rocks may thus have become granitic. These possibilities should be borne in mind when we are endeavouring to explain phenomena that otherwise are often difficult to understand.

It will, perhaps, be useful if we give here the foregoing classification of rocks in a tabular form:—

IGNEOUS ROCKS.

VOLCANIC.

<i>Essentially Feldspathic.</i>	Trachydolerites, or intermediate varieties unnamed.	<i>Feldspar and Augite.</i>
Trachyte.		Dolerite.
Trachytic Porphyry.		Anamesite.
Pearlstone.		Basalt.
Andesite.		Nepheline Dolerite.
Clinkstone.		Leucite Rock.
Obsidian.		Amygdaloid.
Pumice.		Peperino.
Tuff.		

TRAPPEAN.

<i>Siliceo-feldspathic.</i>	Intermediate varieties unnamed.	<i>Feldspar and Hornblende, &c.</i>
Felstone.		Greenstone or Diorite.
Pitchstone.		Melaphyre.
Clinkstone.		Diabase.
Feldspar Porphyry.		Dabbro.
Feldspathic Ash.		Hypersthenite.
		Aphanite.
		Serpentine.
		&c., &c.

GRANITIC OR SUPER-SILICATED ROCKS.

<i>Quartzo-feldspathic.</i>	<i>Quartzo-feldspathic with Hornblende or Mica, &c.</i>
Pegmatite.	Syenite.
Elvanite.	Protogine.
Eurite.	Granite.

AQUEOUS ROCKS.

MECHANICALLY-FORMED.

Arenaceous.....	Gravel or Rubble.
	Conglomerate or Pudding-stone and Breccia.
	Sand.
Argillaceous	Sandstone and Gritstone, and their varieties.
	Clay and Mud.
	Clunch.
	Loam.
	Marl.
	Shale or Slaty Clay.

CHEMICALLY-FORMED.

Calcareous.....	Stalactite and Stalagmite, Travertine, &c.
	Some Dolomites.
Siliceous	Sinter.
Gypseous.....	Gypsum.
Saline	Rock Salt.

ORGANICALLY-DERIVED.

Calcareous, mostly from animals	Limestone and its varieties, compact, crystalline, chalky, oolitic, pisolitic, some magnesian, &c.
Siliceous, probably from animals	
	Flint and Chert.
Carbonaceous, mostly from plants.	Peat.
	Lignite.
	Coal.
	Anthracite.
	Graphite.

AERIAL OR ÆOLIAN ROCKS.

Blown Sand on coasts.
Sandhills of deserts.
Calcareous Sands compacted by rain, &c.
Debris at foot of cliffs.
Volcanic Ashes, &c., falling on land.
Soil.

METAMORPHIC ROCKS.

THOSE IN WHICH THE ORIGINAL STRUCTURE IS STILL APPARENT.

Arenaceous	Quartzite or Quartz rock.
Argillaceous.....	Clay Slate.
Calcareous.....	Primary, Crystalline, or Saccharine Limestone, or Statuary Marble.
	Serpentinous Limestone, Verde Antique, &c.
	Some Dolomites.

THOSE IN WHICH THE ORIGINAL STRUCTURE IS MORE OR LESS COMPLETELY OBSCURED OR OBLITERATED.

Schistose Rocks	Mica Schist.
	Chlorite do.
	Talc do.
	Hornblende do., &c.
	Gneiss.

¹ Such speculations as those in the text may be useless enough as far as any practical result to be derived from them, and may by many persons be thought uncalled for. The old ideas, however, of the original independent origin of mica schist and gneiss still linger in some men's minds, and are even, as we are informed, coming more and more into favour with some continental geologists.

By that division of Geognosy here called Petrology, we may understand the study of rock masses; that is to say, the examination of those characters, structures, and accidents of rocks which can only be studied on the large scale, and only be observed in "the field." This study will comprise the modes of stratification, of separation by divisional planes, those of fracture and disturbance, and those of denudation, as well as the composition of groups or "formations," and the relations of igneous to aqueous rocks.

CHAP. V.—PETROLOGY OF THE AQUEOUS ROCKS.

I.—LAMINATION AND STRATIFICATION.

The lamination and stratification of the aqueous rocks is the very foundation of geology,—that on which all the more important deductions of the science are based. It is therefore necessary to describe these structures in some detail.

We have already mentioned the very fine laminæ (plates or layers) of which some beds of shale are made up. Each of these little layers of earthy matter is obviously the result of a separate act of deposition. The whole bed of shale being formed by the gradual settlement of fine sediment, film after film, upon the bottom of some tranquil or very slowly moving water, we may suppose this sediment to have been carried into the water by successive tides bringing matter from some neighbouring shore, by frequent or periodical floods of some river, by the gradual action of some current, or any other agent by which we could imagine fresh materials to have been transported at different intervals into the water. Or we may perhaps suppose that the supply being continuous, and the water more or less turbid throughout, the act of settlement took place at intervals by little successive fits and starts. Whatever may have been the exact nature of the action, it was clearly a gradual, and not a sudden one; and some time must be allowed for the deposition of a bed even *one* foot thick, when we find it, as we often do, made up of distinct laminæ, fifty or a hundred of which do not exceed an inch in thickness.

Still, although some time was required, and although the acts of deposition were distinct, yet they were not so widely separated in time as to allow of any great consolidation of one layer before the next was deposited upon it.

The whole set of laminæ were made to cohere together, so as ultimately to form *one* bed, which may be quarried and lifted in *single* blocks.

Now the planes of stratification differ in this respect from the planes of lamination, that they mark a total want of coherence between two contiguous layers of rock. It would be impossible to get a block consisting of a part of two beds; there would obviously be *two* blocks.

It follows from these facts, that as the coherence of the laminæ of a bed is the result of the comparative shortness of the intervals between their deposition, so the want of coherence between one bed and another is the result of the length of the interval between the deposition of the beds. Each bed had time to become consolidated, to a greater or less extent, before the next was deposited upon it, so that the latter could not at all coalesce with the former. The planes of stratification, then, mark an interruption in the act of deposition, a pause during which nothing was deposited; the duration of that pause being very considerably longer than that of the intervals between the successive laminæ.

Laminæ or layers, then, are the parts of which a bed is made up. Strata or beds are the distinct sheets or wide tabular masses of aqueous rock which are completely and naturally separated from each other. The planes of lami-

nation often refer only to the direction in which the laminæ are arranged, whether the laminæ are separable or not. The planes of stratification are actual planes of separation between one bed and another.

If we are at a loss to estimate the length of the interval between the deposition of the successive laminæ of a bed, still less have we in general the means of calculating the time which elapsed between the formation of one bed and another. When two or more beds are of precisely similar character, as two beds of the same kind of shale or sandstone, we should naturally be led to suppose that the interval between bed and bed was not indefinitely greater than that between lamina and lamina. If we assigned hours to the one, we might assign days to the other; if days to the one, weeks to the other; and so on. Still we should have no certain grounds to go on, and the interval between bed and bed might be years or centuries for anything we could, in the majority of instances, show to the contrary. When, moreover, the two beds were of totally different characters, as, for instance, where a bed of sandstone or limestone rested on a bed of shale, or *vice versa*, we should generally be right in allowing a larger interval between their deposition than where the beds were similar. Some time must be required for a change to take place in the conditions of the neighbourhood. In the case of a bed of sandstone, destitute of all argillaceous matter, resting on a bed of shales, we should be obliged to suppose some alteration in the strength or direction of the currents, so that all the finer matter was swept away, and only the coarser or heavier deposited. In the case of a shale resting on a sandstone we should suppose that the current had diminished in velocity compared with that formerly acting. In either case the current might come from a new quarter where only one kind of material was to be got.

The same current of water, charged with a mixture of gravel, sand, and mud, and having strength enough to carry it all on together, will, as its strength lessens, sort and separate the materials from each other, depositing them in the order of their coarseness, the pebbles first, chiefly by themselves, next the sand by itself, and lastly, the mud by itself.¹ Three different kinds of rock, then, may be deposited at the same time by the same current; but in order that either sand or gravel may be thrown down at a subsequent period on the top of the mud, a fresh current either of greater velocity or from a nearer source will be required, while an interval will be necessary for the mud to consolidate so far as either not to be removed by the new current, or not to allow the fresh pebbles or sand to sink into it.

In the case of a limestone occurring either on shale or sandstone we are still more forcibly compelled to the supposition of a great change of conditions. If the limestone be a pure carbonate of lime without much admixture of mechanical detritus, it is obvious either that all currents had ceased in the water which had previously deposited the sandstone or the shale, or else that they were no longer able to get any earthy matter and transport it to that place. If, indeed, as seems necessary in the case of all marine limestones, we assign an organic origin to this rock, we are compelled to allow a period prior to its production sufficient for the animals from which it is derived to grow and to secrete their solid materials from the adjacent water.

It is possible, indeed, in some cases, by the aid of the remains of animals and plants found fossil in the rocks, to arrive at something like a rough approximation to the time which has elapsed between the formation of successive beds. There are cases, for instance, in which we find

¹ Just as was previously shown for mud of different degrees of coarseness in Mr Babbage's observations.

Geology. on the surface of a bed of limestone the roots or attachments of a particular class of marine animals, called encrinites, which when alive were fixed to the rock by a solid calcareous base. These attachments belong to animals of all ages, and are in great numbers; and in a bed of clay or shale which rests immediately on the limestone, there are found a multitude of the remains of the upper portions of these animals, likewise of all sizes and ages. Now it is plain that in this case, after the limestone was formed and consolidated, there was an interval during which the sea was quite clear and free from sediment, and therefore well adapted for the growth of these animals; that they, after a time, settled accordingly on the hard limestone at the bottom of the sea, and grew and flourished there for a sufficient period to allow of successive generations arriving at maturity undisturbed, before the time when a quantity of mud, having been carried into the water, was deposited upon them, and killed them, and at the same time buried their remains. Here, then, we have an interval of many years, if not of centuries, between the formation of two beds of clay and limestone which rest directly one upon the other. (Buckland's *Bridgewater Treatise*, vol. i., p. 429.)

Many instances similar to this occur to the geologist when pursuing his investigations, although not often admitting of such clear illustration and description. (See Lyell's *Elements* for other examples.)

On the other hand, we have instances of fossil trees passing through several beds of sandstone, in such a way as to show that the whole number of beds were accumulated after the tree had sunk, and before it had time to rot entirely away. These trees evidently became water-logged, and sunk to the bottom, where they rested in an inclined position, anchored by their roots, while successive deposits of sand were accumulated round them. But a tree thus wholly buried in water will last many years before it is entirely decomposed, so that it might very well have become enclosed in several beds of sandstone, especially when we recollect that it forms an obstacle to the currents flowing by it, and checks their force, and thus causes the deposition of sand around it more rapidly than would otherwise take place. Still, whatever number of years we assign to the accumulation of the whole mass of sandstone, we cannot in this case suppose any great interval to have elapsed between the deposition of one bed and that which rests upon it.

It is possible in some cases, even without the aid of organic remains, to discover that the interval between two adjacent beds was a comparatively long one. For instance, we not unfrequently find that two beds, which in one place are contiguous, do in another place let in one, two, or more separate beds between them, as in fig. 4. It is

Fig. 4.

obvious that if we observed the beds *a*, *e* at the spot marked A, we should only suppose an ordinary interval to have elapsed between the times of their deposition; while on tracing the beds to B, we are compelled to enlarge that space of time sufficiently to allow for the formation of the beds *b*, *c*, and *d*, and the intervals between them. It appears, then, that while we are able to assign a sort of rough limit to the time required for the deposition of one bed, composed of a number of laminæ, we are rarely able to assign

any approximate limit to the time required for the formation of a number of beds. Not only have we to multiply the first period by the number of the beds, but to allow for an equal number of intercalated intervals, of altogether uncertain duration, to represent the pauses that occurred between the formation of each two contiguous beds.

In some cases, if not in most, these intercalated intervals would be probably much greater than the periods of deposition, because we cannot very well imagine any set of circumstances that can keep up a continuous or rapid deposition of earthy matter, whether chemical or mechanical, for a very long and indefinite period of time, in any one particular locality. All we know, or can conceive, of the accumulation of earthy matters in the seas or lakes of the present day points to a discontinuous and interrupted action, a bed of sand being formed here, a patch of mud deposited there, a bank of pebbles accumulated in one place, a bed of oysters or other shells growing in another, so that the bottom of the sea becomes gradually covered by several unconnected and partial patches of deposition of different kinds, lying side by side. All our experience shows that for any great thickness or vertical succession of beds like these to be formed, in other words,—for the depth of water to be materially diminished (except in narrow bays and inlets),—a great length of time is required.

The soundings in shallow seas, such as those round the British islands, do not alter very rapidly, though they *do* alter; and the bottom at one period is found to be very various, "mud," "sand," "sand and shells," "small stones," and similar terms, being scattered over the charts. These "bottoms" remain constant for a sufficient number of years to be used as a guide in navigation. In other words, great intervals commonly occur between the deposition of very different deposits at any particular spot on the bottom of the sea.

Moreover, if we take the whole earth generally, and limit ourselves to the consideration of any given instant of time, we must look upon the deposition of mineral matter as the exception, not the rule. Of many hundred thousand square miles of sea, only one perhaps is receiving, at any given instant, the accession of any mineral matter on to its bed. The next successive depositions may either be in adjacent or in widely separated localities; and a vast number of these partial and detached acts of formation will be required before the whole of any particular area will be covered with one or more beds of rock. In reasoning on the methods of production that have been concerned in the formation of our great series of stratified rocks, we are compelled to suppose a similar gradual, partial, and interrupted action to have taken place.

When we rise from the consideration of single beds to that of groups of beds, we find instances, on a still larger scale, of intervals having taken place in the deposition of rocks which at first appear perfectly continuous. Mr Prestwich, in his paper on the "Correlation of the Eocene Tertiaries of England, France, and Belgium" (*Journal of the Geological Society*, August 1855), shows that on examining the rocks called tertiary above the chalk in France, they appear to have a regular continuous sequence of beds of sand and clay, &c., in which there is no sign of any interval having happened, while in reality a group of the English tertiaries, known as the London clay, having a thickness of 400 feet near London, was deposited in an interval between the formation of two of the French beds.¹

¹ Mr Prestwich's words are:—"It would nevertheless seem that there is a very important interval between the 'Lignites of the Soissonnais' and the 'Lits Coquilliers'; and that at so short a distance as from Kent to the Department of the Oise, there is introduced, wedge-shaped, between these two deposits, the large mass of the London clay, with its multitude of original organic remains. Yet there is not only no evidence either of the great lapse of time,

Geology.

Geology.

We cannot conceive the London clay to have required less than some thousands of years for its formation, and it may more probably have been many tens of thousands, during which interval no corresponding deposition was taking place over parts of the north of France, though deposition did take place both before and after this period, equally in the seas which covered what is now France and what is now England.

Such instances compel us to raise our estimate of the time required for the formation of a great series of stratified rocks to a perfectly illimitable extent.

These considerations, although they may appear somewhat speculative, are important, as leading us to a true interpretation of many of the appearances which the geologist meets with in his course of observation; and the student will do well if he accustom himself to look upon single beds of shale, &c., as the *possible* representative of a century or two, and upon small groups of beds as the product of thousands, or perhaps even millions of years.

II.—EXTENT AND TERMINATION OF BEDS.

In fig. 4 it is shown that, of a set of five beds at B, only two continue so far as A, the other three having thinned out and come to an end before reaching that part. This leads us to another conclusion respecting beds of stratified rock, namely, that although sometimes very widely spread, they are not of indefinite extent, but must end somewhere. This ending is generally a gradual one, the bed becoming thinner and thinner, till at last it disappears. Sometimes, however, though rarely, the termination is much more abrupt. Whether we reason from our own experience, or from the nature of the case, we should never be led to believe that the deposition of sediment in water, whether it be a chemical or a mechanical one, could, except in very rare instances, be coextensive with the whole water. With respect to the sea, we cannot conceive any natural causes which could produce such an universal and simultaneous deposition, and should never expect to find a marine bed, the area of which at all approached in extent that of the water in which it was formed. The wonder perhaps is, that single beds sometimes extend over such very wide areas as we really find them to occupy.

The extent of single beds is most certainly ascertained in coal mining, in which the horizontal (or lateral) extension of beds is followed. Particular beds of coal, or of shale, or other rock having remarkable and recognisable characters, are sometimes known to spread throughout a whole district. For instance, in South Staffordshire a bed of smooth black shale, a little below the thick or ten-yard coal, is known as the "table batt." It has a thickness of from two to four feet, and extends over all the greater portion of the South Staffordshire coal field—places where it is known being ten or twelve miles apart from each other in straight lines and in different directions. Its original extension was probably much greater, since the beds now disappear in one direction by "cropping out," and are buried in others at too great a depth to be followed. Known beds of coal, with a particular designation, such as "Heathen coal," extend over still wider areas, and similar facts occur abundantly in most coal fields.

When from a single thin bed we come to the examination of a group of a few beds, the instances of mineral identity over very wide areas become still more frequent. This is especially observable when the group of beds is of a character quite different from the larger mass of rocks in which

or of the important physical changes which such a formation indicates, but there is even no cause for suspicion of such a fact in the apparently complete and continuous series of the 'Sables Inferieurs' of the north of France."

Geology.

they lie; provided that difference points to a state of greater tranquillity or quietness of action, as would a bed of clay occurring in a group of sandstone beds, or a bed of limestone or coal occurring in others having a purely mechanical origin.

On the other hand, some beds, even of a considerable thickness, have a remarkably small extension, being mere cakes, thick in the middle, and thinning out rapidly in every direction. This happens sometimes with all kinds of aqueous rocks; but is the more usual characteristic of the coarser mechanically-formed rocks, being more common in sandstones than in clays and shales, and more frequent in conglomerates than in sandstones.

Beds of sandstone in the coal districts are sometimes found to thicken or thin out very rapidly. This is easily observable where sandstone beds are known to the colliers by specific names, and where the coal pits are near together. The miners are occasionally thrown out in their calculations as to the depth at which particular coals will be found by these irregularities, which are sometimes so great and rapid, as to be called "faults" by men not accustomed to precision in the terms they use. Such an instance occurs near Wednesbury in South Staffordshire, where a bed of sandstone, known by the name of the "New Mine-rock," thickens out from 9 feet to 78 feet in the course of a few yards' horizontal distance. In other parts of the district this sandstone varies from 15 to 60 feet, and in some places is entirely wanting.

In examining sandstones and conglomerates, the conglomerates or old gravel beds are often found to be very partial and irregular, forming steep-sided banks and mounds enveloped in sand.

In these cases, although it was obviously a work of time for the pebbles to have been worn and ground down from their original large and angular condition to their present small rounded form, and although we may very well suppose them to have been washed about from place to place, and thus to have eventually travelled far from their original site, yet their final deposition in the place where we now find them was probably a rather rapid and sudden action.

Conglomerates, then, may be quoted as examples either of the *length* of time required for their formation, or of its *shortness*, according as we look to the *preparation* of their materials or the actual *deposition* of them. This remark holds good, too, with respect to all other coarse mechanically-formed rocks.

III.—IRREGULAR AND OBLIQUE LAMINATION AND STRATIFICATION.

In shales the laminæ are remarkably thin and regular,

Fig. 5.

all parallel to each other, and parallel also to the planes of

Geology. stratification. In many fined-grained, and in some coarse-grained sandstones, this regularity and parallelism likewise prevails. In other sandstones, however, great irregularity is observable in the laminæ of which the beds are made up, the layers of different-coloured or different-sized grains being oblique to the planes of stratification, and various sets of layers lying sometimes at various angles and inclining in different directions in the same bed, as in fig. 5.

This structure is a proof of frequent change of direction, and probably of strength, in the currents which brought the sand into the water. If we suppose a current of water running over a surface which ends in a slope, as at *a*, in fig. 6, it is clear that any sand which is being drifted along

Fig. 6.

the bottom from *b*, will, on reaching *a*, roll down into the comparatively still water of the deeper part, and remain there probably undisturbed. Layer after layer of sand may thus be deposited in an inclined position according to the slope of the bank.¹ On the other hand, if any obstacle arrests the sand which is being drifted along the bottom of any water, some of it will be piled up into a heap, and a bank will be then formed having laminæ more or less inclined. If the current shifts its direction, another bank may be formed with its laminæ inclined at a different angle or in a different direction. Moreover, after one bank has been formed, a subsequent change in the velocity or the direction of the moving water may cut off and remove a portion of it, or excavate a channel through it, and this hollow or fresh surface may be again filled up or covered over by layers having a different form from the first. In this way water subject to changes of current, especially shallow water full of eddies, will throw down or heap up materials in a very confused and irregular manner.

It is a modification of this action probably which has produced what are called "rolls," "swells, or "horses' backs," in the coal measures, and probably in other rocks where they remain less noticed.

Fig. 7.

In this fig. *a* is black clunch containing balls of ironstone; *bb* beds of coal.

A long ridge, and sometimes one or two parallel ridges, of clay or shale are occasionally found rising from the floor through one or more beds of coal, "cutting them out," for a certain distance, to use the miners' terms. The crest of such a ridge is sometimes 8 feet above the floor of the coal, with a very gentle inclination on either side, the beds of coal ending smoothly and gradually against it. (See *Records of School of Mines*, vol. i., p. 2.) Its formation was obviously anterior to that of the coals which it "cuts out;" those coals and the "swell" itself being regularly covered either by a higher bed of coal, or by the "roof" of the seam,

¹ A very pretty little machine has been invented by Mr Sorby for producing this oblique lamination. Sand poured into a small trough is carried forwards by means of a screw, and falling down into a narrow space between a board and a sheet of glass, arranges itself in inclined layers, according to the rapidity with which the screw is worked and the angle at which the instrument is held.

without any interruption or disturbance. The swells are sometimes 200 or 300 yards long, and 10 or 12 yards wide at the base. (See fig. 7.)

Geology.

IV.—CURRENT MARK OR RIPPLE.

Another effect of current is to produce a "ripple" or "current mark" on the surface of a bed of sandstone or sandy shale. This rippled surface is exactly the same as that which is seen on the sands of the sea-shore when left dry by the tide, and which may occasionally be seen at the bottom of any clear water where a current is moving over a sandy surface. It may be observed also sometimes on sand-hills on dry land, being produced by the drifting action of the wind. Either wind or water, as they roll before them the little grains of sand, tend to pile them into small ridges, which are perpetually advancing one on the other, in consequence of the little grains of sand being successively pushed up the windward or weather side of the ridge, and then rolling over and resting on the lee or sheltered side.

It is produced on the sea-beach, not in consequence of the ripple of the wave impressing its own form on the sand below, which would be an impossibility, but because the moving current of water, as the tide advances or recedes, produces on the surface of the sand below the same form as the moving current of air produces on the surface of the water above. A rippled surface therefore to a rock is no proof of its having been necessarily formed in shallow water, though rippled surfaces are perhaps more frequently formed there, but simply a proof of a current in the water sufficient to move the sand at its bottom gently along, at whatever depth that bottom may be from the surface of the water.

Sandstones of all ages, from the oldest known rocks to the most modern, have occasionally rippled surfaces. Magnificent examples are sometimes shown in the cliffs of the S.W. of Ireland, where highly inclined beds exhibit such markings over spaces frequently of 160 feet in each direction. The size of the ripple, or the distance from crest to crest of the ridges, varies from half an inch to 8 or 10 inches, with a proportionate variation in depth between them.

Mr Sorby has lately shown that inferences may be drawn from the examination of these "current-marks" as to the strength and direction of the currents that caused them, and that we may thus reason back to some conclusions as to the physical geography of particular districts in former geological periods. One important conclusion certainly may be derived from these, as from other structures in rocks, namely, that the strength, velocity, and mode of action of moving water in the old geological periods was precisely of the same kind and intensity as those with which we are familiar at the present day.

In places where the current was troubled and confused, a modification of these rippled surfaces is sometimes produced, the bed being irregularly mammillated on its surface, which is pretty equally, although irregularly, divided into smaller hollows and protuberances of a few inches diameter. This surface structure may be seen in process of production now, on shores where spaces of sand are inclosed by rocks, so that as the tide falls it is made to run in different directions among the rock channels; but it would probably be caused at any depth at which a current could be similarly troubled and confused. It is not unfrequently seen among gritstones, even those of the very oldest rocks. It might be called "dimpled current mark."

V.—CONTEMPORANEOUS EROSION AND FILLING UP.

Instances are not unfrequent in which it appears that a bed, not only of sand, but of clay, coal, or other soft rock, after being formed, has had channels or hollows cut into it

Geology.

by currents of water, and these hollows have been filled up by a part of the bed next deposited.

In fig. 8, taken from a road-cutting in the new red sand-

Fig. 8.

stone at Shipley Common, near Wolverhampton, 1 is a bed of red and white marl or clay; 2 is a chocolate-brown sandstone with irregular beds and patches of marl; 3 is a bed of red marl like 1, but which seems at one time to have been thicker than it now is, and to have had some part of its upper surface carried off before the deposition of 4, which is a brown sandstone, that in like manner seems to have had its upper surface eroded and the hollows filled up by the deposition of 5, which is a mottled red-brown and white calcareous sandstone, or cornstone.

In the tertiary beds near Paris, which are believed to have been deposited in a shallow bay or gulf, receiving rivers, and therefore traversed by currents, this structure is frequent. Two remarkable examples are observable in the large excavation near the terminus of the Rouen railway. In a cliff about 40 feet high, in the fresh-water limestone formation, called the Calcaire St Ouen, two trough-like hollows may be seen about 50 yards apart; the beds previously formed having been excavated for a depth of 20 feet and a width of 15, and the hollows thus formed being filled up by irregular meniscus-shaped¹ expansions of the upper beds. (See fig. 9.)

Fig. 9.

Hollow of erosion in tertiary rocks near Paris, filled up by thickening of the subsequently formed beds.

We are not aware how far the French geologists make a distinction in time between the beds thus eroded and those which fill up the hollows.

Similar trough-like hollows are met with in coal mining, traversing beds of coal, the coal being eaten away, and the hollows filled up by the matter which composes its roof, such as clay, shale, or sandstone. Mr Buddle has described very fully one met with in the forest of Dean, where the miners gave the name of "the horse" to the stuff which thus seemed to come down and press out the coal. This trough was found to branch when traced—as in coal-mining it was necessarily traced—over a considerable area, and to assume all the appearance of a little stream with small tributaries falling into it; the channels of the stream being afterwards filled up by the subsequently deposited materials that were spread over the whole coal.

Another modification of this erosive action is represented in fig. 10, taken from a sketch made in a quarry in the

neighbourhood of Hobart Town, Tasmania, where a bed of soft brown unctuous clay, about a foot thick, *b*, lying

Geology.

Fig. 10.

Eroded termination of bed of clay, with sandstone formed against it (Hobart Town, Tasmania).

between two beds of hard white sandstone, *a* and *d*, suddenly ended, and its place was occupied by sandstone, *c*, similar in character to the beds above and below it. We must in this case suppose that after the formation of the bed of sandstone *aa*, a bed of clay *b* was deposited over a certain portion of the area, and that then a current of water, bringing in sand, wore back the little bed of clay, eating into it so as to form a small cliff or step, and depositing the sand *c* afterwards against it, as represented in the diagram. The two beds, thus exactly on the same level, but *not exactly contemporaneous*, were finally covered by the bed of sandstone *dd*, which spread equally over both of them.

We see in this case proof, that although the bed *c* is exactly on the same level as the bed *b*, both reposing on, and both covered by, the same beds, yet they are still not exactly of the same age, but that *c* was formed subsequently to *b*, inasmuch as *b* was not only formed, but partially destroyed previously to the formation of *c*. Such facts give us farther proof of the length of the intervals which may elapse between the formation of two beds such as *a* and *d*, and also caution us not in all cases to infer strict synchronism from the fact of beds occupying the same geological horizon.

VI.—CONTEMPORANEITY OF BEDS ON SAME HORIZON.

If a group of beds, whether large or small, have the arrangement shown in fig. 11, the order of the formation of

Fig. 11.

the beds is clear enough as regards *a*, *b*, and *c*; but *d*¹ and *d*² may either have been deposited contemporaneously, or one before the other; *e* is clearly subsequent to them both; but *f*¹ and *f*², again, are uncertain in relative age, while there is no doubt about that of *g* and *h*. If we wished to estimate the whole time consumed in the formation of such a set of beds, it would be obviously wrong merely to take their mean thickness, as shown at A B, for the measure of that time. The whole thickness of *a* had been deposited before *b* had been begun, and both were complete before *c* was formed. If, therefore, we assume thickness, or quantity of material deposited, as the measure of time occupied in deposition, it is clear that we should add together the maxima of *a*, *b*, *c*, and not take their mean. Similarly of the whole set, we ought to search out for the maximum

¹ A meniscus is a lens concave on both surfaces.

Geology. thickness of each bed, and add those thicknesses together; and in doing this, we should feel some doubt as to whether we ought not to reckon d^1 and d^2 , and similarly f^1 and f^2 , as two separate and consecutive beds, instead of supposing them to have been formed at the same time. If in the set of beds under examination we found many beds thus ending without overlapping, we should clearly be right in making allowance for the probably successive deposition of some of those which appeared to be contemporaneous.

We have already seen that this irregularity of deposition is most frequently met with in rocks that we supposed to be most hastily accumulated, while those which spread very regularly over extensive areas appeared to be most tranquilly and quietly, and therefore most slowly, deposited. We see now, however, that this very irregularity carries with it, in the long run, its own compensation, and that,—what with partial erosion and removal of some beds, and intervals of greater or less length between the formation of others, together with want of synchronism between beds that seem at first sight to possess it,—although any one bed, or small set of beds, may have been deposited in a comparatively hasty manner, yet the whole amount of time to be allowed for the accumulation of a great series of coarse beds would, if properly estimated, probably not be less than for an equal mass of more gradually and tranquilly formed rocks.

VII.—INTERSTRATIFICATION, ASSOCIATION, AND ALTERATION OF BEDS.

In studying the formation of aqueous rocks, we should soon perceive that no general rule can be laid down as to their association with one another.

Limestones, sandstones, and clays occur either separately or interstratified one with the other in every imaginable variety of disposition.

We have sometimes a series of beds, many hundreds of feet in aggregate thickness, of pure limestone, with scarcely a single seam of mechanically-deposited matter, even so much as an inch thick. Instances of this are shown in the chalk of the south-east of England, and the carboniferous limestone of Derbyshire, and of large portions of Ireland.

Series of beds of sandstone, almost entirely devoid of calcareous or argillaceous matter, and having a total thickness of many hundred feet, likewise frequently occur. Old gravel beds, now compacted into conglomerate, are often associated with these; and the sandstones exhibit every variety of texture, from lines of small pebbles to the finest possible grains. In such masses of sandstone it is rare to find any foreign bodies, and mineral concretions or chemical deposits hardly ever occur in them.

Groups of beds of almost pure clay also occur, with a thickness of several hundred feet, with hardly a single bed of sandstone or limestone to be found in them.

While cases of this accumulation of one particular kind of matter, of great thickness, and therefore through long periods of time, are by no means rare, it is perhaps more usual to find different beds of rock alternating one with the other, sometimes so interstratified that there is never a greater accumulation than twenty or thirty feet of any one sort without others interposed between them.

Beds of limestone are frequently separated by beds of clay or shale, which is most commonly black or brown. These shales are themselves sometimes calcareous, and there seems occasionally to have been such an equal mingling of the two kinds of matter, that it is hard to say whether it would be most proper to call the rock a shale or a limestone. Such are some of the beds known as *calp shale* or *calp limestone* in the middle districts of Ireland.

Beds of sandstone, again, often alternate with such shales; so that we get a series of beds consisting of alternations of

all these kinds. Beds of limestone sometimes alternate with sandstones, some of which may likewise be calcareous; but it is more rare to find pure limestone and pure sandstone interstratified with each other, than to have argillaceous beds alternating with either or with both. Speaking generally, indeed, we find, in examining the vertical succession of beds of rock, an approach to the same kind of passage or gradation that we sometimes perceive in their lateral extension. Beds of very fine and very coarse materials rarely rest directly one upon the other. Conglomerates are generally covered and underlaid by sandstones, and not by clays or shales. Coarse sandstone, in the same way, has usually a bed of finer material, either above or below, before shale or clay occurs.

The transition from the conditions favourable to the deposition of one kind of rock to those conducive to another has generally been gradual rather than abrupt. The tranquil water of the open sea, which seems to be the general producer of limestone, becomes first invaded by gentle currents, bringing in finely suspended mud, before it is traversed by those of sufficient strength to carry out the coarser material of sand. When a single bed varies in grain, we generally find the coarser part at the bottom, as we should expect; for when a quantity of variously sized detritus is delivered into any water, the larger and rounder grains or fragments will be the first to sink. Not unfrequently, however, alternations of finer and coarser grained laminæ occur in one bed, proving that the bed was formed by a succession of actions, and by as many different deliveries of matter into the water as there are sets of alternations.

We will give here two instances of alternation of beds, taken from actual observation and measurement. The first is a section supplied by Mr. G. V. Dunnyer, and represents the top beds of the upper limestone (carboniferous), where they are observed to pass into the lower coal measures, in county Carlow, from a quarry close to Old Loughlin.¹ (Fig. 12.)

Fig. 12.

¹ In this section the rule as to numbering is not observed, as the numbers refer to the woodcut.

Geology.

No.	Feet.	Inches.
1. Hard earthy black splintery shale	3	0
2. Earthy rotten black shale	2	0
3. Hard black shale	0	2
4. Brown earthy layer	0	5
5. Crystalline gray crinoidal limestone	3	4
6. Soft brown earthy shale, containing abundance of fossils, and very numerous layers of black chert	11	6
7. Hard gray shale, encrinurite stems, and shells	0	9
8. Gray compact limestone	3	6
9. Chert layer, black	0	4
10. Gray compact limestone	1	0
11. Thin irregularly bedded shaly limestone, with gray shale on top	1	9
12. Compact limestone	0	9
13. Light gray compact limestone	4	8
14. Black chert layers in hard black shale	1	0
15. Gray compact limestone, forming floor of quarry.		

The following is another example of the alternation of beds, derived from the Bristol coal-fields (*Mem. Geol. Survey*, vol. i., p. 210).¹

No.	Feet.	Inches.
23. Argillaceous shale	185	0
22. Sandstone	4	0
21. Coal	1	6
20. Underclay	2	0
19. Argillaceous shale	64	0
18. Coal and shale	4	0
17. Coal	1	0
16. Underclay	4	0
15. Argillaceous shale	4	0
14. Sandstone	2	0
13. Argillaceous shale	23	0
12. Coal	9	0
11. Underclay	3	6
10. Coal	0	6
9. Underclay	2	0
8. Argillaceous shale	7	0
7. Sandstone	1	0
6. Argillaceous shale	2	0
5. Sandstone	6	0
4. Argillaceous shale	4	0
3. Coal	2	4
2. Underclay	2	0
1. Sandstone	3	0

The whole section, of which this is a portion, enumerates 294 similar alternations, having a total thickness of 5084 feet, below which is a series of beds, 1200 feet thick, principally composed of hard sandstone.

It is to be specially noted, as regards the occurrence of coal, that it almost invariably rests on a fine argillaceous bed, often what is called "fireclay." This fact is familiar even to the miners, so that it has received the name of "underclay" in the South Welsh district, and in others is called "coal seat." The general order of superposition (or of time of formation, for these are convertible terms), is 1. Sandstone; 2. Clay; 3. Coal; 4. Clay. If we disregard the minor alternations, we should see this rule carried out in almost all sections of coal measures, the clay above the coal (the roof) being generally thinner and stronger (more shaly) than that immediately below. In some few instances the coal seat is arenaceous, and still more frequently a sandstone or "rock" roof may be found.

VIII.—LATERAL VARIATION OF BEDS.

We should in many cases find that, of the beds which we had noted at one locality, many, or most, or all gradually thinned out and died away as we followed their lateral extension, and that their places were supplied by others which as gradually came in. Now, these new beds might either

be of similar character to those which had died away, or altogether different.

We might, for instance, in one locality, have a series of limestones of 1000 feet in thickness, resting one upon the other, without the intervention of any other beds. As we traced this group across a country, we should perhaps find that little "partings" of shale began to make their appearance between some of the beds of limestone, and that as we proceeded these shales became thicker and more numerous, while the limestones became thinner in proportion. Some of the limestones would perhaps then altogether disappear, and the series be split up into two or more groups of limestone, with one or two intermediate sets of shale-beds.

Fig. 13.

In this diagram the white bands are meant for limestones, the black for shales, and the dotted for sandstones.

Still farther on, the limestones might be more and more subdivided by beds of shale, and the shales themselves split up by beds of sandstone, until at length we should find our series consist almost entirely of sandstones and shales, with only one or two very subordinate beds of limestone, at one or two levels, to represent the purely calcareous group with which we commenced. The diagram (fig. 13) gives a rough representation of this lateral change, but requires to be drawn out to twenty or thirty times its length before it could be taken as a proximate delineation of the facts as they occur in nature.

In the same way, groups that consist principally of sandstone and conglomerate in one district, may in another be composed chiefly of limestone and shale or clay, with or without any beds of sandstone.

The scale upon which these lateral changes of character are carried out is altogether indefinite. We see it sometimes take place with respect to a small group of beds within the limits of a single quarry; in other cases, a distance of a few hundred yards or a few miles is requisite before the alteration is apparent. Some groups of beds, indeed, preserve their mineral characters but little altered over whole countries or across whole continents. Still, judging from what we know, we must always hold ourselves prepared for change even in the rocks that seem most constant in their characters; and as a matter of fact, we know of no one group of aqueous rocks that preserve the same mineral characters in all parts of the earth.

Combining thus actual observation with probable speculations, we should be quite ready to understand that the same set of beds may, within the space even of the British Islands, put on very variable characters. Of this we may now advantageously examine some instances. Let us compare the two following sections, which are descriptive of the beds which intervene between the two great continuous groups of argillaceous rock, called respectively the Oxford clay, and the Lias. These intervening beds are called generally the Lower or Bath oolite, because the oolitic limestones contained in them near Bath and elsewhere are the most striking and valuable portions of them. The section near Bath is taken from Conybeare and Phillips, that for Yorkshire from Professor Phillips's *Geology of Yorkshire* :—

¹ In all tabular lists of beds or formations in this article, the series will be arranged on the page in their order of superposition, but they will be numbered in order of age, beginning with the oldest or first formed.

Geology. NEAR BATH AND IN GLOUCESTERSHIRE.			YORKSHIRE.

We see that, while in the south of England these beds are largely characterized by the presence of oolitic limestones, those in the north are almost destitute of them, but contain instead great beds of sandstone and shale, together with thin beds of coal, which are equally wanting in the south. If we examined the fossils they contained, we should find an equal change, as the beds in the north are full of carbonized plants and vegetables, which are almost altogether absent in the south, where the fossils consist of the remains of mollusca and other marine animals that are rare or wanting in the north. It seems as if in proceeding from the south to the north, we were approaching the shore of the old sea, and therefore get a greater quantity of mechanically-formed rocks, together with the products of the land, in the shape of plants that had been drifted from it, while the marine products proportionably decreased.

Had the Yorkshire rocks been those which were first examined and described, the term "oolitic" would never have been applied to them, although they may now be called "oolitic," as having been formed at the same time with those which had previously received the name of "oolitic" rocks in Gloucestershire, and other parts of the world.

Similar results would be arrived at if we traced over a large area another group of rocks, which are called carboniferous, from their containing in some places beds of coal. These rest upon certain beds of red sandstone, called old red sandstone; and if we compare them as they occur in the south of England and South Wales, in central and northern England, and in Scotland, we shall find that, while essentially made up of the same kind of materials throughout, these materials are differently arranged in different places.

We have in South Wales and the border counties—

4. Coal measures, alternations of sandstones, clays, and shales, with occasional beds of coal.....	7,000 to 12,000
3. Millstone grit, chiefly white quartzose sandstone.....	200 ... 900
2. Limestones with thin shaly partings, called carboniferous, or mountain limestone.....	400 ... 1,800
1. Lower limestone shale, alternations of shales, with thin limestones....	160 ... 500
Old red sandstone.	

(Memoirs of Geological Survey, vol. i.)

In Derbyshire and some adjacent counties, and in North Wales, this series becomes :—

4. Coal measures, as before.....	3000 to 6000
3. Millstone grit, as before, about.....	800
2. Upper limestone shale, dark shale with occasional beds of limestone.....	500
1. Carboniferous limestone, as before.....	800 ... 1000
Old red sandstone.	

The chief difference between these two sections is the occurrence of a group of beds of black shale *above* the carboniferous limestone in the north, while there is little or none *underneath* it, the reverse being the case in the south.

In tracing these beds, however, from Derbyshire through Yorkshire and Durham to Northumberland, we find a gradual change coming in, so that while No. 4, the coal measures, retain their character of a multiform alternation of beds, No. 3, the millstone grit, becomes split up by shales with beds of coal, thus blending with the coal measures, while No. 2 acquires many beds of limestone and some of sandstone, and eventually also of coal, and even No. 1, the great limestone series itself, becomes interstratified with shales, sandstones, and coals; so that instead of the unbroken succession of beds of limestone which we have in Derbyshire, we get such sections as the following in Durham and Northumberland for the composition of No. 1.

g. Main limestone.....	Feet. 70
f. Various alternations of shales, &c.....	80
e. Underset limestone.....	24
d. Various, including one coal-seam, one or more limestones, several shales, one or two principal grit rocks, flagstones, &c.	150 to 350
c. Scaur limestone.....	15 ... 40
b. Various alternations, including a bed of coal, and one or more beds of limestone.....	125 ... 225
a. Tyne bottom limestone.....	25 ... 50
	489 to 839

(Aldstone Moor, as given by Mr Forster.)

In Scotland we have nothing above the old red sandstone but one great series of alternations throughout, containing beds of coal from the top of the series to the bottom, so that the great carboniferous formation is no longer separable into distinct groups as in the south. All that can be said of the Scotch carboniferous series is, that it is *all* coal measures, beds of limestone being more frequent in the lower than in the upper part of the formation, where they are commonly altogether wanting.

General Conclusions.—As general conclusions from what we have hitherto said, we may state the following:—

1st. For the production of mechanically-formed aqueous rocks the existence of *dry land* is absolutely necessary, since such rocks are the result, almost entirely, of the wear and tear of other previously existing rocks *at or above the level of the sea*.

2d. For the production of calcareous rocks animal life was necessary; for that of carbonaceous rocks vegetable life was necessary. The animal life may have been entirely aquatic, the vegetable life may have been either aquatic or terrestrial.

IX.—JOINTS.

We should not long have studied the laminated and stratified structure of rocks, and paid attention to their separation into beds by planes of division which were obviously the result of distinctness and succession in the acts of deposition, without being struck by the occurrence of other planes of division, which cut the first at various angles, and assist them in dividing the rocks into regular or irregular blocks.

We should, indeed, very soon perceive that *all* rocks, stratified or unstratified, igneous, aqueous, and metamor-

Geology.

phic, were traversed by numerous planes of division of this kind. They may be seen in any quarry, or in any natural or artificial excavation in any solid rock, traversing the rock in various directions, and separating it into blocks of correspondingly various shapes and sizes.

These divisional planes are called "*joints*."

Without natural joints the quarrying of stratified rocks would be very difficult, and that of unstratified rocks almost impossible. If beds of sandstone or limestone were undivided by natural joints, each block would have to be cut or split by artificial means on every side from the rest of the bed; but in rocks, such as granite or greenstone, which have no beds, the blocks would not only have to be cut away on each side, but *underneath* also. It would obviously be a most impracticable task to *dig out* a large block of granite from the midst of a solid mass untraversed by any natural planes of division of any kind.

For the production of natural blocks of rock there must clearly be *at least* two sets of joints in stratified, and three sets in unstratified rocks, each set more or less nearly at right angles to each other. (See figs. 14 and 15.)

Fig. 14.

Joints in granite. (Large quarries in Killiney Hill, near Dublin.—G. V. D.)

Fig. 15.

Joints in limestone. The planes of stratification are shown by the parallel lines dipping from the spectator and towards the left. The other lines are the ends of joint planes, which also form the smooth surfaces of the rock nearly at right angles to each other, as shown by the projecting corners. (Quarry near Mallow, Co. Cork.—G. V. D.)

Professor Phillips tried many years ago, in his *Geology of Yorkshire*, whether the directions of the principal joints were not related in some way to the magnetic meridian, and arrived at results showing a tendency in the two principal sets of the joints of the Yorkshire rocks to arrange themselves according to certain magnetic bearings. This, however, seems to be only another way of stating that there are two principal sets of joints in the district, those of each set being parallel to each other.

Professor Sedgwick refers the directions of joints chiefly to the lines of upheaval and disturbance in rocks, calling those which run along or parallel to the "strike" of the beds, "*strike joints*," and those parallel to the "dip," "*dip joints*."¹ All other joints he calls "*diagonal*" joints.

¹ For the explanation of the words "strike" and "dip," see *postea*, chap. vi., §.2.

These are useful terms, whether the two things be or be not related in the way of cause and effect.

Geology.

It is certain that some joints have been produced in all rocks anteriorly to, and independently of, the action of the forces of upheaval which have elevated them; but it is very likely that the direction of the lines of upheaval may have been governed or modified by that of the principal joints, and that other joints may have been the result of the action of these disturbing forces.

In some localities, very widely extended planes of division may be seen traversing a great series of beds in perfectly parallel lines, running at wide intervals down whole mountain sides, so as to be visible at a distance of several miles, but without producing any dislocation or shifting of the beds.¹ Such unlimited joints were very probably produced, not from any internal shrinking on the mere consolidation of the beds, but from a simultaneous yielding of the whole mass to a great expansive or stretching force. When we come, however, to examine the joints of igneous rocks, more especially those of the highly crystalline kinds, such as granite, we see an amount of irregularity and want of symmetry in their arrangement which would make it difficult to attribute their origin to any widely spread polar force or any mechanical power acting in one or two given directions.² It is true that over small areas, as, for instance, in single quarries, the regularity of the arrangement of the joints in granite is often very remarkable. One set of planes will be seen to run at such equal distances, and so strictly parallel, that if they be horizontal, or nearly so, they produce the appearance of stratification in the rock, and the workmen frequently speak of the *beds* of rock between such planes (fig. 14). In very large quarries, however, or in long cliffs, this appearance of regularity is found to be very inconsistent and deceptive. One set of joints will most resemble stratification at one spot, and another set at another, each set being gradually obscured by the occurrence of other sets of joints cutting them irregularly and promiscuously.

The shape and the width of joints of stratified rocks vary much according to the nature of the rock. They are generally close, regular, and symmetrical, in proportion to the fineness of the grain and the compactness of the rock, being most irregular and uneven in coarse sandstones and conglomerates. The power of the force which produces them is, however, well shown in hard and well consolidated conglomerates, since the hardest pebbles of pure white quartz are often cut as clean through by the joints as the compacted sand in which they lie. In sandstones, joints are frequently open; in shales, they are closer, but more smooth and regular, being frequently perfect planes. In limestones, there are both close and open joints; but the open joints have frequently been widened by the action of water percolating through them, and dissolving a portion of the rock. Great fissures are sometimes formed in this way; and this has doubtless been the origin of many of the caverns which occur so abundantly in limestone rocks. In highly argillaceous limestones, the joints are often beautifully smooth, regular, and close.

In some cases, it would seem as if each bed had its system of joints formed before the other was deposited upon it, inasmuch as the joints formed in one do not penetrate the other. In other cases, a set of joints is seen to be common to a whole set of beds, and to have been produced ap-

¹ The peninsula that runs out from Glengarriff to Berehaven, along the north side of Bantry Bay, is especially remarkable for these vast joints.

² We are aware that some great parallel joints may in some localities be traced coursing through granite and other adjacent rocks; but we should class such joints among those subsequent ones just spoken of, and not among the original structural and congenital joints of granite and other rocks.

Geology. parently in the whole simultaneously. It is not uncommon for joints, in passing from one bed to another, to shift a little, or slightly change their angle. In such cases it may be doubtful whether a joint previously formed in the one bed may not have given rise to the formation, or at least have modified the position, of the other, in the bed above. There does not seem either to be any reason why all the joints traversing any bed or any set of beds should necessarily be of one age, but the contrary, inasmuch as we may imagine the process of solidification to take place at intervals, being at first incomplete, and afterwards becoming more perfect. Subsequent contraction would not have been so likely perhaps to widen the old joints as to produce new ones, since the shrinkage could hardly exert such a force as to overcome the effects of friction, and cause any large masses of rock to move and slide one over the other even to the most trifling extent.

Joints then may be caused, first, by the consolidation of each bed separately; secondly, by subsequent acts of consolidation, common to several beds; and thirdly, to widely spread mechanical force, affecting whole formations at once.

In the gypsum quarries of Chaumont, near Montmartre, Paris, two thick beds of granular gypsum occur, which, instead of being divided by two principal sets of joints into quadrangular blocks, are traversed by three equally strong sets crossing each other at equal angles; and the whole mass is accordingly split into triangular and hexagonal blocks, giving the beds a columnar appearance like that so well known in basaltic rocks. (See fig. 16.)

Fig. 16.

Joints in beds of granular gypsum. (Chaumont, near Paris.)

The hexagons and triangles are frequently quite regular and perfect, and the result very curious, and, as far as I am aware, unique in unaltered aqueous rocks. If three sets of equidistant planes cross each other at equal angles, the angle of intersection between any two will of course be 60° . If all three planes meet at the same points, triangular forms only would be produced; but if they be so arranged as that no more than two sets should ever intersect each other at the same point, and that each point of intersection be exactly half way between the other set of planes, as in fig. 16, alternate triangles and hexagons of perfectly regular form will be the result.

These conditions seem to have been exactly fulfilled in the quarries near Paris, and the symmetry of arrangement has not been disturbed or obscured by additional irregular joints, which may possibly mask this, or some other symmetrical arrangement of joints in other places.

We have already said that in massive igneous rocks there must necessarily be at least three sets of planes, all more

or less nearly at right angles to each other, for the mass to be separated into blocks, while in stratified rocks there must be at least two sets of joints cutting across the beds. If the planes be equidistant and exactly at right angles, the blocks would be perfect cubes. This exact regularity however, is not to be expected as common, nevertheless the approach to it is frequent, and it would be still more so if it were not for the occurrence of other irregularly disposed diagonal joints. We may, therefore, in practice look upon such blocks as more or less universally cuboidal, and speak of the joints producing them as cuboidal or quadrangular joints. We have just seen that, even in aqueous rocks, other symmetrical arrangements of joints may exist, producing regular forms other than cubes; but this is more especially remarkable in those igneous rocks which occur in comparatively thin sheets, whether as beds or as "dykes," that is, as wall-like sheets traversing other rocks. In these the joints often divide the mass into long prisms.

The sides of these prisms are sometimes regular and equal, producing either hexagonal, pentagonal, or other forms. Sometimes, however, they are unequal and irregular, dividing the rock into uneven and wrinkled prisms like those exhibited by the common substance "starch."

That this prismatic arrangement is the result of contraction on consolidation is shown by the prisms usually being at right angles to the greatest extension of the mass, being vertical in a horizontal bed, horizontal in a vertical dyke, proving that the fissuring commenced at the cooling surfaces, and struck thence directly towards the centre of the mass.

Sometimes it is found that the two sets of prisms thus originating at each surface did not exactly fit when they met in the centre, as is shown in fig. 17. At other times, however, they proceed uninterruptedly from one side to the other, the two sets either having coalesced, or one surface having cooled before the other, and given rise to divisions that were carried right across to the other.

Fig. 17.

Dyke of columnar basalt, the columns not continuous across.

In addition to these prismatic joints, other irregular joints, more or less nearly at right angles to the prisms, also occur; and in very regularly columnar basalt and greenstone the columns are articulated, or separated at regular or irregular intervals into short blocks, by divisions, which are sometimes quite flat, sometimes curved into concave and convex surfaces, forming a kind of approach to a ball and socket joint. The origin of this structure is explained by the celebrated observations of the great Gregory Watt. If a mass of basalt be melted in a furnace, and allowed to cool again, the following results may be observed. If a small part be removed and allowed to cool quickly, a kind of slag-like glass is obtained, not differing in appearance from

Geology. obsidian. If it cool in larger mass more slowly, it returns to its original stony state. During this process small globules make their appearance, which, very small at first, increase by the successive formation of external concentric coats, like those of an onion, and the simultaneous obliteration of the previously formed internal coats, so that ultimately a number of solid balls are formed, each enveloped in several concentric coats. As these balls increase in size, their external coats at length touch, and then mutually compress each other. Now, in a layer of equal-sized balls, each ball is touched by exactly six others (see fig. 18), and if these be then squeezed together by an equal force

Fig. 18.

acting in every direction, every ball will be squeezed into a regular hexagon. But the same result will follow from an equal expansive force acting from the centre of each ball, or from the tendency to indefinite enlargement in their concentric coats. Each spheroidal mass, therefore, will be converted into a short hexagonal pillar. But if there are many piles of balls one above another, each ball resting directly and centrally on the one below it, we should have a long column of these hexagonal joints, and the top and bottom of each joint either flat, concave, or convex, according to variations in the amount and direction of the pressure at the ends of the columns.

There is no apparent reason why, in a cooling mass of basalt, the balls should be so arranged as that their centres should be in straight lines, and that the hexagonal vertebræ should form straight continuous pillars rather than separate discontinuous pavements. This, however, is probably the result of the simultaneous tendency in the mass to split into prisms in consequence of the joint-forming contraction on consolidation, the two tendencies acting together to produce the columns with the short ball and socket articulations.

In the case of curved columns, it is probable that the accidental arrangement of the centres of the balls overpowered the tendency to produce straight prismatic joints. Many other irregularities, resulting from the unequal action of one or the other tendency, may frequently be observed, since there are not only curved, but oblique and radiating columns; not only hexagonal, but pentagonal, triangular, and other irregular shapes; and in some instances, small uncompressed, or nearly uncompressed balls, may be found in the interstices between unequal and irregular columns. The pillars of basalt are usually from 6 to 18 inches in diameter, and vary in length from 5 or 6 to 100 or 150 feet. Columnar greenstone is commonly on a larger scale, the pillars being sometimes 5 or 6 or even 8 feet in diameter, and the columnar form of the rock is often only to be perceived at a distance. Almost all greenstone exhibits the tendency to decompose into rounded spheroidal blocks, on which we have just seen the columnar structure partly to depend. Felstone is sometimes also beautifully columnar; of which an admirable example may be seen in a small pass to the southward of Lough Gitane, near Killarney. (See papers by Messrs Dunoyer and Foot in the *Journal of*

the *Geological Society of Dublin*, in 1856.) Neither is this tendency confined to basalt, greenstone, and felstone, since it is sometimes perceptible even in granite, producing in that rock the "logging stones," or "rocking stones," the "cheese wrings," the "tors," as well as the "pots and pans," and "sacrificial basins," and other curious natural forms occurring in that rock, of which many have been attributed to ancient artificial processes.

The study of joints and the other divisional planes of rocks, and the different forms assumed by them in consequence, both when freshly exposed and when modified by "weathering," is as necessary for the landscape painter who wishes to reproduce nature, as is the study of anatomy to the figure painter. Mr Ruskin has handled this subject in his usual masterly style.

CHAP. VI.—FORCES OF DISTURBANCE.

I.—ELEVATION OF AQUEOUS ROCKS.

In the preceding chapter we have been principally engaged with the facts relating to the deposition and consolidation of those rocks that have been formed under water. It will be convenient now to examine the problem of the elevation of these rocks into dry land.

It is clear that all rocks which were formed at the bottom of the sea, and which are now dry land, must have gained their present situation either by the sinking of the sea level or by the uplifting of the sea bottom. If, however, the level of the sea be materially lowered in any one part of the globe, it must be equally lowered over its whole surface. But we find aqueous rocks on the summits of some of our highest mountains, and if these had been laid dry solely by the sinking of the sea, it is difficult to understand what can have become of a shell of water ten or twenty thousand feet deep enveloping the whole globe.

Partial floods and inundations are out of the question. Laplace determined that though the sea is often agitated by storms and earthquakes which raise it into great waves, and make it locally and temporarily overstep its limits, yet *the equilibrium of the ocean is stable if its density is less than the mean density of the earth*. Now, experiments on the attraction of the mountains of Schiehallion in Scotland, and Mount Cenis in the Alps, as well as those made by Mr Cavendish, and Reich and Baily, with balls of lead, demonstrate that the earth has a mean density at least five times that of water, and hence the stability of the sea and the invariability of its level is beyond a doubt.¹ (Brewster's *Life of Newton*, vol. i., p. 363).

We must therefore look upon the level of the sea all over the surface of the globe as absolutely invariable, unless by very great changes taking place in the form of its bed,—the elevation of some parts, or the depression of others. To effect either relative or absolute change of level, then, in the surface of the sea, it is the *solid* part of the earth's crust that must first move. Even then we shall not effect absolute change of level in the upper surface of the sea, unless the elevation of its bed in one place be materially greater than its depression in another, or *vice versa*. But this we have no reason to suppose probable, and no right to assume as having taken place.

Wherever, then, we find that a change has occurred in the relative levels of land and sea in any portion of the globe, we must believe that the elevation or depression has taken place in the land,—*in the solid rock*, and not in the

¹ More recent observations by the Astronomer Royal on the pendulum at the surface and at the bottom of deep mines, give a mean of 6.809 for the earth's specific gravity, while those made by the Ordnance Survey on the deflection of the plumb line at Edinburgh give it as 5.14.

Geology. fluid ocean. The very fluidity, indeed, of the ocean, which might at first lead us to look to its motion and change of place as the cause of the appearance of dry land, renders any permanent *local* or *partial* change in its level impossible, while a local change in the level of solid rock is more easily possible than a general or universal one.

If, therefore, we can prove that elevation has occurred in one place while depression happened in another, or if we can prove that any alteration of level whatever took place that was not common to the whole globe and equal all over it, it must necessarily have been the rock that moved, and not the sea.

We may arrive at this conclusion in another way. We could not continue our observations upon stratified or aqueous rocks very long without perceiving that their beds were not invariably horizontal, but were, on the contrary, generally inclined to the horizon. Now we have already seen that in certain cases beds of stratified rock may be formed on a considerable slope, or may have an original inclination due to the very circumstances of their deposition. These cases, however, are by their very nature limited to small areas. A steep slope cannot be of indefinite extent in every direction, and could not have strictly parallel beds deposited on it over its whole area if it were. Whenever, then, we have very widely spread beds maintaining an equal thickness and strict or approximate parallelism over a large extent of ground, we may feel perfectly sure that those beds when first formed were horizontal. If such beds are now found in an inclined position, we may be equally certain that they have been moved since their formation, and moved more in one direction than in another. They must have been *tilted*, either by being lifted up at one end or depressed at the other. In many cases we find this motion to have been very great; the beds have been tilted and set on edge so as to rest at very great angles, and in some cases to be absolutely vertical. Beds consisting of alternations of clay and sand, with their seams of round pebbles that must clearly have been deposited horizontally, have been tilted up till they are now perpendicular (see fig. 19).

Fig. 19.

Beds containing layers of round pebbles, which must therefore have been deposited horizontally, now in a vertical position.

No one could look at a cliff exhibiting these facts without feeling certain that in this case, at all events, some subterranean and internal forces had acted upon previously horizontal beds, and lifted them into their present position.

If we still hesitated to believe such motion in the solid frame-work of the earth possible, our scepticism must at length give way before the knowledge of the fact that it is still going on even in our own day in various parts of the earth. For a compendious account of movements of elevation and depression in the lands of the present day, either occurring within the times of history or still in progress, we must refer the reader to Sir C. Lyell's *Principles of Geology*, chapters xxix., xxx., and xxxi. He will there find an account of the gradual rise of Sweden and Norway,

which is now going on at the rate of about three feet in a century; of the frequent elevation of land along the west coast of South America¹ simultaneously with the occurrence of earthquakes; of the depression of the coast of Greenland, and of both the elevation and depression of the temple of Jupiter Serapis and its neighbourhood in the Bay of Naples, and other similar facts in other parts of the globe.²

It must suffice here to say, that these movements seem to be very slow, and to require immense periods of time before any great permanent change is effected. They may either be continuous and insensible in small periods of time, with no earthquake movement, or they may occur simultaneously with earthquakes in little shocks and starts of a few feet or a few inches at a time. It is probable that no earthquake ever occurs without being accompanied by some change of level in some part of the rock shaken by it.

For the cause of these movements we must look to fluctuations of temperature in the heated interior of the earth, —great accessions of heat rising nearer the surface in one part than another, causing expansion of the rocks affected by it in every direction, and thus producing an outward bulging or elevation of these rocks, accompanied by injection of molten matter among them; depression, on the other hand, being due to local refrigeration, and consequent shrinkage and contraction. As to the cause of the fluctuations of temperature, we are perhaps not in a condition to give even a guess.

To such movements as these, operating thus slowly and gradually, we must ascribe the elevation of the whole of the present lands of our globe above the waters of the sea. We say the whole of our present lands, because by far the greater portion of the dry land is covered by or made of rock that has been deposited on the bottom of the sea; and of the remainder, where igneous rocks now prevail at the surface, we have every reason to believe the greater part at least, if not the whole, was once covered by aqueous rock. With the exception, then, of those spots which are composed of matter actually ejected from the mouth of a recent volcano, we either know or must believe that the whole of our present lands have been once beneath the sea, and have been gradually elevated above it.

To such gradually acting forces as those we have mentioned we must ascribe not merely the elevation of all land, but all those effects of unequal elevation, of tension, of disturbance, and of great pressure resulting in fracture and contortion, which I am about to describe. If we know that such is the character of the forces now in action, and if such forces be capable of producing the effects, provided only a sufficient amount of time be allowed them, we have no right to assume that these forces have ever had a different character or a different intensity, unless good reason

¹ Mr Mallet, in his Report on Earthquakes in the Proceedings of the British Association, points out that these movements are not caused by the earthquake, which is a mere undulation, but accompany it; and that it would probably be more correct to say, that the earthquake was caused by the movement.

² More recent movements still were mentioned by Sir C. Lyell, in a lecture to the Royal Institution in 1856, as having occurred in New Zealand simultaneously with the earthquake of January 1855. A step of rock, bared of earth, nine feet high, was traceable for ninety miles at the edge of a plain along the foot of a range of hills. An elevation of five feet took place on the north side of Cook's Straits, so as almost to exclude the tide from the river Hutt, and a corresponding depression on the other side of the straits allowed the tide to flow up the river Wairua several miles higher than before.

That these permanent changes of level have not been more often observed is probably in great part owing to the want of a natural standard of level. A change of level diffused over a considerable area could only be detected on the sea-coast, or by accurate measurement referring to some standard of level which had not itself been disturbed. Our only natural standard of level is that of the upper surface of the sea.

Geology. can be given why the amount of time could not have been large enough. If, however, it is proved from other sources that the time occupied by geological action is practically illimitable, we are not warranted in diminishing the amount of time and increasing the intensity of force simply to suit our preconceived ideas. This caution is necessary because errors in estimating the nature of the forces in operation not only lead to false theoretical reasoning, but occasionally even to practical mistakes based upon that reasoning.

II.—INCLINATION OF BEDS.

The inclination of beds downwards into the earth is

Geology. technically called their "dip." It is measured by the angle between the plane of the beds and the plane of the horizon. In fig. 20 the beds dip to the south at an angle increasing from 35° to 50° . When we speak of the opposite of "dip," we use the term "rise." For instance, in fig. 20 the beds *dip* to the south and *rise* to the north. The place where each bed rises out to the surface of the ground is called its "outcrop" or "basset." We say that such and such beds "crop out" to the surface, and we speak of the "basset" edges of the beds. Miners use these and other terms, such as "coming out to the day," "rising up to the grass," when speaking of the "outcrop" of any bed or beds. The line at right angles to the dip, that is, the line of outcrop of a bed along a level surface, is called its "strike," a term in-

Fig. 20.

roduced from the German by Professor Sedgwick. It is magnetic.¹ It may be called the "range" of a bed or beds described by its line of compass bearing, either true or across a country. Coal miners commonly speak of this as

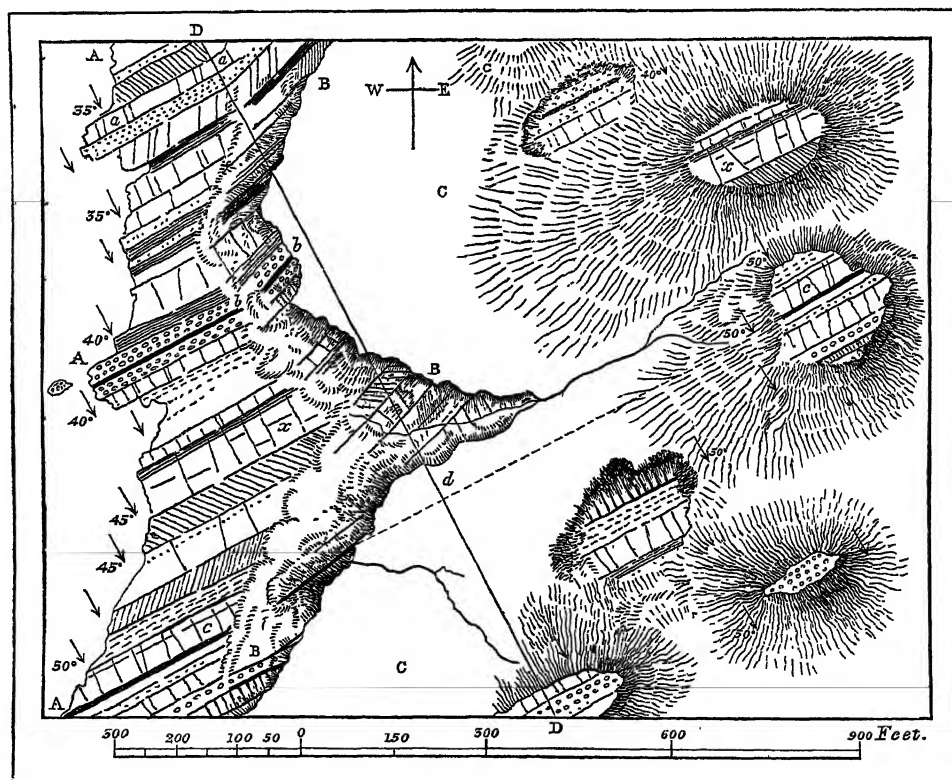

Fig. 21.

the "level bearing" of a bed, seeing that if you draw a line or drive a gallery along a bed exactly at right angles to its line of dip or inclination, it must of necessity be on a true level, or have no inclination either way.

If, then, a bed "dips" due north or due south, its

"strike" will be due east and west. If we know the direction of the "dip" of a bed accordingly, we also know

¹ Geologists generally use true compass bearings, a practice that ought to be adopted universally in all land operations.

Geology. the exact bearing of its "strike;" but if we only know the strike, we do not necessarily learn either the direction or amount of its "dip," because it may incline to either side of the line of strike, and to any amount from the horizontal plane. In making observations, then, in field geology, it is most important to observe accurately the direction of the dip of all stratified rocks. It is also important to know its amount; but this need not be observed with such minute accuracy, since it is apt to vary continually to the amount of 3° or 4° . In figs. 20 and 21 we have a rough map and section of a piece of country, which will explain these terms. In fig. 21, let A A be a rocky beach exposed at low water; B B a line of cliff about 100 feet in height; and C C the surface of a country above the cliff, with the rock bared of grass and soil, and exposed in several places, either on the summits of eminences or the bottoms of quarries. The arrows point out the direction of the dip, the figures showing its amount. This amount increases from 35° on the north to 50° on the south; and we may assume this increase to be quite gradual, or that the beds are parts of curves and not of perfectly straight planes. Then let D D be a line of section, or supposed cutting, at right angles to the strike of the beds, and let this section (fig. 20) be drawn so as to give the true outline of the ground across which it passes, and representing the beds in the true position they would be seen to occupy were such a cutting or cliff really formed. Being drawn at right angles to the strike, it runs of course along the line of the direction of the dip, and its bearing, as here drawn, is about 28° west of north, and 28° east of south. The latter, then, is the *direction* of the dip. The bearing of the strike marked by the ranges of the beds across the map will consequently be 28° north of east if we look in one direction, 28° south of west if we look in the other. In such a locality as this, if we marked out the boundaries of the beds correctly on our map, we should feel sure of the correctness not only of the map, but of the section, and we should know the position of the beds not only above the level of the sea, but for a considerable distance below it. If, for instance, at the point *d* in the map it was of importance to sink a shaft, so as to come down upon the bed *b*, we should see at once that the depth of *b* under *d* would be, according to the scale, rather more than 425 feet. If we wished to reach the bed *a* in the same way, it would be easy, either by construction or calculation, to ascertain the depth at which it would be found in a perpendicular shaft under *d*.

It would be easy for us also to ascertain the total actual thickness of the whole set of beds shown on the map, either by actual measurement of each bed along the shore, or by constructing a section founded on the observation of their angle of dip and the width of their outcrop. The actual thickness of the beds cut by the sea-level line in the section Fig. 20, for instance, would be a little over 850 feet. That is to say, those beds, if they were horizontal, would be 850 feet from top to bottom; if they were vertical, it would be 850 feet directly across them; while, in their present inclined position, a straight line across their outcrop measures 1200 feet.

If we proceeded to trace those beds into the country *along their strike*, however much the direction of the strike or the *angle* of the *dip* might vary, or however they might be concealed by grass, soil, or superficial covering, we should always have to recollect that there was a thickness of 850 feet of beds to be found or allowed for somewhere; and if in the course of a few miles we came to a quarry or a cutting where the bed *x*, for instance, was shown, and we were able certainly to identify it, we should expect there to find all the other beds above and below it that we had found above and below it where they were clearly exhibited. We should feel sure we were right in this, if in the expected spots, at the requisite distance on either side of it,

we found one or more of the beds *a*, *b*, or *c*, shown in other quarries, or cuttings, or cliffs in the neighbourhood.¹ It is in this way, by getting a knowledge of the true sections of a series or group of beds where they are well exhibited, and following them across a country, picking out one of them here, and another of them there, in ditches, brooks, river banks, cliffs, or ravines, wells, mines, road or railway cuttings, and quarries, that geological maps are constructed, showing the boundaries of the several groups of rock, their range or strike across a country, and the area of surface they occupy with their outcrops or "basset edges."

Geology.

III.—CONTORTIONS.

Where the dip and strike of the rocks are very steady, or where they run in nearly straight lines across a country, and their edges are not too much concealed by superficial covering, this is a task of no great difficulty. In many instances, however, neither the dip nor the strike of a set of beds remain constant over any considerable spaces. The beds are bent and contorted, and twisted about, so that, instead of running in straight lines, the basset edges, or outcrops of any set of beds, follow crooked and curved lines, often doubling back and running altogether out of their former course. Moreover, after dipping down in a certain direction for some distance, such beds are frequently curved up again, and rise to the surface at some other locality, forming basin or trough-shaped hollows; or, again, after cropping out to the surface, the beds underneath them are bent over in a ridge-like form, so that the first beds come in and take the ground again, dipping in an opposite direction.

These bendings and twistings of the beds occur on every possible scale, from mere little local crumplings on the side of a bank, to curves of which the radii are miles, and the nuclei are mountain chains. When on the small scale, they are commonly called "contortions," as in fig. 22.

Fig. 22.

There are in some instances wonderfully regular curves visible in beds even of the hardest stone, such as beds of limestone, arches both upwards and downwards, succeeding each other with all the regularity of masonry, as in fig. 23.

Fig. 23.

Contortions in limestone and shale (borders of Staffordshire and Derbyshire).

In other cases, especially where there are alternations of

¹ In diagram fig. 21, the supposed quarries or exposures of rock in the interior of the country are thickly grouped together; but if the reader will imagine them separated by much wider intervals, and scattered over a far larger space, he will have a truer notion of what usually occurs in nature.

Geology. softer and more yielding beds with hard ones, the softer are seen to be puckered and crumpled, as if they had been subjected to lateral pressure and squeezed back, while the harder ones are less broken. This is shown at one part of fig. 22.

Very curious and almost inexplicable contortions may be seen occasionally, but we must recollect, that the conditions under which they were produced, were such as it is not often possible for us to imitate, nor easy even to imagine. When the rocks were thus contorted, they were buried under vast thicknesses, often many thousands of feet, of other rock; the rocks above and below them were also of unequal densities, and offering unequal resistances to force; the forces of disturbance, therefore, even if uniform in their origin, would become complicated in direction, and unequal in intensity, by reason of these inequalities in the structure and position of the rocks, and inequalities in the pressure of the superincumbent masses. We might expect *a priori*, therefore, to meet sometimes with results not capable of any ready or simple explanation.

IV.—ANTICLINAL AND SYNCLINAL CURVES.

When the curves of the rocks are of greater extent, we cease to speak of them as mere "contortions." If the curves have longly-extended axes, that is to say, if the beds are bent up into ridges, or down into troughs, which continue for considerable lengths, in proportion to their widths, we speak of them as "anticlinal" and "synclinal" curves. If, on the contrary, no diameter of the curved area be much longer than another, we call them either dome-shaped elevations, or basin-shaped depressions, as the case may be.

In fig. 24, A is an anticlinal, and B is a synclinal curve, the beds numbered 6, 7, 8, being repeated on each side of both. At A, the lower beds 1, 2, 3, 4, 5 are seen rising out from underneath them in the form of an arch. At B, the upper beds 9 to 13 repose upon them in the form of a trough. It matters not whether we suppose the spaces 1, 2, 3, &c., to represent single beds, and the hill at A a slight elevation, or whether they be taken as groups of beds, and A be supposed to be a mountain chain. The straight line which may be supposed to run directly from the eye of the spectator along the top of the ridge A, or the bottom of the trough B, is called the "axis" of the curve in each case. This axis may be either horizontal or inclined; if horizontal, the section across it will cut the same beds

Fig. 24.

wherever it be taken, the variations in its outline only resulting from those in the outline of the ground. If, however, the axis be inclined, different sections will cut different beds, even should the outline of the ground remain the same. This will be best shown if we look at fig. 24, which is a supposed plan of the ground of which fig. 25 is a section, and suppose the axis AA¹ and BB¹ to incline downwards to the north, or from the line of section to the other end of the map, as shown by the arrows, it is obvious that the bed 4, which forms the apex of the ridge in the section, will slope downwards along the inclined axis, and if the ridge of the hill be kept up to the same height, the beds 5, 6, 7, 8, will necessarily arch over it. In the same way, if the synclinal axis BB¹ slope in the same direction, there

must either be a corresponding slope and hollow in the surface of the ground, or fresh beds, 14, 15, 16, &c., must come in, resting in the hollow of 13.

Fig. 25.

Plan of anticlinal and synclinal curves.

In countries traversed by many lines of disturbance, such forms as these are by no means unfrequent. They necessitate great labour in tracing them out, and making an accurate map of them, especially where the ground is itself lofty, broken, and uneven, and the complexity underneath obscured by perplexing irregularities on the surface.

Sometimes the axes of the curves slope both ways from a central point, producing long oval forms like that of an inverted boat, and there is a regular gradation from these to the circular elevations or depressions mentioned before, in which the beds are said to have a *quaquaversal dip* from or to a central point, according to whether it be a dome or a basin that is produced.

These flexures are in some instances carried out so far, both on the large and small scale, as to produce actual inversion (see fig. 26) of the beds, so that the lower surfaces appear to be the upper ones.

Fig. 26.

Section of beds partially inverted.

This inversion may be seen in some cases in cliffs among highly contorted beds; in other cases it requires a more widely extended observation in order to show that the apparent order of superposition of any set of beds, in any particular locality, is the inverse of that order which is to be observed generally, and where the beds are undisturbed.

Inversion of beds is occasionally to be detected by means of the "ripple," or "current mark," or other structure produced on the surface of beds, when the peculiarities in the forms of these marks are of such a kind as that a "cast" of them shall be plainly distinguishable from the original form. In these cases the "cast" may sometimes be seen on the now upper surface of a bed, dipping under what appears to be the bottom of the superincumbent bed, but which was originally the really upper surface or "mould" on which the materials were deposited that formed the "cast" at the bottom of the succeeding bed.

The inversion of beds is likewise occasionally detected in coal mining, as in Belgium and the south-west of Ireland, where beds of coal are sometimes found with the "coal-

Geology. seat" uppermost, and the "coal-roof" undermost. In a disturbed part of the South Staffordshire coal-field also, the same bed of coal was passed through three times in the same vertical shaft, first in its right position, then inverted, and then again right side uppermost. It must accordingly have been bent into the shape of the letter S or Z.

We shall see presently that no mere "fault" can thus bring part of the same bed twice into a vertical shaft.

V.—FAULTS OR DISLOCATIONS.

It may easily be conceived, that the force which was sufficient to raise vast masses of solid rock, of unknown but immense thickness, from the bottom of the sea high into the air, in order to form the dry land, and to bend them into the folds and contortions we have just described, was also sufficient to crack and break them through. We find, accordingly, very frequent instances of cracks and fissures running through great thicknesses of rock. Sometimes these are mere fissures; but quite as frequently there is not only a severance but a displacement of the rocks that have been severed. Beds that were once continuous are now not only broken through, but are left at very different levels on opposite sides of the fissure, many feet, or many hundreds of feet above or below the parts with which they were once continuous. When this is the case, these fractures are called "faults" or "dislocations" by geologists, for which miners in different districts use in addition the terms "slip," "slide," "heave," "dyke," "thing," "throw," "trouble," "check," and other expressions.

The amount of dislocation, measured in a *vertical direction*, produced by a fault, is called its "throw," a fault being said to be an "upthrow" or a "downthrow" or an "upcast" or "downcast," according to the side from which we view it. Its amount is stated in fathoms, yards, or feet, measured perpendicularly from the surface, provided the surface be horizontal, from a given horizontal plane if it be not. If, for instance, a bed of coal, where it is cut by a fault, as at A (fig. 27), be 100 yards from the surface, and

Fig. 27.

the other part of the bed immediately on the other side of the fault, as at B, be 200 yards from the surface, or from the assumed horizontal datum, the throw of the fault is said to be 100 yards, without regard to the distance measured laterally from A to B along the surface,¹ or from *a* to *b* along the fault.

Faults vary in character and in effect,—

1st, According to the nature of the rocks which they

¹ In taking accounts from miners as to the characters of faults, it is necessary to be on one's guard, and be quite sure that the sense in which they use these terms is properly understood. In some districts they would speak of the distance AB, measured along the surface of the ground, or the horizontal distance between the ends of the beds, as the "width" of the fault, looking only to the extent of "barren ground" as to that particular bed, and paying no attention to the real width of the actual fissure itself, which might be not more than a few inches, or perhaps even not more than one.

Geology. traverse, whether they be hard or soft, or an alternation of both.

2dly, According to the position of the beds which they traverse, whether these be horizontal, inclined, or contorted.

3dly, According to the number of lines of fracture, their direction, inclination, and combination.

1. When faults traverse a mass of rather soft and yielding rocks, such as shales and thin sandstones, the fissures themselves are often mere planes of division, just as if the rock had been cut through with a knife. Very frequently, in this case, the two contiguous surfaces of the fault are found to be quite smooth and polished by the enormous friction that has taken place, producing the appearance well known to geologists under the name of "slickenside." In some cases, although the fracture seems quite clean and sharp, yet the beds on each side are found to be traversed by a great number of small, irregular, and discontinuous "slickenside" surfaces, as if a jarring and tremulous grinding motion had been produced in the mass of the beds. Sometimes the beds end abruptly without any distortion (fig. 28); but sometimes they seem to have bent and pulled down along the plane of the fault to a certain extent, as in fig. 29.

Fig. 28.

Section of beds with fault.

In fig. 29 the beds would be said to "rise towards the upthrow," and "dip towards the downthrow," and this is naturally the most usual occurrence, though we believe not invariable, as there are said to be instances where the very opposite of this takes place, and the beds seem to "rise" to a downthrow fault.

When faults traverse very hard and unyielding rocks, such as thick hard gritstones, hard limestones, or hard siliceous

Fig. 29.

Section of hard beds with faults.

slates, and still more, if they penetrate igneous rocks such as granites and felstones, the fissures are apt to be much wider, and often very irregular. If the original fracture shall have taken place not in one plane, but so as to produce two jagged, and broken, or uneven and irregular surfaces, with cavities and protuberances as in fig. 30, and these two surfaces slide one over the other, it is very unlikely that they would ever, unless restored to their original posi-

Geology. tion, be made to *fit exactly*, so as to close again upon each other throughout their extent. Protuberance might rest

Fig. 30.
Section of hard beds with irregular fault.

against protuberance, or come against a hollow not large enough, or not of the requisite form, to receive it, and thus the two walls of the fissure would be kept partially and irregularly apart, the fissure being closed in some places and open in others. In fig. 30, an uneven fracture having traversed the hard beds A, B, C, D, and dislocation taken place, the result would be the irregular fissure EF.

It is true that the grinding process, as the surfaces moved upon each, would often greatly diminish this irregularity, and in soft rocks probably obliterate it; but in hard rocks it is much more usual to find the irregular openings above described still remaining.

Where alternations of hard and soft beds occur, there may be a combination of the two effects, the fissure being quite closed where soft beds are brought together, or even where soft beds are brought against hard, but more or less open where two hard beds come in contact.

When we speak of open fissures, however, we by no means intend to assert the frequency of fissures now open and empty. They are almost invariably filled with materials either derived from the ruins of the adjacent rocks at the time of the fracture occurring, or accumulated there afterwards.

Some fissures, even in the most soft and yielding rocks, have similarly been kept open, or rather the sides of the fault kept apart by fragments and debris that were dragged into them at the time of their occurrence. Such fragments, often of large size, are found along the lines of faults both vertically and laterally, for it is not unfrequent, in tracing the line of a fault along the surface of the ground, to find lumps and patches, some yards in diameter, of the broken beds caught and resting in the gaps of the fracture.

2. As it is comparatively rare to find beds in a strictly horizontal position over any considerable area, it is neces-

Fig. 31.

Fault traversing inclined beds, and producing apparent lateral shift. (Plan.)

sary to study the effect of faults on inclined beds, and on beds with an inclination varying either in angle, in direc-

tion, or in both. If any bed or set of beds "striking" in a given direction, and "dipping" at a given angle, be broken through by a fault, the effect of the vertical "throw" is to produce at the surface the appearance of a lateral "shift."

Let us suppose fig. 31 to be a horizontal plan of the outcrop of a set of beds, of which we may suppose *aa* to be a limestone interstratified with sandstones and shales, and that they all dip steadily to the N. at an angle of 25° , and that these beds are traversed by the fault *bb*, causing a "down-throw" to the E., or an "upthrow" to the W., which is the same thing. It is evident, then, that the outcrop of the beds will be farther S. on the E. side of the fault than they are on the W.

To render this more evident, let fig. 32 be a diagrammatic section along the direction of the line of fault, show-

Fig. 32.

Diagrammatic section of Fig. 31.

ing the beds on both sides of it, and let us look only at the limestone *aa*, disregarding the other beds. If we suppose the part *b* dropped vertically down to *c*, and the part *d* in the former continuation of the bed down to *e*, it is clear that a vertical throw of the bed *aa* on one side of the fault will place it in the position *a'a'* on the other side of the fault, the respective outcrops of the two pieces of the same bed being, at the present surface of the ground, at the points *bc*. In other words, the apparently lateral shift of the outcrop of *aa* in the plan (fig. 31), has been produced by the vertical throw of the inclined beds on opposite sides of the fault. It follows, also, that the higher the angle at which the beds dip, the less will be the apparent shift at the surface produced by the same amount of throw. In fig. 33 the angle

Fig. 33.

of inclination is increased to 60° , the vertical throw, or the distance between *b* and *c*, remains the same as in fig. 32; but it is obvious that the apparent lateral shift or distance between *b* and *e* is greatly diminished. This diminution would continue with the increase of the angle of inclination, until the beds were actually vertical, when it is plain that no amount of vertical throw could produce any apparent lateral shifting, for the ends of the beds on the opposite sides of the fault would merely slide up or down along each other. In a set of vertical beds, then, it would be almost impossible to detect a fault, however great may have been the real fissure and dislocation. On the contrary, when the beds lie at a very low angle, a very small dislocation shifts the outcrop of the beds in a very remarkable manner.

It is obvious, from an inspection of figs. 32 and 33, that if we know the inclination of the beds, and the amount of

Geology. the vertical "throw" of the fault, we may easily calculate what will be the apparent shift of their outcrop at the surface; and if, therefore, we find the outcrop of one, it will be easy to discover the outcrop of the other.

On the other hand, if we know the distance between the outcrop of the beds on opposite sides of the fault and their angle of inclination, it will be easy to calculate the amount of the vertical "throw," or to discover the depth (or distance, *bc*) at which the one part of the bed will be found lower than the corresponding point on the other side of the fault.

In practice, allowances have to be made for irregularity in the surface of the ground, and for variations in the angle of inclination of the beds, and also for changes in the amount of "throw" in the fault, but in the above consideration of the simplest case lie the elements of much practical utility in mining and other operations.

That this apparent lateral shift at the surface is really due to vertical elevation or depression, may be shown further by examining its effect on beds thrown into anticlinal and synclinal curves.

Let fig. 34 be a plan in which *aaa* is a bed having a synclinal or basin-shaped depression at *SS*, and an anticlinal

Fig. 34.
Fault across synclinal and anticlinal curves. (Plan.)

form at *AA*, dipping, as shown by the arrows, at an angle of 60° in each direction, and let it be traversed by the fault *FF*. It is clear that no lateral shifting will account for the places of the broken ends of *aa* on opposite sides of the fault, since they are shifted in opposite directions; while their present positions are easily and obviously accounted for on the supposition of a vertical elevation on the side of the fault marked *uu*, or depression on that marked *dd*, and a subsequent planing down of the whole to one level surface. If we draw two sections parallel to the fault, and on opposite sides of it, one, as in fig. 35, along *uu*, the upcast

Fig. 35.

side, and the other, as in fig. 36, along *dd*, the downcast side, putting in the beds with a dip of 60°, as directed by the arrows in the plan, we should at once see that, in fig. 35, on the upcast side of the fault, the beds will meet below *S*, at a point much nearer the surface than they do in fig. 36 on the downcast side; in other words, that the bottom of the synclinal is at a higher level in the first than the last case. In the same way the point *A*, where the anticlinal lines would meet if produced, is higher above the surface

in fig. 35 than in fig. 36, or the whole of the bed *aa* is more nearly out of the ground in fig. 35 than in fig. 36.

Fig. 36.

It is plain that these appearances are the result of the vertical elevation of the beds on one side of the fault *FF* in fig. 34, or their vertical depression on the other side of it. The greater the throw on the downcast side the more widely will the outcrops of a synclinal curved bed be separated, and the more nearly will the outcrops of an anticlinal curved bed be brought together, while on the upcast side of the fault the reverse is the case, the outcrops of a synclinal curve will be brought together, and those of an anticlinal will be separated. When either the angle of the dip or direction of the strike of the beds vary along the course of a fault, its effect upon the position and form of their outcrop becomes equally various. This effect may be still farther complicated by a change in the amount of the "throw" of a fault in different parts of its course.

3. We have hitherto supposed the fault to run directly across the beds, or nearly so, but some faults may either, in whole or in part of their course, run obliquely to the strike of the beds, instead of directly across it, and instances may occur of dislocations even running along the strike, so as to entirely conceal some of the beds, as in fig. 37, which

Fig. 37.

Fault along strike. (Plan.)

is a plan, where the fault *FF*, running directly along the strike of the beds, conceals part of No. 2, the whole of 3 and 4, and part of No. 5, as may be seen by the section, fig. 38.

Fig. 38.
Section of Fig. 37.

If the magnitude or throw of the fault diminishes in one direction, we should have some of these beds coming out in that direction, as in fig. 39, producing a slight variation in the strike of the beds.

Geology.

Many other modifications may arise according to the variations in the direction of the faults, with respect to the strike of the beds, or in the amount of their "throw."

Fig. 39.

Fault along strike, with variation in throw. (Plan.)

4. The number and association of faults also requires consideration in order to properly understand their effects.

If we suppose a single line of fault only to exist, it involves the assumption that the beds have been bent or bulged either upwards or downwards on one side of the fault, or upwards on one side and downwards on the other.

If in fig. 40 we suppose the line *ab* to be a crack or fissure traversing a set of beds, or if we suppose it to be a crack in a plank of wood, or any other flexible substance, ending each way without meeting with any other crack or

Fig. 40.

fissure, it is obvious that although the parts will be severed along it, they will not be shifted vertically unless some force be applied to push or bend upwards or downwards, as in fig. 41, the part on one side of the fissure, while the other part is held fast, or pushed in the opposite direction.

Fig. 41.

Single line fault, produced by bending of beds on one side of fissure.

In fig. 41 some beds are supposed to be cracked by the fissure *ab*, and the part *c* to have been bent down, but we might just as easily have supposed the part *d* bent up, or both operations to have taken place simultaneously. Without some such bending, no dislocation could have occurred.

Such "single line faults" have been produced, as is proved in coal-mining. They generally have one, but sometimes more points of maximum "throw" near the centre, and gradually diminishing each way till they die out. Not unfrequently they split towards one or both extremities, as is shown in the plan, fig. 42, in which the main fault *ab* is seen to be split into three at one end and two at the other.

The figures represent the amount of the downthrow at each point in feet, yards, or fathoms, as the case may be.

Geology.

Fig. 42.

Plan of fault splitting at the ends.

It is possible that this bending of the beds along the line of fault may occur more than once, so that they may be thrown into undulations, and thus more than one maximum throw may be produced. This undulation, too, may also become so great that the downthrow may change sides, as is attempted to be shown in fig. 43. This actually occurs

Fig. 43.

Single-lined fault, with alterations of throw produced by undulations of beds along it.

in nature sometimes, the fault appearing to die away when the beds come together, and then to set on again with a dislocation in the opposite direction. The fig. 43, however, is to be taken as a mere diagram to help the explanation, and not as an actual representation of nature, where the undulations are rarely if ever so rapid. Single lines of fracture are probably in general much more extensive than the actual dislocated spaces, since such bendings and bulgings as are here shown to be necessary to cause dislocation, would be more likely to occur near the central portions of a fracture than near its extremities.

When there is more than one line of fracture, the fact of dislocation becomes more easy to understand, since there is no difficulty in conceiving that the angle, or corner of ground included between the intersection of two faults, has been dropped down below, or squeezed up above the corresponding beds on the outside of them. In the plan fig. 44, let *ab* and *cb* be two faults meeting in the point *b*, the included part *d* may be either depressed below, or raised above *abc*. Even in this case, however, the beds on one side or other of the faults must be bent up or down in the direction of *ed*, because, as the two faults end or die out at *a* and *c*, the whole of the beds must be on the same level there, and one part or other must change that level in proceeding in the direction *ed*.

Fig. 44.

Dislocation by two fissures.

There is a modification of this case shown in fig. 45, where we have one long continuous fault *AB*, with one or more lateral branches, *cd*, *ef*, *ih*, &c., proceeding out of it, or leading into it, as we may choose to consider them, and either on one or both sides of it. In this case, while the whole mass of ground is thrown down on one side of *AB*, with respect to the other, the particular portions between *cd*, *ef*, or the corners between any one of them and the main fault may have additional minor dislocations of their own.

Geology. A long powerful fault is often composed in the whole, or part of its course, of a number of parallel fissures very close

Fig. 45.
Great fault with lateral branches. (Plan.)

together, along a narrow band of country, breaking the rocks into a corresponding number of steps, as in fig. 46, which either "throw" all in the same direction, or having some

Fig. 46.
Step faults.

steps in opposite directions, produce a balance of "throw" in one direction, so that it is treated as one wide fault.

In order to have any mass of beds entirely cut off on all sides from those that surround them, and wholly depressed below, or raised above them on every side, it is obviously necessary that we should have at least three straight faults, or one or two curvilinear faults surrounding the fractured piece of ground. Such dice-like masses of ground let in bodily among a strange set of beds do occur in nature, though they are very rarely met with.¹

Faults and fissures are sometimes vertical, as at A, fig. 47, but more commonly inclined at various angles, even so low in some instances as 20°, as at B, fig. 47.

Fig. 47.
Varied inclination of faults.

In speaking of the inclination of a fault, it is better not to use the term "dip," as if it were a bed, but to adopt that of "hade" or "underlie." In inclined faults,—and it almost always happens that faults are inclined,—there is one nearly invariable rule, which is, *that the fault "hades" or "underlies" in the direction of the downthrow.*

As a corollary of this rule also, another equally important one may be stated, namely, that however inclined may be the fault, *no part of any bed will ever be brought vertically under another part of it*, and therefore superior beds can never be brought by any fault under those originally below them.

Small exceptions to these rules may sometimes occur in rare instances; when they do, the fault that produces them is called a *reversed fault*.

In fig. 47, for instance, the fault between B and C hades under the downcast piece of the bed aa; and it is ob-

viously impossible for a vertical fault, or one inclining in the proper direction, to bring any part of the bed aa vertically beneath another part, and consequently no part of the beds above aa can ever be brought underneath it.

We have never met with any exception to this rule, except on a very small scale, and where it might easily happen that the exception was more apparent than real, the apparent inclination of the fault being merely a local bend or indentation in a vertical or nearly vertical fault.

The reason of this rule is sufficiently easy to understand when we come to look at faults on the large scale. Suppose that in diagram fig. 48 we have a portion of the earth's

Fig. 48.

crust, of which AB is the surface, and CD a plane acted on by some wide-spread force of expansion tending to bulge upwards the part ABCD. If, then, a fracture take place along the line EF, it is obvious that the expanding force will, on the side of AC, have the widest base CF to act upon, while it will have a proportionately less mass to move in the part AECF, which grows gradually smaller towards the surface, than on the other side of the fault, where, with the smaller base FD, the mass FDBE continually grows larger towards the surface. The mass G will consequently be much more easily raised into the position AeCf, than the mass H into the position Df'Be, the elevation of which could hardly take place without leaving a great open gap along the line of fault between FE and f'e, and, moreover, without leaving the projecting piece e overhanging without any support.

This is yet more clearly perceptible if we suppose two such fissures, as in fig. 49, inclining towards each other,

Fig. 49.

since, if we suppose the included piece I to be elevated into the position indicated by the dotted lines, it becomes utterly unsupported unless we suppose huge dykes or ejections of igneous rock to issue out along each fault. But this would remove the case from the class of fractures we are at present considering.

In another case which we might imagine, that of two parallel faults inclining in the same direction, as in fig. 50;

Fig. 50.

the included piece I might be elevated without leaving an open fissure, but still the part I would overhang in an unsupported condition, and the enormous friction along two

¹ In the neighbourhood of Bunmahon, in county Waterford, detached masses of old red sandstones are let in among the Silurian rocks, so as to be entirely inclosed by them on every side.

Geology. sides of the piece I, would have to be overcome. We are not aware, indeed, of any case similar to this having been even supposed by any one.

Professor H. D. Rogers, in his paper on the "Laws of Structure of the more disturbed Zones of the Earth's Crust," (*Trans. Royal Soc. Edin.*, vol. xxi., p. 3), in describing faults along the axes of anticlinal curves, where inversion has taken place on one side of the anticlinal, speaks of the uninverted part of the anticlinal having been thrust up the inclined plane of the fault, over some of the inverted beds, as in fig. 51.

Fig. 51.
Inversion, with reversed fault.

Professor Rogers does not allude to the fact of this form producing a *reversed* fault, nor is it quite clear in his paper whether the structure thus described has been absolutely observed in sections, or is merely introduced hypothetically as an explanation of certain puzzling phenomena. If actually observed, a detailed description of the locality would be very interesting, neither are we prepared to combat the hypothesis, if it be one, since it is just in such greatly disturbed districts that "reversed" faults are likely to occur.

Another published example of a reversed fault on a large scale is given in the Rev. Professor Haughton's paper on the "Mining District of Kenmare" (*Journal Geological Society, Dublin*, vol. vi., p. 2). In this case also, no notice is taken of the fault, as drawn, being a reversed one; and though it is in a highly disturbed district, and running parallel to the axis of a synclinal curve, yet as its plane does not coincide with that axis, but cuts across it obliquely, and buries some of the upper rock under the lower in a very peculiar manner, it appears to us a far less probable form of fault than that described by Professor Rogers.

Faults ordinarily extend indefinitely downwards. We cannot comprehend the possibility of fracture and displacement having taken place in any uncontorted set of beds without all those below having been equally disturbed, unless we come to a part where another fracture occurs, producing an equal amount of displacement in an opposite direction. This junction between two opposite faults produces what is often called a "trough," the faults being called a "pair of trough faults." The opposite faults of a trough may be either unequal in "throw," as *ac* and *bc*, in the trough A, or equal, as *de*, *fe*, in trough B. In the former case, the displacement affects the whole mass of the sur-

Fig. 52.
Trough faults.

rounding rock, as may be seen by tracing the bed X through the dislocations; in the latter case, it only affects the mass B, which is included between the faults. In the

latter case we may see that the bed X on the outside of the trough B is on the same level on both sides. **Geology.**

The mode of explanation of these trough faults that seems to us the most probable, if not the only one, is the following:

Fig. 53.

Suppose the beds AA, BB, &c., to have been formerly in a state of tension, arising from the bulging tendency of an internal force, and one fissure, FE, to have been formed below, which on its course to the surface splits into two, ED and EC, as in fig. 53. If the elevatory force were then continued, the wedge-like piece of rock W between these two fissures, being unsupported, as the rocks on each side separated, would settle down into the gap, as in fig. 54. If the elevatory action were greater near the fissure than farther from it, the single fissure below would have a tendency to gape upwards, and swallow down the wedge, so that eventually this might settle down, and become fixed at a point much below its previous relative position. Considerable friction and destruction of the rocks, so as to cut off the corner *gh* (fig. 54) on either side, would probably take place along the sides of the fissures, and thus widen the gap, and allow the wedge-shaped piece W to settle down still farther.

Fig. 54.

When the forces of elevation were withdrawn, the rocks would doubtless have a tendency to settle down again, but these newly included wedge-shaped, and other masses, would no longer fit into the old spaces, so that great compression and great *lateral* pressure might then take place.

The reader must recollect that the figs. 53 and 54 are mere diagrams to assist his comprehension, and not actual representations, in which there would necessarily be introduced a much greater amount of irregularity and complexity. This may be seen by an inspection of fig. 55, which represents the commencement of a trough fault, on the small scale, in the middle of the thick coal of South Staffordshire. This was carefully drawn to scale by a competent observer, Mr Johnson of Dudley, and will show that fractures similar to those just spoken of actually occur in nature, and what are the circumstances attending them. (See *Records of the Geological Survey*, vol. i., part 2, p. 313.) In this fig. the coal CC has apparently once been more completely arched, and on the cessation of the elevatory action, has tended to settle down again. The insertion of the wedge-shaped piece of the upper beds A has prevented its gaining the original horizontal position; but the

Geology. pressure of the superincumbent mass has caused it to crack in various places, and the part of the coal next the wedge BB was completely crushed, and its grain or lamination and internal structure destroyed by the compression under which it suffered, being reduced to a state as if made of "a paste of coal-dust and very small coal."

Examples of "trough faults" are by no means uncommon in disturbed coal-measure districts, and are doubtless equally common elsewhere, where they cannot be detected. Their study is instructive, as giving us often more accurate

ideas than we should otherwise possess as to the nature of faults.

We have already seen, in tracing faults superficially along what may be called their lateral extension, that it is impossible to conceive displacement to occur except in consequence of a second fault meeting the first, or in consequence of a bulging of the beds along a part of the line of the fault.

Similar reasoning will apply to the vertical extension of a fault.

Fig. 55.

Mr W. Hopkins has shown us that fractures in the crust of the globe have taken place in obedience to certain mechanical or physical laws. If a tract of country of indefinite length and breadth, composed of a set of nearly homogeneous beds, supposed to be originally horizontal, and nearly equally tenacious all over, be acted on by an expansive force from below, such as an elastic gas or a molten fluid would exert, those beds will be strained so as to tend towards bulging upwards, until a number of parallel fissures are formed, commencing at points below the surface, and running up to it. They may be crossed either then or subsequently by another set of parallel fissures at right angles to the first set. These are the normal results which may, in actual fact, be complicated by many irregularities arising from conditions different from those which were assumed.

It seems to follow from these results, that for displacement to have taken place among the fractured masses, two or more faults should meet below, so as entirely to sever the masses from each other, and allow of unequal motions being communicated to them, or that faults should gradually end downwards on the surfaces of highly-curved, undulated, and contorted beds.

The intrusion of igneous rock will in some instances increase the dislocations; but the student must be on his guard against attributing to local intrusion of igneous rock effects of elevation, or contortion, or fracture, which are due probably to very widely-extended accessions of heat expanding large masses of rock of all kinds simultaneously over great countries, and the subsequent contractions when that heat is diminished or taken away. Small local intrusions of igneous rock act principally as stays and wedges to prevent the dislocated beds settling back into their former places, but can rarely be looked on as the actual causes of disturbance. When we come, indeed, to consider large intrusions of great granitic masses into the rocks above them, we see a fertile source of dislocation, first, by the expansion of the superior rocks from the mere protusion of the bulk of the molten mass, and afterwards from contraction in consequence of the cooling of that mass which contraction, as we have already seen (chap. ii., §. 3.) might amount to even one-fourth of its bulk.

Where any large mass of matter, too, has been ejected over the surface of the ground, the withdrawal of its bulk will have tended to leave a void space in the interior, which, if it were not filled up with other igneous matter, would be followed by subsequent sinkings and dislocations of the rocks over it.

VI.—MINERAL VEINS, THE RESULT OF CAVITIES FORMED BY DISLOCATIONS.

In studying faults, our object was principally to describe
VOL. XV.

their effect in dislocating the beds which they traverse; the form, the width, and the extent of the fissures themselves was only noted as affecting the beds; and the contents of the fissures, when any spaces or cavities existed between their walls, was scarcely spoken of at all.

It was shown, however, that when faults traversed hard rock, they must necessarily, unless the fissure be a perfect plane, be more or less open in places, some portions of their walls being kept apart by the protuberances of other parts. It was said also, that fragments of the fractured rocks were often found in the fissures, and these fragments must necessarily contribute to keep the sides of the dislocated portions apart from each other.

Now, in some districts, these more or less open faults and fissures have become the repositories of minerals that have been subsequently introduced into them.

These minerals are usually in a crystalline form, and consist commonly of quartz, calc, heavy, fluor, and other spars, together with the ores of one or more metals, such as lead, copper, tin, iron, zinc, antimony, mercury, silver, gold, and platina.

Fissures containing minerals in this form are called "mineral veins," or "lodes."

Spars and ores, however, are not confined to fissures such as we have been describing. They are found occasionally in all kinds of cracks and cavities, whatever may have been the cause of the hollows, and even in little nests, lining detached holes, often no larger than the fist, and entirely surrounded by solid rock. They are found also in long pipe-like hollows in limestone, which are due apparently to the corroding action of acidulous waters; in the interstices between beds and joints similarly or otherwise enlarged, as well as in cracks, resulting from desiccation in the middle of nodules. Those in pipe-like and irregular cavities are called "pipe veins," as distinguished from "lodes," which are also called "rake veins." Wherever, indeed, permanent hollows and interstices of any kind, size, shape, or origin, exist in hard rocks, and where they are kept open for great periods of time, there appears to be a possibility, and, in particular districts, a probability, of crystallized minerals, spars, and ores, being formed in them.

That they occur most frequently and in most abundance in such fissures as we have described under the head of faults and dislocations, is due, probably, to the great range and extent of those fissures, and to the fact of their necessarily having many hollows and cavities throughout that extent wherever they traverse hard and solid rocks.

There is also another reason why the quantities of crystallized minerals should be greater in such fissures than elsewhere, and that is, that any subsequent disturbances in the mass of the rocks will tend to produce subsequent motions along the lines of the old fissures, and thus form

Geology. additional cavities, which may be filled up by fresh accessions of spars and ores. (See *Geological Report on Cornwall, &c.*, by Sir H. T. De la Beche, p. 344, &c.)

We have already said that faults, and therefore mineral veins, are sometimes perpendicular, but more often inclined. This inclination, however, is generally a high one—more often above than below an angle of 45° . Now, any subsequent fractures and dislocations which may traverse the original faults or veins, will shift or displace their course at the surface of the ground, just as if they were similarly inclined beds. What has been said, therefore, at p. 172 as to the apparent lateral shifting of inclined beds being due to vertical elevation or depression, will also be true with regard to the intersection and shifting of veins. If, in figs. 31, 32, and 33, *aa* be a vein instead of a bed, the explanation of the positions at the surface of the various parts of it will equally hold good.

In studying the intersection of fissures or veins, however, it may happen that the apparent shifting at the surface may not be due to any dislocation of one vein by the other at all. They may both have been produced simultaneously, one or the other not having been continued exactly in the same straight line. It may happen, too, that instead of *bb'* having cut through and shifted *aa* (fig. 56), *bb'* may have been the first formed, and that when *aa* was subsequently produced, it ran along *bb'* for a certain space before it was continued into the "country" on the other side of it.

Fig. 55.

Great care, therefore, is necessary in examining the intersections of mineral veins before deciding on the relative age or on the exact nature of the dislocations that have caused or affected them. Having said so much here as to the connection of mineral veins with faults and dislocations, we shall defer their further consideration to a future place.

VII.—CLEAVAGE: ANOTHER RESULT OF THE PHYSICAL FORCES BROUGHT TO BEAR ON ROCKS SUBSEQUENT TO THEIR CONSOLIDATION.

We have now described three kinds of divisional planes traversing rock—those, namely, which we might call *congenital*, or planes of lamination and stratification; those which are necessarily *resultant* on consolidation or joint planes; and those which we may term *accidental*, such as fissures, faults, and veins. There is yet another kind to be described, which we may call *superinduced* planes of division; and these are planes of "cleavage" and "foliation."

By "cleavage," or "transverse" or "slaty cleavage," as it is sometimes called, we understand a tendency in rocks to split into very thin plates, having a certain given direction over wide areas independently of any original lamination or stratification of the rocks. It is a structure which is most especially remarkable in clay slate, but is sometimes apparent in sandstones and limestones. Where it exists it is always most perfect in the finest grained rocks, splitting them into an indefinite number of thin leaves or plates, perfectly smooth and parallel to each other. The coarser the rock, the fainter, the wider apart, and the more rough and irregular do the cleavage planes become.

This cleavage may either coincide with the original lamination of the rock, or cut across it at any angle. When it cuts across the bedding of the rock, the original lamination, or tendency to split along the planes of deposition, is generally obliterated, the laminae being sealed up, or, as it were,

welded together. This cementation of the original plates of lamination is not quite invariably the case. I have met

Geology.

Fig. 57.

Sketch of a block of variegated slate from Devil's Glen, county Wicklow. The crumpled horizontal bands are the beds, the fine perpendicular strise in front are the cleavage planes; the fine lines on the darkened side merely represent shadow, and must not be taken for planes of division in the rock, like those in the front, which do not pass through the white bands.

with at least one instance where the rock, an indurated shale, split as readily along the original lamination as along the cleavage planes, and was thus minced into long, needle-shaped spiculæ of slate. (*Report of Geological Survey of Newfoundland*, p. 75.)

Transverse cleavage in sandstone usually divides the rock into coarse slabs only, the upper and under surfaces of the sandstone often breaking into dog-toothed indentations. In traversing conglomerates, the cleavage planes leave the pebbles standing out in relief, and do not cut through them as joint planes do. (*Professor Sedgwick*.)

Cleaved limestone generally has the original bedding greatly obliterated and obscured; the slabs are thick and uneven, and their surfaces often coated by argillaceous films, sometimes giving to the cleavage the exact appearance of bedding. Among trap rocks, some very fine-grained feldspathic and hornblendic ashes are often so affected.

The direction of cleavage planes is generally constant over considerable areas, retaining the same compass bearing through whole mountain chains, or across large countries, without paying any regard to the contortions and convolutions of the rocks. One of the best examples of this steady direction in the strike of the cleavage planes is the south of Ireland, over the whole of which, from Dublin to the Mizen Head and the Dingle Promontory, the direction of the cleavage never varies 10° from E. 25° N., whatever rocks it traverses, and however different these rocks may be in lithological character and geological age.

This steady direction generally coincides with that of the main lines or axes of elevation and disturbance which traverse the district, and consequently with the "strike" of the beds.

The inclination of the cleavage planes varies from perpendicularity to within a few degrees of horizontality, but has no apparent reference to the dip or inclination of the beds.

In passing through beds of different texture, the cleavage planes often vary their angle a little, having a tendency to strike more perpendicularly across the coarser than the finer grained beds. When the inclination of the cleavage planes

Geology. and that of the original planes of lamination become nearly coincident in any locality, they sometimes appear to coincide entirely, as if the cleavage went a little out of its way, as it were, to coincide with the bedding.

The finest and largest roofing-slates seem to be those of a bluish gray or pale green colour. Where they become either very red or quite black, they are more brittle, and more readily decompose, owing probably to the presence of peroxide of iron in the one, and carbonaceous matter in the other. Bands of colour, such as faint red, green, white, or gray, may sometimes be observed on the sides of slates, often coinciding with slight changes of grain or texture. These, which are called the "stripe" of the slate by Professor Sedgwick, mark its original stratification. The bands in the block, about 18 inches in height, which is figured in fig. 57, show this stripe very well. The white bands are pale greenish, or grayish fine-grained grit—the intermediate parts being purple slate of various tints and degrees of colour. They are the original laminæ of deposition of the rock. Irregular blotches, however, of different colours, occasionally occur; and sometimes even pretty regular broad bands of colour are to be seen, which do not coincide with the bedding, but go sometimes directly across it, as proved by beds of sandstone interstratified with the slate. Care must be taken, therefore, in field observations, not to rely too implicitly on mere bands of colour in slate colours.

Professor Sedgwick was the first to systematically observe and describe the phenomena of slaty cleavage. His observations will be found in the *Transactions of the Geological Society*, vol. iii., on *The Structure of large Mineral Masses*, and also in his *Introduction to a Synopsis of the British Palæozoic Rocks*, 3d Fasciculus, p. 33. In the latter, he gives the following as the results at which he had arrived:—

"1st. That the strike of the cleavage planes, when they were well developed, and passed through well-defined mountain ridges, was nearly coincident with the strike of the beds.

"2d. That the dip of these planes (whether in quantity or direction) was not regulated by the dip of the beds, inasmuch as the cleavage planes would often remain unchanged, while they passed through beds that changed their prevailing dip, or were contorted.

"3d. That where the features of the country or the strike of the beds were ill-defined, the state of the cleavage became also ill-defined, so as sometimes to be inclined to the strike of the beds at a considerable angle.

"4th. Lastly, that in all cases where the cleavage planes were well developed among the finer slate rocks, they had produced a new arrangement of the minutest particles of the beds through which they pass.

One of the most striking effects of cleavage is the distortion it produces on fossils or other small bodies embedded in the rocks, lengthening and pulling them, as it were, in the direction of the cleavage, and contracting them in the opposite direction. Relying on these facts, which were first distinctly noticed by Professor John Phillips, Mr Sharpe attributed the production of cleavage to the action of great forces of compression squeezing the particles of rock in one direction and lengthening them in the opposite. (*Quarterly Journal Geological Society*, vol. iii., p. 87.) Mr Sharp believed that the fossils were lengthened in the direction of the dip of the cleavage, but Professor Haughton believes this to be impossible, and that the lengthening must always be in the direction of the strike of the cleavage. Mr Darwin also, from his observations in South America, formed similar ideas as to the origin of cleavage, and speaks of cleavage planes as being probably parts of great curves, of such large radius as that any portions of them that can be seen at one view appear to be straight. More recently, Mr Sorby, resting on the fact of beds of sandstone which occur in slate being contorted, and their dimen-

sions being contracted at the sides, and expanded at the tops and bottoms of the curves, the axes of which curves coincide in direction with the cleavage planes, while the beds of slate above the sandstone are little or at all bent, shows that the particles of the slates must have been compressed at right angles to the cleavage planes, and lengthened along them, so as to allow of their being squeezed into the same contracted space as the sandstones, without much bending of the surfaces of the beds. (See *New Philosophical Journal*, 1853, vol. lv., p. 137; or *Lyell's Manual*, 5th edition, p. 611.)

By microscopical examination, Mr Sorby found that the minute particles of clay-slate were either lengthened in the direction of the cleavage planes, or that those minute particles, which were of unequal dimensions, were so rearranged as that their longer dimensions coincided with the planes of the cleavage.

Professor Sedgwick at one time thought that he could perceive a tendency to a symmetrical arrangement of the inclination of the planes of cleavage with respect to the axes of lines of elevation, the dip of the cleavage being inwards on each side of the mountain ranges. He afterwards, however, saw reason to abandon this conclusion. Mr Darwin speaks of the fan-like arrangements of the cleavage planes which have been described by Von Buch, Stüder, and others; and Mr Sharpe says that this apparent fan-like arrangement is due to parts of two contiguous curves meeting where their adjacent sides become perpendicular. But we must refer the reader to his papers on this subject, in the third and fifth volumes of the *Journal of the Geological Society* before quoted, and in the *Philosophical Transactions* for 1852. A second cleavage plane cutting across the first at right angles, and also across the bedding, is described by Mr Sharpe in his second paper on cleavage in the *Geological Journal*, vol. v., p. 3, and was also long before observed and mentioned by Professors Sedgwick, Phillips, and others. Mr Sharpe attributes this likewise to compression.

The subject has recently been investigated by Professor Tyndal, who, in a paper in the *Philosophical Magazine*, vol. xii., distinctly refers the origin of cleavage to the same force of compression, acting at right angles to the cleavage planes, that Mr Sorby and Mr Sharpe had referred it. Professor Haughton, in a paper in the same volume, has deduced mathematically a value for the compression of the rocks, from examining the amount of distortion suffered by fossils in some particular instances in consequence of this compression.

There seems, indeed, now little doubt that mechanical compression is the true cause of cleavage; but the whole subject requires still more accurate and detailed observations than have yet been made on it. We have seen reason to suspect—in some districts of North Wales, for instance—that subsequent movements and dislocations have affected large

Fig. 58.
Surface-bending of cleavage planes.

cleaved districts in such a way as may have altered both the

Geology.

Geology.

dip and strike of the cleavage from their original position. Only direct observation, then, will now lead us astray, unless it be corrected by a more accurate knowledge than we yet possess of the amount and direction of these dislocations, and of their relative age compared with that of the cleavage. The dip of the cleavage, especially, is very easily mistaken, unless it be observed in very clear and deep excavations. Superficial causes have frequently affected, and sometimes completely reversed it, to very considerable depths, as may be seen in fig. 58.

When these superficial bendings of slate occur on deeply inclined ground, they may perhaps be referred to the action of gravitation on substances loosened by weathering, or the "weight of the hill," as it has been called. In other cases their origin is more obscure, and we have seen one instance in North Wales, where, on the horizontal surface of an isolated boss of rock, the slates were so sharply and abruptly bent back and laid nearly flat, and partly consolidated in that position, as to give the idea of its being due to some sudden and great force, such as the grounding of an iceberg.¹

Thoroughly to work out the subject of the "cleavage" of any district would require months of continuous and laborious observation in a country the geological structure of which had in other respects been thoroughly and accurately surveyed; and, with the exception, perhaps, of North Wales, no country has yet been surveyed with anything like an approach to such accuracy.

VIII.—FOLIATION.

The *foliation* of the *schists* appears to be equally a superinduced structure with the *cleavage* of *slates*. It is, however, quite clear that even if the cleavage of slates have a mechanical origin, the foliation of schist cannot be due to such a cause alone. Mechanical pressure may be readily supposed to communicate a certain mechanical texture, but cannot by itself cause a difference in chemical composition. Now, "foliation" is defined by Mr Darwin, to whom we owe the recent technical use of the term, first introduced by Professor Sedgwick, to mean "a separation into layers of different chemical composition;" while "cleavage" means only a "tendency to split" in a mass of the same composition.

Nevertheless, the folia of schist are in some districts arranged in certain given directions by compass over very wide areas. Mr Darwin says that the gneiss and mica schist of South America, for instance, have their layers or folia always arranged in a certain given direction, even for hundreds of miles. For 300 miles, at least, in the Chonos and Chiloe islands, it does not vary a point of the compass from N. 19° W. and S. 19° E. Over the eastern parts of Banda Oriental the foliation strikes N.N.E. and S.S.W., and over the western parts W. by N. and E. by S. In Venezuela, according to Humboldt, it is uniformly N.E. and S.W. (Darwin, *Volcanic Islands*, p. 163.)

According to Mr Sharpe (*Transactions Geological Society*), the foliation of the gneiss and mica schist strikes across Scotland in directions varying from N. 50° E. in the south of the Highlands to N. 25° E. in the north. The dip of the folia of schist resembles that of the dip of cleavage planes, in being much more uncertain in direction and quantity than that of the strike.

Some geologists have held that gneiss, mica schist, &c., were originally formed nearly as they are now, being the direct result of the erosion of granitic rocks, of which the quartz, feldspar, and mica were arranged in regular layers as we now find them, the only change having been a mere

consolidation or induration. The perfect parallelism of these layers, however, over such wide areas as those before mentioned, would of itself be against this supposition, and in favour of the rearrangement of the particles of the rocks, in obedience to some wide and general force.

As to the nature of this force, Mr Darwin and Mr Sharpe, as well as Professor Sedgwick, agree in looking on foliation as the extreme term of cleavage,—"that foliation and cleavage are parts of the same process; in cleavage, there being only an incipient separation of the constituent minerals; in foliation, a much more complete separation and crystallization." If, however, this be true, we do not see how this process can be the merely mechanical one to which we have just seen reason to assign the production of cleavage.

Mr Darwin even appears to look upon many of the great divisions of foliated rocks, which are ordinarily termed beds or strata, as merely farther results of the process, different mineral substances having been segregated from each other on the large scale.

In large greatly altered districts, however, the very amount of the alteration has so completely changed the character and texture of the rocks, that it is more difficult to detect that it is a change than in other districts, where the alteration having taken place on a smaller scale, and to a less extent, its nature may be more readily grasped.

In the S.E. of Ireland, one great mass of granite has been erupted through the clay-slates of the district, forming a continuous range of granite hills from Dublin Bay to the neighbourhood of New Ross, a distance of 70 miles. Between this range and the coast, other smaller intrusive bosses of granite make their appearance at the surface through the clay-slate rocks. The clay-slates are dark-gray, blue, or black, but sometimes pale-green, or greenish-gray, with occasionally red or purple bands. They are generally of a dull earthy texture, and without lustre. Small bands of gray siliceous grit frequently occur in them.

Wherever the granite comes to the surface, a belt of slates surrounding it is converted into mica schist, with, in some few places, beds of perfect gneiss. Crystals of garnet, schorl, andalusite, staurolite, &c., make their appearance in these altered slates in greater and greater abundance as they approach the granite. The width of the metamorphosed belt is generally proportioned to the size of the granite mass which it surrounds. Round the smaller granite bosses it is sometimes not more than 50 yards wide; round the main granite mass it sometimes reaches to two miles. It matters not through what part of the slate rocks the granite rises, or which beds strike toward the granite; they are all found to be affected in the same way as they approach it.

In going towards the main granite ridge, it is found sometimes at a distance of 2 miles from the outcrop of the granite (which is, however, much nearer probably in a vertical direction), and that the slates have acquired a "glaze," as it were, or micaceous lustre, with a soapy feel. This lustre is apparent throughout the mass when the slates are broken, and even when they are ground down into sand or powder. This micaceous resemblance increases as we approach the granite, till at last distinct plates and folia of mica are to be seen, and the whole assumes the ordinary character of mica schist, occasionally passing into a kind of gneiss.

Together with the micaceous lustre on the surface of the slates, the rocks often assume the puckered and corrugated structure of mica schist. We at one time thought that this corrugated structure might be a metamorphic one, like the foliation; but on examining localities where the small bands of siliceous grit were interstratified with the slates, we found these grit bands to be equally corrugated and puckered. The structure, then, must be ascribed simply to a mechanical force compressing the rock laterally.

Geology.

¹ Without intending to impeach the accuracy of any recorded observations, we yet cannot feel sure that many even of our own registered observations on cleavage in different localities may not be affected by errors of the kinds alluded to above.

Geology.

In the majority of instances, too, the folia of the mica schist, whether straight or puckered, were parallel to the grit bands, and therefore to the original lamination and stratification of the rock. In these instances, the micaceous folia were largest and best developed. In other cases, the foliation ran across the bedding, coinciding apparently with the cleavage, as remarked by Professor Ramsay in a similar case in North Wales. In these instances we generally found the micaceous folia short and discontinuous, being apparently interrupted by the changes of texture or composition in the original lamination of the rock. We could, however, easily conceive that where the rock was quite homogeneous, the folia of mica schist might be almost as extensive as the planes of clay-slate.

Some of the beds of gneiss in this district are obviously beds of sandstone, originally interstratified with the shales, the rocks having all the appearance of interstratified beds of shale and sandstone at a distance, and until they are broken open and found to be perfect mica schist and gneiss. Other gneiss beds are massive and thick-bedded, and containing large crystals of feldspar (apparently orthoclase) becoming quite porphyritic and completely mineralized, but still having a foliation parallel to what is apparently the original stratification of the mass, which in one conspicuous instance (near Graiguenamanagh), is nearly horizontal.

We do not think that the person most sceptical as to the fact of the metamorphic origin of mica schist and gneiss could examine the rocks bordering the southern end of the granite range in Carlow, Kilkenny, and Wexford, without becoming a complete convert to the theory. For ourselves, we can no longer feel the slightest hesitation in accepting the metamorphic origin of all those which have been described under that head in Lithology.

IX.—DENUDATION: A CONSEQUENCE OF THE ELEVATION OF ROCK.

In a previous section we have spoken of the erosive action of moving water upon aqueous rocks while in course of formation; and in treating of the formation of mechanically-formed aqueous rocks, we have tacitly assumed the fact of great disintegration and erosion of previously existing rock, in order to afford the materials of which these mechanically-formed rocks were composed. We have now also considered the general effects of disturbing forces in elevating aqueous rocks from the bottom of the sea into dry land, so far as regards the new positions into which these rocks have been thrown, and the divisional planes and dislocations which have been produced in them. It yet remains to study some other of the less immediate results of these elevating forces.

In examining the outcrop of a set of beds along the surface of the ground, either in "the field" or by aid of geological maps and sections, we must be often struck with the fact that the present terminations of the beds are not their former or original terminations. Beds rise successively to the surface, and end there abruptly, that were once obviously continued beyond or above the present surface of the ground. In fig. 20 the beds on the beach and those in the cliff are the same. It is clear that they have been cut down on the beach to their present level, and that before they were so cut down they rose upwards to the same height as those in the cliff. In the same way, those in the cliff itself, and which stretch from it into the land, formerly extended upwards to a greater height than they now do. Now in many instances we can tell how far they formerly extended upwards. In figs. 24 and 25, the anticlinal and synclinal curves into which the beds are thrown enable us to estimate the amount of this cutting down or denudation for the beds there drawn. In fig. 24 we see that beds 2, 3, 4, bend continuously over No. 1; and we should naturally conclude

that beds 5, 6, 7, 8, &c., once equally extended continuously over the anticlinal A. If we doubted the fact, we should be convinced of it when we traced them in the map (fig. 25), and found them gradually meeting and continuous over the anticlinal farther towards the north.

Similarly in the synclinal curve B, though we might suppose by the section that No. 13 was the highest bed, we should find that towards the north it was overlaid by beds 14, 15, &c.; and we should be compelled to conclude that the latter had once been continuous over the whole. The dotted lines in fig. 24 would, if completely carried out, and bed 13 were represented as arching continuously over A, give us the measure of the amount of solid rock removed by denudation from above the present surface of the ground EF, so far as the beds there drawn are concerned.

It makes no material difference in this reasoning whether we suppose the spaces 1, 2, 3, &c., to represent single small beds of a foot or two in thickness, or groups of such beds, and suppose the whole series, 1 to 15, to represent a vertical thickness of many hundreds or many thousands of feet.

Neither would it make any difference in our reasoning, so far as the amount of denudation is concerned, if we were to modify our conclusions by supposing, in all those cases in which great thicknesses are concerned, that the whole mass of beds were never continuous over the anticlinal curves *after* the total amount of elevation had been reached. We may suppose that soon after the elevation commenced, and simultaneously with the first arching of the beds, the denuding forces began to act, that they took advantage of the very first cracks that were formed to commence the erosive process, and that long before the bed No. 1 attained its present position on the axis of the curve, more or less of the higher beds 7, 8, or 12, 13, &c., had been removed, and a surface given to the rocks more or less approximating to the surface they at present possess.

Another very clear case in which we can estimate the amount of denudation is that of an "outlier," as it is called. It often happens that a number of beds, rising at a slight angle from beneath the surface, end in a steep slope or "escarpment," as at A in fig. 59. In front of this escarp-

Fig. 59.

Escarpment and outlying hill.

ment there often rises an isolated hill as B. In descending the escarpment, we pass over the edges of the beds 11, 10, 9, 8, &c., in regular succession, and find 4 coming out from beneath them, and stretching continuously across the intermediate flat or valley, and forming the base of the hill B; and on ascending the side of B, we find the very same beds 5, 6, 7, 8, resting on each other in the same order as we saw them in the escarpment A, and at the same angle of inclination, so that the conclusion becomes irresistible that they were once continuous across the intervening space C. This space, then, is due to the erosive action which has removed the upper beds, and denuded or laid bare the lower bed No. 4, across the valley C, and for an indefinite distance on the other side of the hill B. We should feel quite certain that not only the beds 1, 2, 3, 4, but also 5, 6, 7, &c., had stretched across this space formerly, and had also extended beyond the hill B for some indefinite distance in the direction of D. This latter conclusion we should in many cases find confirmed by the occurrence, at a distance perhaps of many miles beyond B, in the direction of D, a locality where the beds dipping in an opposite direction from that

Geology.

Geology. in fig. 59, these very same beds (1 to 8 of fig. 59) are brought in again in the very same order and with exactly the same character as before (fig. 60). In some cases, such a little isolated basin forms the only remaining patch of

Fig. 60.
Outlying basin.

the beds left in this new district, by having been dipped down below the level of the surface formed by the denuding agent, and remaining as a monument of their former extension over the wide intervening space between this new locality and that of the escarpment and outlier before mentioned.¹

Geological maps of large countries often enable us to prove by such reasoning as this the former extension of a great mass of beds over very wide areas, and consequently the very large amount of denudation that has taken place. In many instances we can show the geological date of this denudation; that is, we can prove it to have taken place before the time when such and such beds were deposited, the age of which is known, and which we find lying across the edges of the denuded beds. This leads us to the next subject of unconformability. We must, however, always guard ourselves against attributing to the last period of denudation that occurred, with respect to any set of beds, effects, a large part of which perhaps took place at previous periods. Almost all lands have risen from the bed of the sea, not once only, but many times, having passed through many periods of alternate elevation and depression, suffering denudation at each passage through the upper surface of the sea, and during each period of existence as dry land. It appears probable, from the observations of Mr Darwin and others, as also from the very nature of the case, that a period of slow and gradual elevation is the one most favourable to the action of the destruction of pre-existing rock, or to denudation, while a period of depression is that most favourable to the deposition and formation of new rocks on the surface of the old. Many districts, however, might be depressed without being covered by the deposition of new rock, or by so thin a skirt of it, that it might be easily stripped off during a subsequent elevation; and in every new period of elevation the erosive forces would most probably act again upon their old lines, deepening former hollows, and thus intensifying the previous features of the old lands on their re-emergence from the sea.

X.—UNCONFORMABILITY: THE RESULT USUALLY OF ELEVATION, DENUDATION, AND SUBSEQUENT DEPRESSION.

When one set of beds have been elevated and denuded, and another set of beds are deposited on this denuded sur-

Fig. 61.
Unconformable beds.

face, the two sets are said to be *unconformable* to each

other. In fig. 61 the arched and denuded set of beds A are covered by the unconformable set of beds C. Whenever two sets of beds lie at different angles of inclination, they are *apparently or obviously unconformable*. In fig. 61 this discordance of inclination is seen strikingly at either end of the figure, but if we confined our attention to the central part *d*, we should not perceive any unconformability.

Beds, then, may repose apparently at the same angles over considerable spaces, and yet be unconformable in reality. In fig. 62, again, two sets of beds, A and C, are

Fig. 62.
Unconformability in horizontal beds, in consequence of denudation of lower group.

shown, which are both horizontal, A ending in a broken cliff, with C abutting directly against it in that part, although it rests in apparent conformity on A at the point *d*.

The essential point in unconformability is, that the upper group of beds shall rest upon different parts of the lower group at different places, and this could not happen without previous elevation and consequent denudation having affected the lower group. It proves, then, the lapse of a considerable interval between the deposition of the two sets of beds.

Now, although this interval may have been occupied by the process of destruction going on in one locality, there is no reason why production may not have been taking place at the same time in another locality. Whenever, then, we find two sets of beds unconformable to each other, we must suppose that there is a set of beds wanting there which may elsewhere be found, and that where they are found there will be probably no unconformability. If fig. 63 re-

Fig. 63.
Three conformable sets of beds, A, B, C.

present the state of things at one locality, where the three sets of beds ABC were deposited in regular continuous succession, figs. 62 or 61 may represent the other localities, where the interval here occupied by the deposition of B was there employed by the forces of elevation and denudation in the destruction of a previously existing part of A. It is even quite possible that the materials which were used in the locality represented in fig. 63 in the composition of B, were partly derived from this destruction and breaking up of a portion of A in one of the other localities, and that we may accordingly find in B pebbles or angular fragments of A.

XI.—OVERLAP: THE RESULT OF DEPRESSION, WITH OR WITHOUT PREVIOUS DENUDATION.

There is a minor degree of unconformability to which the term overlap is applied. This consists in a greater ex-

¹ For some striking details on the subject of denudation, see Professor Ramsay's paper on the Denudation of South Wales, &c., in *Memoirs of the Geological Survey of Great Britain*, vol. i.

Geology. tension of the superior set of beds than that possessed by those on which they rest, so that they overlap and conceal their edges. In fig. 64 the beds 1, 2, 3 are successively overlapped by those above them. This may in some in-

Fig. 64.
Overlap.

stances have been the result of a more partial deposition in the lower beds, from the defect of material or other cause, but in other cases it has been the result of the gradual depression of the old land, and the consequent extension of the area of water in which alone deposition can take place.

While unconformability, therefore, proves an elevation and denudation, and an absence of continuous deposition, overlap may take place in a perfectly continuous series, merely proving the fact of a depression of the area contemporaneously with that deposition.

CHAP. VII.—PETROLOGY OF THE IGNEOUS ROCKS.

We will now consider the general forms and modes of occurrence of the principal kinds of igneous rock, and their relations to the aqueous rocks. We have previously spoken, under the head of Lithology, of the different kinds of igneous rock, and shown that these differences partly depended on the difference of their chemical composition, and partly on the texture resulting from the physical circumstances—as pressure and rate of cooling—under which their consolidation took place. The granitic rocks, or those which are most completely crystalline and most thoroughly saturated, as it were, with silica, cooled slowly and under great pressure, that is to say, at some considerable depth in the interior of the crust of the globe.

The volcanic rocks, on the other hand, were consolidated at the surface, while the intermediate and variable class which we have called trappean may have been solidified under various and intermediate conditions.

I.—FUNDAMENTAL GRANITE.

As a matter of fact, it has been found that in all parts of the globe, wherever the base of the aqueous rocks has been brought up to the surface and exposed to view, that base rests upon granitic rocks. By the “base of the aqueous rocks” is meant the lowest aqueous or sedimentary rocks known in the particular locality, *whatever may be their age*, whether they be some of the oldest known rocks, or whether they be of a much later date than those, and whether they retain their original characters unaltered, or have been metamorphosed into mica-schist, gneiss, or any similar rock.

It is by no means intended to assert that the converse of this is true, and that wherever granite is found at the surface, there the lowest of all known rocks, or even the lowest rocks of that particular locality, will be found reposing on it. On the contrary, we shall show presently that granite frequently comes *through* great masses of rock, without bringing them up along with it. But at every place where any rock does make its appearance at the surface *from underneath the lowest of the stratified rocks* known in that locality, that rock is a granitic one, and wherever any large mass of granite comes to the surface, we have no reason to believe that any other rock but granite would be found underneath it. We do not here speak of any veins, or intrusive dykes or sheets of granite, but of large, widely extended masses. In short, we have every

reason to believe that if we pierced vertically downwards into the earth at any part of its surface whatever, we should eventually come either to granite or to yet molten and unconsolidated rock, which on cooling would form granite. Again, in many parts of the world granite is found occupying large areas of the surface; and we have no reason to suppose that any other rock but granite would be found under those surfaces, although, if we sank deep enough, we might perhaps come eventually to red-hot granite, and ultimately to yet molten granite. These facts and these opinions have naturally led many early geologists to the conclusion that the earth was once a molten globe of fiery matter, and that on cooling there was formed about it a primæval crust of granite; and they hence inferred that much of the granite now to be found at or near the surface was actually part of this primeval crust. At one time, indeed, it was held that all granite had this primeval character; but this notion has long been exploded, since *intrusive*, and therefore subsequently consolidated masses of granite, have been found penetrating rocks of almost all ages in different parts of the earth.

Now the hypothesis of the earth having once been a molten globe of fiery matter is one for which more or less good argument may perhaps be brought forward; but it is one with which the geologist has properly little or nothing to do. The geologist may grant the probability or possibility of this molten globe having existed, of its having cooled down till a granitic¹ crust was formed about it, of the temperature having been gradually lowered till the existence of water and air become possible upon it, and yet maintain that no part of this primæval crust is now in existence, and that none of the rocks now open to our observation can date back their formation to this quasi-fabulous and mythical age of the earth, this pre-historic or pre-geological period of its duration.

Whatever may have been the nature of the primæval crust of the globe, that crust had been more or less completely destroyed and remodelled by the erosive action of water, and the remelting action of heat, before the commencement of even the earliest of our geological periods. The very lowest of the unaltered stratified rocks of which the age is known, namely, the Cambrian of North Wales and Ireland, are made up of indurated clays, sands, and gravels, which were derived from the waste of previously existing stratified rocks, exactly like themselves. (*Professor Ramsay*.) The crust of the earth, then, was, before that earliest of our periods, made up of stratified and unstratified aqueous and igneous rocks, as it is now made up of them. Just so much of these earlier rocks are preserved to us as have not been since destroyed by the action either of fire or of water. Over very large areas, very early rocks, having been attacked from above, have been eroded and destroyed by the action of water; and the old base on which they rested has been denuded, and is either now exposed at the surface, or has been re-covered by other rocks subsequently deposited upon it. Over very large areas, very early rocks having been attacked from below, have been so baked, so altered and metamorphosed by the action of heat, and by the many physical and chemical forces which heat has set in motion, as to have been altogether transformed from their original state, and many of both aqueous and igneous origin actually remelted down perhaps, and re-absorbed into the molten masses of the interior, in which they either still remain as molten rock, or from which they

¹ If we were inclined to speculate on such a state of things as the first cooling of the crust of a molten globe, in which the expansive power of heat must have been acting intensely even at the surface, we might perhaps reasonably doubt the possibility of so dense a rock as granite being formed upon that surface. Porous trachyte, pumice, and obsidian, would occur to us as more probable productions than granite.

Geology.

Geology. may have been subsequently reconsolidated as newer igneous rock. Some ancient rocks have been in other areas spared by both these processes; but as these processes are continually going on, and continually shifting their areas of action, it is clear that, in proportion to their antiquity, all rocks must have been more or less affected by them, and that we can reason back to a period in the earth's history, the coeval rocks of which have only one or two undestroyed or unaltered areas still left upon the globe; and going one or two steps still farther back, we arrive at a period of which *none* of the coeval rocks can remain in their original recognisable state.

Dismissing, then, all speculations as to the primæval crust of the globe, and the primitive character of granite, let us come to what we know to be true.

II.—INTERNAL HEAT OF GLOBE.

That the earth has a great internal heat, is rendered almost certain by the following facts:—

1. The specific gravity of the globe is, according to the old observations, about 5.0, or according to the recent experiments of the Astronomer-Royal, Mr Airey, about 6.7. Now, the specific gravity of granite varies from 2.6 to 2.9; that of basalt is about 3.0; that of rock in general is from 2.5 to 3.0. The earth, therefore, is more than twice as heavy as it would be if made of any known rock, such as that rock appears at the surface. The pressure of gravity, however, would render any such rock, as granite, for instance, much more than twice as dense as it is at the surface long before it reached the centre.¹ We should expect, then, that the globe would have a much greater specific gravity than 5 or 6, if it were not for some expansive force in its interior counteracting the pressure resulting from gravitation. We know of no such force except that of heat.

2. As a matter of direct observation, it is found that in all deep mines the temperature of the rock increases as we descend, at the rate of 1° of Fahrenheit for every 50 or 60 feet of descent after the first 100. This is the case in every part of the globe, and in all kinds of rock.

Deep springs also, and wells, such as the deep Artesian well of Grenelle, at Paris, are always found to have a high temperature. At Grenelle, the water brought from a depth of 1798 feet has a constant temperature of 81°·7 of Fahrenheit, while the mean temperature of the air in the cellar of the Paris Observatory is only 53°. Very accurate and careful observations have lately been made by M. Walferdin on the temperature of two borings at Creuzot, within a mile of each other, commencing at a height of 1030 feet above the sea, and going down to a depth, the one of 2678 feet, the other about 1900 feet. The results, after every possible precaution had been taken to ensure correctness, gave a rise of 1° Fahrenheit for every 55 feet, down to a depth of 1800 feet, beyond which the rise of temperature was more rapid, being 1° Fahrenheit for every 44 feet of descent. (*Cosmos*, May 15, 1857.)

Hot springs are usually found to proceed from great faults or fissures which penetrate deeply into the crust of the globe.

3. As another result of direct observation, we may state that all igneous rocks proceed from below upwards, coming out of the interior of the earth; and that, as just observed, whenever we are able to see the actual base of the aqueous rocks in any district, we find them reposing upon

cooled igneous rocks, generally granite, and that *cæteris paribus*, the lower the rocks, or the deeper they have formerly been buried, the more marks do they bear of having been subjected to a great heat.

We may look, then, upon the great internal heat of the globe generally as a fact pretty well established; and it appears that if the increase of heat towards the centre goes on at the same rate that it does near the surface, all water would be boiling at a depth of 9000 feet under the British Islands, and that at the comparatively small depth of 20 or 30 miles, the heat would be sufficient to fuse any of the substances we know at the surface.

There are said to be, however, certain general astronomical and physical considerations which make against the supposition of the earth's being a molten fluid mass, with only a slight external crust, and render it probable, that, however intense the temperature, the mass is still solid, either entirely or in part, to a very great depth into the interior.¹

In this case, it appears that the molten masses which have formed, on cooling, the igneous rocks we are acquainted with, either proceed from detached lakes of fiery liquid, or were rendered fluid by some special and locally acting circumstances.

Speculations, however, on the general state of the interior mass of the globe, although interesting, have, like those on its primæval condition, little theoretical and no practical importance; and as we shall be for ever probably condemned to remain in ignorance concerning it beyond a few general facts such as those before mentioned, they need not occupy more of our attention.

III.—POSITION AND FORM OF GRANITE.

Granite generally makes its appearance at the surface in large masses, occupying considerable areas, and extending for a great but unknown depth into the interior. Veins of granite, often branching and crossing each other, sometimes proceed from these masses, penetrating the adjoining rocks; and dykes, or wall-like sheets, of granite-rock are frequently found in their neighbourhood, running sometimes for several miles in straight lines through other rocks.

Smaller bosses of granite are likewise not unfrequent in such districts, apparently the tops and eminences of larger masses that are still concealed below.

Granite generally forms high mountainous ground, and hills composed of it have commonly a heavy rounded outline and sombre aspect. Sometimes, however, granite is found as the surface rock over considerable spaces of low gently

Fig. 65.
Supposed position of granite.

undulating ground, in which case the plain is commonly diversified by small rounded knobs and bosses of rock.

Granite is also found not unfrequently as the rock form-

¹ According to Leslie, water would be as heavy as mercury at a depth of 362 miles, air as heavy as water at 34 miles. At the centre of the globe, steel would be compressed into one-fourth of the dimensions it has at the surface, and most stone into one-eighth, if the law of compression be supposed to be uniform from the surface to the centre.

¹ Mr W. Hopkins gives 800 miles as the minimum thickness of the solid external crust of the globe. Professors Henessy and Haughton, however, and also, I believe, Professor Jellet, dissent from a part of the reasoning on which that conclusion is based, and think that no certain conclusion can as yet be arrived at respecting the thickness of the solid crust of the globe. (See *Papers in Phil. Trans.*, and in *Trans. of R. I. Academy*).

Geology. ing the axis of mountain chains, or the nucleus of mountain masses.

When it forms the true axis of a mountain mass, the rocks which rest upon it dip from it in every direction, and the lowest of the stratified rocks are found nearest to the granite, as in fig. 65, where G is a mass of granite forming the axis of a range, and 1, 2, 3, are the stratified rocks dipping from it in each direction, the lowest or oldest, No. 1, being next to the granite, and the highest or newest, No. 3, the furthest from it. This central and fundamental position is the one usually assigned to granite where it appears in a mountain chain. Without attempting to deny that it frequently does hold this position, we are yet rather inclined to doubt whether it has not in many cases been assigned to it as a matter of course, without adequate investigation. We are disposed to suspect that the rocks nearest the granite having been most altered, and the most altered rocks having been assumed to be the oldest or lowest, this position may often have been taken for granted instead of proved. We know, at all events, that in many cases granite, where it occurs as the constituent of a mountain range, and as the geographical axis of such a range, is not the true geological axis, inasmuch as it does not bring up with it the lowest rocks of the country, and has not the central and fundamental position, nor has it exercised the elevatory action assigned to it in fig. 65.

The granitic district in the S.E. of Ireland, extending from Dublin Bay to near New Ross in county Wexford, is one of the largest and most persistent masses of granite in the British islands, being 70 miles long, and from 7 to 17 miles wide. There were in this district at least two great geological formations, each consisting of slates or shales and sandstones, and each several thousand feet thick, at the time of the intrusion of this granite. These two formations are known as the Cambrian, which is the lowest or oldest, and the Lower Silurian, which rests unconformably upon the Cambrian. Now in no instance is any part of the lower or Cambrian formation found reposing on or coming against the granite at the surface, though it does come to the surface in some places within 2 or 3 miles of the granite, as shown in fig. 66.

The Silurian rocks, however, have been broken into, and lifted and altered by the granite, which has sent veins into them, as in fig. 67; and we are compelled to suppose, therefore, that the granite must have *come through* the Cambrian rock below, before it can have penetrated into the Silurian rocks which now rest upon it. Neither, although the main direction of the granite is parallel to the general strike of the rocks and principal lines of disturbance in the district, does the eruption of the granite seem to have had much effect on the general elevation of the country, but simply to have partaken of it, along with the other rocks, and to have had its direction governed by the direction of the forces of disturbance that were acting at the time of its intrusion. The Silurian slates, which are frequently vertical and greatly contorted over all the district, often appear to dip at or towards the granite, at a distance of about 2 or 3 miles from its present surface boundary, and to have been only so far affected by the proper elevatory action of the granite as to be crumpled up or dog-eared against it for a short distance close upon its flanks (see fig. 66).

VOL. XV.

Geology. If we passed from Ireland into Cornwall and Devon, similar conclusions could be drawn from the relations of the granitic masses there with rocks of a still newer date, namely, with those called Carboniferous and Devonian. The granite penetrates and alters rocks of both those periods, and is therefore newer than both. It has not, however, by its irruption brought up the lowest rock, namely, the Devonian, everywhere on its flanks. On the contrary, where it cuts into and alters the Carboniferous rocks, we are compelled to suppose that it has passed through and left behind the Devonian. Neither does the granite of Cornwall and Devon appear to have acted in any sense as a geological axis or centre of elevation, but simply to have partaken with the rocks of the district of whatever disturbances occurred during or since its intrusion; and the granitic veins appear to have been shot into the cracks and crevices of the rocks, which were opened for them by those disturbances, and not to have made any of those cracks and fissures for themselves.

In other parts of the world, as has been said before, granite is found in the same way bursting through, sending veins into, and altering rocks of still newer date, rocks of what are called the Secondary periods, and rocks of what are called the Tertiary periods; and granite must be forming now wherever molten rock of the proper chemical composition is cooling under the requisite physical conditions, that is, deeply seated under the pressure of great masses of other rock.

It is doubtless true that granite is found more frequently associated with the older rocks than with the newer; in other words, with the lower rather than the higher rocks. The reason of this, however, is clear from the very fact of the source of granite being in the interior of the earth. Granite, in order to reach the higher, must pass through whatever lower rocks there may be in the way. Many eruptions of granite may have proceeded a certain distance from the interior, penetrating only the lower rocks; but none can have reached the upper without penetrating the lower. That granite should be most frequently associated with the lowest rocks follows, too, from the very nature of granite. Molten rock that reached or came near to the surface would not, on consolidating, form granite, but some other kind of igneous rock—a felsite trap or a trachytic lava, as the case might be. There is also still another reason why granite is found principally in connection with low rocks that have formerly been deep-seated, and that is, that all granite now found at the surface must be there in consequence of vast denudation having taken place, by which great masses of other rocks have been removed, together perhaps with much of the granite that once existed above the present surface. This denudation of course exposes the lower rock to view, while the parts of the higher rocks that were perhaps equally penetrated by the granite have been swept off and removed (see fig. 67); the other parts

The dotted lines represent the former extension of stratified rocks, equally penetrated by g, the granite, but the penetrated parts removed by denudation.

which remain being now at a distance from the granite, and showing no signs of such penetration.

It is therefore where the lowest or oldest rocks come up to the surface that we should expect most frequently to meet with surface granite, as we find to be the case.

2 A

Geology. IV.—AGE OF CONSOLIDATION OF GRANITES, AND OF PRODUCTION OF SURFACES OF LAND.

There is a remarkable class of results which follow from this deep-seated origin of granite, and from the necessity of great denudation having taken place before it can appear at the surface.

In the first place, it proves the fact of this denudation having occurred. Wherever we find granite forming the surface of the ground, however lofty may be the summits of the granite mountains, or however widely spread the extent of the granite plains, we may feel sure that at the time of its consolidation it was covered with a thickness of at least several thousand feet of other rock, and that this thickness has been removed by the gradual action of erosion by moving water.

2dly, We may in many cases ascertain the date of this denudation, namely, that it took place and was completed before such and such a geological period; and thus we get a geological date for the production of the present outline of the surface of the ground.

3dly, We get a date for the formation or consolidation of the granite itself, since we know that this must have occurred previously to the denudation.

In the case, for instance, of the granites of the west of England and the S.E. of Ireland, mentioned before, we are able to prove that the granite of Wicklow, &c., is older than the granite of Cornwall. We saw, indeed, that the Wicklow granite penetrated older rocks than did that of Cornwall; but, so far, there was nothing to tell us when the Wicklow granite penetrated those rocks. It might have been that the granites were produced at the same time, that of Wicklow only reaching so far as the Silurian rocks, while that of Cornwall burst through into the rock above, namely, the Devonian and Carboniferous.

If, however, we follow the Wicklow granite into the adjacent counties of Carlow and Kilkenny, we should find that rocks of nearly the same age as those of Devon and Cornwall, namely, those called Old red sandstone and Carboniferous limestone, reposed directly upon the granite in such a way as to show that not only had the granite been cooled and consolidated, but that it had been denuded and brought to the surface in that locality before the Old red sandstone had commenced to be deposited.

For a space of about 25 miles, the Old red sandstone first, and then the Carboniferous limestone, overlap the Silurian, and come across it on to the granite. They are quite unaltered by the granite. The granite sends no veins into them, and moreover the lower rock, namely, the Old red sandstone, is more or less made up of sand derived from the materials of the granite, as in fig. 68, when the sandstone

Fig. 68.

Sandstone *s* resting upon granite *g*, and made out of the sand derived from it.

s is partly, or entirely made up of the debris of the granite *g*. It is clear, then, that the *bare* granite formed the bottom of the sea in which those rocks were deposited; in other words, that all the vast mass of Silurian rock which had covered the granite at the time of its consolidation had been removed by denudation before the period in which the lowest of those newer rocks came into existence.

But the granite of Cornwall and Devon penetrates rocks which were deposited at the same time, or nearly so, with

the Old red sandstone and Carboniferous limestone of Carlow and Kilkenny, and is therefore newer than those rocks, and consequently much newer than the Wicklow granite. But we may draw this yet further conclusion. The surface upon which the Old red sandstone of Kilkenny reposes is of course older than that rock; but that surface is continuous, with only slight modifications, over all the adjacent granitic and Silurian district of Wexford and Wicklow. The conditions as to denudation and form, &c., of the surface covered by the Old red sandstone and Carboniferous rocks, are obviously, by inspection of the map, nearly the very same conditions as those of the adjoining surface, which is uncovered by those rocks. Moreover, there is reason to believe that those rocks did once extend over much more of that surface than they do now, because detached patches of them are found here and there resting upon it. Therefore it follows that the main outlines, and all the principal features of the surface of the ground which now forms the counties of Wexford and Wicklow, and parts of the adjacent counties, are older than the period of the Old red sandstone. The principal part of the denudation by which that surface was formed took place before the period of the Old red sandstone, and any subsequent action, either atmospheric, when it was dry land, or marine, when it may have been passing through the surface of the sea, has been principally efficacious in removing rocks subsequently deposited upon it, or in modifying features, the outlines of which were graven at that ancient date.¹

These views on the nature and origin of granite are not exactly those which the student will find expressed in most geological works, though they are implied in the recent writings of many geologists. They are based upon what may now fairly be called the Lyellian philosophy of geology, a philosophy daily becoming more prevalent as its truth becomes more apparent and its applications more extended. The student, however, must expect still to meet with difficulties arising from the use of the old nomenclature, which is apt to still adhere to our tongues after the corresponding ideas have passed away from our thoughts.

V.—GRANITE VEINS.

Granite veins often differ sensibly in lithological character from the parent mass which they proceed from; and sometimes the external margin of the granite differs also from its deeper and more central portions. Veins very frequently become more fine-grained, and they lose commonly the mica and sometimes more or less of the quartz which the mass contains, becoming less crystalline and

Fig. 69.

Railway cutting at Killiney (Dublin), showing junction of granite and slate with granite veins.

a, Granite.
b, Black slate unaltered.
c, Gray slate converted into mica-schist.

more earthy. Sometimes they take up into their constitution additional materials, derived from the rock which they penetrate and traverse (fig. 69). A striking instance of this latter occurrence is described by Professor Haughton in his paper in the *Journal of the Geological Society*, London, vol. xii., p. 3, where he describes the granite of Carlingford

¹ This conclusion is one admitting of a much wider application than has yet been given to it. The present surface of the ground in most of the areas which are occupied by old rocks are surfaces of very ancient date, recent denudation having had but comparatively slight effect upon them.

Geology.

Geology. mountain as sending veins into, and cutting through some beds of the carboniferous limestone, and having its feldspar changed from an orthoclase, which was the feldspar of the granitic mass, into anorthite, in consequence of the addition of the lime which it had taken up from the limestone. Anorthite is said by the continental geologists never to occur except in recent volcanic rocks, and they appear to look upon its production as a mark of age, and suppose it, therefore, to be an impossible constituent of granite. This case, however, proves that it is a mark not of age, but of place, and of peculiarity of condition, and that a molten mass proceeding from actual granite may, in different parts of its course, contain different minerals, and become changed into different rocks according to the circumstances in which it is placed.

Other veins are to be found in granite itself, different in character from the surrounding rock, such as veins of eurite (see *ante*, p. 79), traversing coarsely crystalline and highly micaceous granite. Such veins may sometimes be due to subsequent intrusion of molten matter into the cracks of the granite; and when they do not consist of granitic rock, but of traps, such as greenstone and basalt, they undoubtedly are so due. In many instances, however, we believe them to be contemporaneous veins, either segregated from the mass while it was quite fluid, or perhaps more frequently, on the first commencement of consolidation, portions of the still molten mass below were injected into the cracks and fissures formed on the first attempt at consolidation of its upper portion. This we believe to be the generally true explanation of veins of eurite or other granitic matter differing from the mass of the granite. Such veins are commonly found to be confined entirely to the granite, and not to penetrate into the surrounding rocks, even when the granite itself does send off many veins into those rocks. In other cases, however, veins of "eurite," or of granite differing in texture from the surrounding granite, are seen to pass from the granite into the adjacent slates. These are of course formed subsequently to the consolidation of the granite which they traverse, but still they may in many instances be not long subsequent to that consolidation, and their consolidation may have been contemporaneous with that of lower portions of the granite.

The elvans or veins of quartziferous porphyry,—that is, a granular crystalline mixture of feldspar and quartz, which are common both in Cornwall and Devon, and near the granite of the S.E. of Ireland, are probably in reality granite veins, or veins proceeding from a granitic mass. Large masses of similar rock, however, occur in Wicklow and Wexford, forming mountainous hills with all the character of granite hills, except that the rock differs somewhat in texture from granite, and contains no mica.¹ These rocks, for which we have suggested the name of elvanite, but which continental geologists might possibly call pegmatite, are probably one of the intermediate varieties between true granite and a purely feldspathic or feldspatho-siliceous trap (felstone). They should, however, still be retained among the granitic rocks. The other granitic rocks described in Part I. resemble granite in their mode of occurrence, being generally massive and underlying. Pegmatite, protogine, and syenite are indeed commonly mere local varieties of granite. Large masses of greenstone-porphyry, or felstone-porphyry, or quartziferous-porphyry (elvanite), also occur in some districts as massive, deep-seated, underlying rocks, with all the petrological character of granite. These rocks, however, are by no means universally found as underlying rocks, since all kinds of porphyry often occur in bed-like masses, either as great intrusive

veins or dykes, more or less nearly horizontal, or as contemporaneous traps.

Geology.

VI.—FORM AND POSITION OF TRAP ROCKS.

The *Trappean rocks* may be especially characterized as being intrusive and overlying rocks when compared with the granitic class; but, inasmuch as they always proceed from below, it is obvious that every "overlying" mass of igneous rock must have a connection with some underlying mass by means of an intrusive pipe, dyke, or vein (see fig. 70). The terms "pipe" and "vein" sufficiently ex-

Fig. 70.

Overlying trap proceeding from underlying mass.

a, The overlying igneous rock.

b, The underlying igneous rock.

c, The previously existing rock, whether igneous or aqueous.

plain themselves. "Dyke" is a North British term for a "wall;" it is sometimes by miners applied to a mere fault, or fissure, but by geologists is always understood to mean a wall-like mass of igneous rock filling up a fissure in other rocks. A dyke may come up through any kind of previously existing rock, whether igneous or aqueous, trap dykes sometimes traversing granite, and overlying masses of trap resting on that or any other kind of rock whatever.

They may also reach and flow along all kinds of places,—the surface of the dry land, when they become volcanic rocks, and would be called lava; the bottom of the sea, when they would probably be called lava or trap, according to its depth and the circumstances of time and pressure under which they cooled; and in between the beds of aqueous rocks at different depths, or perhaps between the horizontal or other joints of previously cooled igneous rocks, whether granitic or trappean.

Those portions of trap rocks which have spread out upon the bottom of the sea, and have thus become buried between two consecutive deposits of aqueous matter, are called "contemporaneous traps."

In the old Silurian districts of the British islands great sheets of *felstone* and of *feldspathic ash* are thus interstratified with the aqueous rocks, and have since suffered with them all the accidents of flexure, contortion, and fracture that subsequent disturbing forces have brought upon those districts. Some fine-grained traps and ashes have undoubtedly been even affected by slaty cleavage and made into trappean slate, though as some of them, like the clinkstones of Mont Dor and Velay, may assume a finely laminated or slaty structure on cooling, this character requires to be very carefully observed before it is attributed to the same cause that cleaved the aqueous rocks.

Felstones, both contemporaneous and intrusive, occur also in great variety and in important masses in the Devonian and Carboniferous rocks of the S.W. of Ireland, near Killybeg and near Berehaven.

Greenstones occur likewise in contemporaneous beds interstratified with both "ash" and aqueous rocks. The beds of "toadstone"¹ in the limestone of Derbyshire form one

¹ Recent explorations in company with Professor Haughton, induce us to believe that this elvan-like rock is only the external skin, as it were, of true granite below.

¹ Toadstone is a local name, either given because the rock often

Geology. instance of this, and other instances occur abundantly in Ireland and other parts of the British islands.

In other cases both felstones and greenstones have been injected as great sheets, or as dykes, or as veins, into the previously existing rocks.

In the case of intrusive sheets of trap running in between beds of other rock, we may suppose that having been forced up through previously formed fissures to a certain height, the molten rock then met with such an opposition above that it was as easy for the expansive force which was impelling it to lift the beds above as to break through them. The planes of stratification then became those of least resistance; some horizontal cavities or some marked division between the beds was perhaps taken advantage of, and the molten stream, beginning to flow in, was injected with sufficient force to float the mass above upon its surface.

Sheets of greenstone thus injected have been traced by the government surveyors sometimes for miles among the Silurian rocks of North Wales. They have been found also by mining in the South Staffordshire coal-field over an area of above 20 square miles, with a thickness varying from 15 to 60 feet. (*Records of School of Mines*, vol. i., part ii., p. 244.)

VII.—DISTINCTION BETWEEN INTRUSIVE AND CONTEMPORANEOUS TRAP.

It is sometimes not very easy to distinguish between such injected sheets and beds of contemporaneous trap.

If a sheet of trap rock (whether felstone or greenstone), after running for some distance between two certain beds, cut up or down and proceed between other beds, as in fig. 71, it is obviously intrusive and not contemporaneous.

Fig. 71.
s, Stratified Rock.
t, Trap running partly between, partly across the beds.

If the beds above a sheet of trap be as much altered or "baked" by the igneous rock as those below, or if it send any veins up into the beds above it, it is equally plain that it must be an intrusive sheet.

If, however, the bed below the trap be altered, while that above it, composed of equally alterable materials, is quite unaffected, we may conclude that the trap was poured out and flowed over the surface of the lower bed, and that the upper bed was subsequently deposited upon it; in other words, that the trap is contemporaneous and not intrusive as regards the beds in that place.

This conclusion would be confirmed if the upper surface of the trap be rugged and uneven, and if the stratification and lamination of the bed above conformed to these rugosities, as suggested in fig. 72.

In the "toadstone" of Derbyshire globular masses of the upper surface are often almost completely included in the superincumbent limestone, clearly showing that the lime-

stone was deposited at the bottom of the sea on the uneven surface of the cooled trap. **Geology.**

Fig. 72.

s, Stratified rock, the lamination of which conforms to the rugged surface of t, a trap, in such a way as to show that it was deposited upon it.

If, again, the bed above the trap contained any fragments clearly derived from the erosion of the trap, it would prove the trap to be a contemporaneous one. At Carrig-o-gunnel, near Limerick, a great mass of greenstone, sometime amygdaloidal, is overlaid by a still larger mass of brecciated "ash," consisting of fragments of trap and fragments of limestone, and the beds of limestone immediately above this contain rounded pebbles and small flakes of the trap, demonstrating that it was formed by an outburst in the bed of the sea in which the adjacent limestone was being deposited.

When beds of trap (whether purely feldspathic or feldspatho-hornblendic) are clearly interstratified with beds of "ash" or "tufa" of the same character, whether that ash were subaerial or submarine ash,¹ it becomes almost certain that the trap is contemporaneous; for that ash is clearly derived from some contemporaneous trap somewhere, and the chances would be greatly against a sheet of similar trap being subsequently injected into those ashes without producing in them great and obvious alteration, or cutting them with dykes and veins so as to clearly show its intrusive character.

Even should the ash show a considerable amount of alteration from its original state as a mechanical deposit, such, for instance, as the production of crystals of feldspar, it would not be conclusive evidence against its being an "ash," or against the contemporaneous age of the trap beds associated with it, since such alteration might be the result of a subsequent general action which had taken place with regard to the whole mass of the rocks, but had produced a greater effect on the "ash" than on the other rocks, because its nature made it more easily impressible, and more open and liable to change than the solid igneous or the simple and more homogeneous aqueous rocks.

It is partly, perhaps, for this reason, as well as on account of the original alternation and partial blending² of the results of aqueous deposition and igneous outflows and dejections, that in some highly and generally altered districts such as North Wales and the lake district in England, the south-east of Ireland, and the Border Highlands of Scotland, it is often difficult to determine the difference between actual trap and "ash" or between ash and other mechanically-formed rocks, such as some varieties of sandstone or slate. In such districts we get great irregular bosses and mountainous masses of trap of various kinds, apparently the centres or foci of eruption; we get huge continuous sheets of

¹ The student must regard the term "ash," introduced by Sir H. De la Beche, as merely an English synonym of the Italian word "tuff" or "tufa," when the latter is applied to igneous materials. The advantage of using the term "ash" is the avoidance of the ambiguity arising from "tufa" being sometimes applied to calcareous or other depositions of a soft friable character.

² See the "Memoirs" of Professor Sedgwick in *Proceedings of Geological Society*; also his "Letters to Wordsworth" in the *Guide to the Lakes*, and *Introduction to Palæozoic Rocks*, 3d Fasciculus; also Murchison's *Silurian System*, and the Maps and Sections of North Wales and south-east of Ireland, published by the Geological Survey.

resembles a toad in colour, or more probably derived from the German word "todstein" or "dead stone," because the lead veins "die out" on approaching the toadstone, and were supposed not to reappear beneath it.

Geology. felstone and other kinds of trap spreading over great areas interstratified with "ash," sandstone, and slate; we get still more widely-spread sheets of "ash," sometimes hardly distinguishable from trap when near the igneous foci, but becoming thinner and more obviously mechanical, more completely conglomeritic or brecciated, or more calcareous and more regularly bedded, as we proceed from these foci, and we get the whole of these rocks cut through and penetrated in different places by subsequently formed dykes, veins, and intrusive sheets of other traps (greenstones, felstones, syenites, elvanites, &c.), altering the rocks more or less entirely according either to their chemical composition or to the mass of the intrusive trap, and thus completing the complexity and confusion which the geologist has to unravel.

When such a district has been greatly upheaved and disturbed, thrown into many and complicated folds, and broken by many faults running in various directions, heaving and dislocating the rocks now one way and now another, and with ever-varying amounts, sometimes throwing them as much as three or four thousand feet from the level of the corresponding beds on the other side of the fault; when, in addition to this, such a district has been worn and eroded into all kinds of hollows, valleys, and glens, with precipitous cliffs and crags, separated by more or less inaccessible ravines; and when, yet more, the rocks are frequently disguised by partial decomposition, and concealed over wide intervening spaces by soil, by vegetation, or by superficial accumulations of gravel, clay, and sand, it will be readily understood that it is no easy or unlaborious task, though often a healthy and delightful one, to trace out all this complexity, to restore order to all this confusion, to delineate the outlines and positions of the rocks as they now are, and to reason back to their original state, and to the causes which produced them.

VIII.—RELATIONS BETWEEN FELSTONE AND GREENSTONE.

We have occasionally been struck in some of the districts just alluded to with the association of felstone and greenstone, it being rare to find any considerable mountain mass of felstone without irregular patches of crystalline greenstone disseminated about it. The irregular outline of these greenstone patches gave them the appearance of being subsequently intrusive into the felstone, but the frequent association of the two has sometimes led us to speculate on the possibility of the two rocks having been part of the same molten mass, and having settled or segregated apart from each other on the cooling of the whole. There seems no very cogent reason why we should necessarily suppose the whole molten mass to have been completely homogeneous; but granting that it was so, is it not possible that, when a deep-seated mass of trap commences to cool, a separation may take place, and one more fusible portion of it may be segregated from the rest, and thus one or more local centres might be established, into which the greater portion of the more fusible bases (silicates of lime and iron) should be concentrated? These local patches, which, on the ultimate complete refrigeration of the whole, would form greenstone, while the rest of the mass was felstone or elvanite (quartziferous porphyry) as the case may be, *might* retain their fluidity for a time, till, on the consolidation and consequent contraction of the other mass, they were squeezed in various directions into the cracks and fissures that would then be caused, and then cool rapidly in consequence of their greater extent of surface.

IX.—TRAP DYKES AND VEINS.

There do occur, however, quite a sufficient number of independent intrusive masses of greenstone, inclosed en-

tirely in slate or other rock, to render these speculations unnecessary in many instances.

As a good instance of an intrusive vein of igneous rock we give the following (fig. 73), taken from *Rec. Sch., Mines*, vol. i., part, 2, p. 242, as having been drawn carefully to scale.

Fig. 73.
a, "White rock" trap. b, Altered coal. c, Sandstone.

The igneous rock here is a white trap springing out of the greenstone ("green rock") of the neighbourhood. Its chemical composition, as determined by Mr Henry, is—

Silica.....	38.830
Alumina.....	13.250
Lime.....	3.925
Magnesia.....	4.180
Soda.....	0.971
Potash.....	0.422
Protoxide of iron.....	13.830
Peroxide of iron.....	4.335
Carbonic acid.....	9.320
Water.....	11.010

100.073

showing a great amount of variation from any ordinary greenstone, in the presence of so large a quantity of carbonic acid. This alteration is probably the result of its having come in contact with a coal, and having been consequently affected by the subsequent percolation of carbonic acid, which has converted the silicates of lime and iron into carbonates. The alteration of the coal, in consequence of the heat of the trap, is equally great, as it has in many places lost its bright lustre, and its regular "face" has parted with much of its bituminous or inflammable character, and more nearly resembles anthracite than bituminous coal, though different from both, being often full of concretions of iron pyrites, or of carbonate of lime, or other minerals. In the language of the colliers, the coal is said to be "blackened," and to be now "brazil," or "brassil," and consequently not worth the trouble of "getting."

A wonderful example of a trap dyke is the one so well known in the north of England as the Cockfield Fell dyke, a nearly vertical wall of trap, 18 or 20 yards thick, which runs in a nearly straight line from north-west to south-east, for a distance of about 70 miles, cutting through all the rocks from the coal measures into the lower oolites, and baking the lias and every other rock it meets with for a distance of some yards from its sides. Its effect on one of the coal beds under Cockfield Fell, is well described by Mr Witham in the *Transactions of the Natural History Society of Newcastle*, vol. ii., p. 343. The coal, I believe, is originally about 6 or 8 feet thick, one of the principal bituminous coals of the district. In approaching the dyke, it begins to be affected at a distance of 50 yards from it; it first loses the calcareous spar which lines the joints and faces of the coal, and begins to look dull, grows tender and short, and also loses its quality for burning. As it comes nearer it assumes the appearance of half-burnt cinder, and approaching still nearer the dyke, it grows less and less in thickness, becoming a pretty hard cinder only 2 feet 6 inches in thickness. Eight yards further it is converted into real cinder, and more immediately in contact with the dyke, it becomes by degrees a black substance, called by the miners "dawk," or "swad," resembling soot caked together, the seam being reduced to 9 inches in thickness. There is also a large portion of pyrites lodged in the roof of that part of the seam which has been reduced to cinder.

Basalt is rarely, if ever, found as an underlying rock, and not often as an intrusive sheet. It occurs commonly either as a dyke, or as an overlying mass. One of the most celebrated plateaux of basalt is that in the north-east of Ireland, covering almost the whole county of Antrim with a mass 300 or 400 feet in thickness, and 50 miles long by 30 wide, or about 1200 square miles in area. The basalt occurs in three or four sheets, in many places beautifully columnar and interstratified with beds of ash or "ochre," as it is called, associated with beds of lignite; one of the columnar beds dipping gradually into the sea on the north coast is known as the Giant's Causeway. Many dykes are perceivable in the district, cutting through different kinds of rock, altering the Lias shales into a Lydian stone, and the Chalk into a crystalline marble. The basalt of the west of Scotland is likewise beautifully columnar, as at Fingall's Cave and other places, while that of Arthur's Seat is massive, and often crystalline, showing distinct crystals of olivine, and being highly magnetic from the abundance of magnetic oxide of iron.

The ash associated with the basalt of the Calton Hill is very admirably exhibited on all sides of it.

The greenstone of Salisbury Crags has greatly altered and indurated the gritstone below it (one of the Carboniferous sandstones), which is converted into a kind of quartz rock.¹

It is probable that all these basalts and greenstones were of submarine formation, but the lower part of many lava streams proceeding from subaerial volcanoes, or at all events from volcanoes which are now subaerial, are as regularly columnar basalt as the Giant's Causeway itself.

XI.—FORMS AND POSITIONS OF VOLCANIC ROCKS.

Lavas differ from traps partly in mineral character, such as the occurrence of augite instead of hornblende, and of labradorite or anorthite instead of orthoclase, &c., but principally in the texture and form of the rocks, rather than their composition.

True lavas have always been poured out either on the dry land or in shallow water, forming regular flows or "coulées" of molten rock. Cooled under these circumstances, the upper surface of a lava stream is generally quite porous and vesicular, from the escape of the gases pent up within. The upper portion of such a bed consists of loose blocks of cinders of all sizes, from rough masses of 2 or 3 feet in diameter, to those of as many inches. It might be likened to a mass of clinkers, slags, and cinders from a huge foundry. The far end of a lava stream has been described as a slowly-moving mass of loose porous blocks, gradually rolling and tumbling over each other with a loud rattling noise, giving evidence of the pressure of a viscid mass of cooling lava within. The upper end of a lava stream, where it issues perfectly fluid from the intense heat of the volcanic orifice, moves much more rapidly.

All rock is a bad conductor of heat, so that, when once a lava stream acquires a cooled crust, the mass within may remain glowing hot for a considerable period of time. We are told of persons walking about on the cooled surface of a lava stream while able to roast eggs or light cigars in the cracks and crevices of the crust. Caverns are sometimes formed in lava streams by the sudden escape of the molten

mass below, leaving the cooled crust standing like the roof of a tunnel.

In such a mass it is obvious that, while the upper surface was light, porous, and cindery, the lower portion, cooling much more slowly, and under pressure, might be solid, compact, or crystalline. As a matter of fact, wherever old lava streams have been cut into, either naturally or artificially, and their lower portions laid open to our inspection, we find the vesicular character of the upper surface gradually disappearing below, and the rock passing quickly into a hard, compact stone, often columnar, and frequently quite crystalline.

The hornblendic or augitic lavas more readily assume the columnar form than the feldspathic lavas or trachytes, which, however, on the other hand, are often much more highly crystalline than the augitic dolerites or basalts.

The lower parts of many lava streams are not to be distinguished by any internal characters (and probably not by any differences in chemical composition) from columnar basalt.

Many old basalts, indeed, which are ordinarily considered as trappean rocks, may have had a porous cindery upper surface at the time of their formation, that surface having been subsequently washed away by denudation.

Almost all true lavas are embedded in, and surrounded by, vast piles of ashes, dust, and fragments, ejected from the volcanic orifice from which they themselves proceed, or from some neighbouring orifice. They commonly issue from a cup-like hole, or crater, either on the summit or on the flanks of a great conical pile of such loose ejectaments.

XII.—ELEVATION THEORY OF CRATERS.

Von Buch and other geologists formerly took it for granted that lava would not solidify into thick masses of compact or crystalline stone, if it had been poured out down a slope having an inclination of more than 3° or 4° to the horizon. It has been shown, however, by Sir C. Lyell and others, that this assumption was a gratuitous one.

Upon it was based the "elevation theory" of cones and craters, which supposed it necessary that all lava streams, and the associated beds of ashes, &c., should have been once nearly horizontal, and subsequently elevated into their present inclined position and quaqua-versal dip, by an upheaving force acting on a central point. This theory is here mentioned chiefly that the student may know what the elevation-crater theory was.

It is not intended to deny the possibility of such an elevation, since a dome-shaped elevation and quaqua-versal dip is a common occurrence among stratified rocks, and may have been given equally to igneous rocks, as in the case of Mount Jorullo, stated by Humboldt to have swollen up like a bladder to a height of 1600 feet above the surrounding ground. But we wish to guard the student against supposing it the necessary mode of formation of all volcanic cones and all crateriform hollows from which beds of lava incline downwards in all directions. All, or nearly all, volcanic cones have been formed by the frequent ejection into the air of cinders, blocks, and ashes, from one central orifice, round which they have fallen nearly equally in all directions (except perhaps that from which the wind was blowing at the time), together with the occasional outflow of a molten lava stream, which has either broken down one side of the lip of the crater, or has broken through at some lower and weaker point in the flanks of the cone.

On the flanks of a great volcanic mountain minor lateral cones and craters are frequent at the surface, and are probably much more numerous within; many former excrescences having been buried and concealed by subsequent accumulations (whether of lava streams or ashes) ejected from the central region.

¹ Professor Ramsay informs us that Professor Edward Forbes had conceived the idea, which has lately been completely confirmed by the Geological Survey, that the igneous rocks around Edinburgh belonged to two very different periods, the one part probably Carboniferous, and the other much more recent, probably Tertiary, perhaps contemporaneous with the Miocene (?) basalts of the north of Ireland and the west of England.

XIII.—CONE WITHIN CRATER.

In great volcanic mountains it is not unfrequent to find the ruins of a former grand central cone, from the interior of which a new central cone is commencing to grow. This is the case in the Peak of Teneriffe, where the present cone rises from a corner of the space now called the Pumice Plains, that was once the interior of a much grander cone, the ruined walls of which may still be traced in a line of crags surrounding the plains.

In the volcanic mountain of the Bromo in Java,¹ which lies in the centre of a great volcanic range, from one end of which Mount Semiru rises to a height of 12,000 feet, and from the other Mount Arjuno to 11,000 feet, there is an excellent example of a similar structure. The Bromo is a flat-topped mountain, about 8000 feet high, formed by a narrow circular ridge sloping steeply down on the outside, and having a perpendicular precipice within, only broken and accessible at one or two points, and being generally 1000 feet in height. The circular space within this great wall is 4 or 5 miles in diameter, and a large part of it is a flat expanse of fine sand, called the Laut Pasir, or Sandy Sea. From near the centre of this rises a rough conical mound, 600 or 800 feet high, deeply furrowed on all sides, and having on one side a number of subordinate cones and craters, partly growing out of it, as it were. One of these had been frequently active in 1845, when we visited it, and was then belching out much smoke and steam, with a great rumbling noise proceeding from the depths of the funnel-like crater.

For further details of volcanic mountains, and an account of their distribution, we must refer the reader to Lyell's *Principles of Geology*, Daubeny on *Volcanoes*, Wilkes's *Voyage*, Scrope's *Central France*, Johnstone's *Physical Atlas*, Walterhausen's *Ætna*, &c. See also a very interesting paper by Mr Scrope in the *Geological Journal*, vol. xii., p. 4.

XIV.—DYKES AND VEINS OF LAVA.

Just as among the trap rocks we found dykes and veins frequent, seeming sometimes to be the mere extensions of the mass below into the cracks and crevices of the rocks above or around it, sometimes apparently the feeders of overlying masses, so we should find volcanic cones and the surrounding districts penetrated in every direction by dykes and veins of compact lava, serving often to bind together or to support the otherwise rather incoherent materials; and we should know, although we could not see it, that every lava stream had its central pipe or feeder in the interior of the mass from which it had proceeded. It is probable that, both in the case of traps and lavas, the size of the dykes or feeders often bears but a small proportion to the mass of the overlying rocks that proceeded from them.

It is not absolutely necessary, in the case of a volcanic cone, that the flow of lava and the central pipe or feeder should remain in connection, and cool and consolidate together; for when the lava ceased to be impelled so as to flow over the crater, the portion left in the funnel might sink down, and perhaps ultimately cool and consolidate at a considerable distance below, and might possibly make even a different kind of rock from the ejected mass.

This may sometimes occur also among trap rocks, since it is quite easy to conceive that an overlying mass or an injected bed might be deserted by its feeder on the internal impelling power being withdrawn, and the orifice by which it rose might be closed, so that two kinds of rock may be formed at different places, and possibly of rather different

character, though once perhaps actually forming part of the same molten mass.

XV.—ASSOCIATION OF TRACHYTES AND DOLERITES.

In many volcanic regions there appears to be an alternation, or to have been a succession, in the different products; the lavas being at one time trachyte, and at another dolerite. It was formerly supposed that the trachyte was always the lower, or the older of the two, and that flows of trachyte were never found above flows of basalt or dolerite. We are not prepared to say how far this relation of position has been borne out or not by recent researches.

Bunsen, however, in a paper formerly cited (*Sc. Memoirs*), in speaking of the trachytic and angitic lavas of Iceland, refers their origin to two separate volcanic foci, and even speaks of a third separate volcanic focus for the intermediate lavas, though he also speaks favourably in another place of all the volcanic rocks arising from one mass.

The identity or very great similarity of the various volcanic products in all parts of the world seems to point to a common origin for them. The frequent association in all parts of the earth of the two great classes of these products, trachytic or purely feldspathic (or highly siliceous, with little alkali, lime, or iron), and those in which the feldspathic minerals are largely mingled with hornblende or augitic (containing much alkali, lime, and iron), seems to show that their separation is not so much due to diversity of origin, as to some cause tending to segregate the one from the other, out of a generally diffused mass, in which the constituents of both may be equally mingled.

The association previously mentioned of felstone and greenstone among the traps seems to be reproduced in that of trachyte and dolerite among the lavas. In both instances the occurrence of pure or unmixed feldspathic rocks is less frequent and less universal than that of those in which the feldspar is mingled with the more basic minerals. Trachytes and feldstones seem both to be confined to certain localities, in which, however, they are very abundant, sometimes alone, and sometimes largely mingled with dolerites, basalts, or greenstones. These latter rocks, on the contrary, are not only found in association with the former, almost wherever these igneous rocks appear, but also in many other districts, in large or small quantities, unaccompanied by any other igneous rocks.

If we assume all igneous rocks to proceed either from one central molten mass of equable constitution throughout, or from separately fused portions of perfectly similar constitution, might we not suppose that the difference in the constitution of the various products which we find at the surface depended on the circumstances and conditions in which they had been placed? The portions now open to our examination had probably to pass through different thicknesses and different kinds of other rocks; they would be placed then under different conditions of temperature and pressure, which might perhaps alone cause a separation to take place in their different ingredients; they might also take up in their passage other ingredients of different character from those which they originally possessed, or larger proportions of one or other of their original ingredients. In those places, or at those times, when violent accessions of heat approached most nearly to the surface, trachytes and felstones might be poured out, while at other periods of less intensity no molten rock could reach the surface unless it were composed of more easily fusible minerals. These more readily fusible substances might be conceived either to have separated in liquid strings and veins from the consolidating rocks below, or to have been acquired by the upper portion of the mass from the rocks it met with in its passage towards the surface, the substances thus added having acted as an additional flux to matter which would

¹ See *Voyage of H. M. S. Fly*, vol. ii., p. 68.

Geology.

otherwise have solidified before it could have been poured out.

Some such hypothesis as this seems less forced than one which obliges us to suppose separate deep-seated foci or reservoirs for every variety of igneous rock, those varieties frequently occurring in the same district, and alternating one with the other over the same space of ground.

If it be well founded, it will enable us to account for the gradual changes in one connected igneous mass, as also for the veins and patches of different character sometimes to be found occurring very abruptly in such masses, independently of the supposition of a subsequent intrusion of one igneous rock through the body of another. This would often relieve us of a difficulty where the veins are confined to the igneous rock and do not penetrate the adjacent aqueous rocks. We might then look upon such veins as veins of segregation, occurring probably at the time of the contraction consequent upon the mass of the rock passing from a molten to a solid state, or from a pasty to a crystalline state (see *ante*, p. 84), while yet some parts of it remained fluid.

XVI.—ORIGIN OF VOLCANIC ACTION.

It still remains an undecided question whether the heat by which rocks are molten in the interior of the earth be due to an original central heat or to mere local causes. Dr Daubeny maintains Davy's hypothesis of the probability of volcanoes arising from the heat generated by the oxidation of large masses of the metallic bases of the earths and alkalis, independently of any central heat. We have, however, already seen that there is a high degree of probability for the existence of a great internal temperature.

Professor Phillips has remarked that the fact of internal heat by no means excludes the hypothesis of the local intensity of volcanic action near the surface being due to the local chemical causes to which Dr Daubeny ascribes them. The linear arrangement, however, of the great volcanic bands of the earth's surface suggests, as Humboldt says, the idea of their being arranged over great cracks in the crust of it, by which the molten matter of the interior escapes to the surface. The existence of these cracks, on the other hand, may be equally efficient, as allowing the access of water to the elementary or simple substances of the interior, and their consequent oxidization and combustion.

Even granting the central heat and fluidity of the earth to be a fact, there still seems to be a difficulty in supposing our lava streams to have any direct connection with this central fluid portion. If they had, they would apparently be kept constantly molten, and constantly at the same height in all volcanoes, unless, indeed, we suppose the attraction of gravitation not to be universally perpendicular to the earth's mean surface.

XVII.—THE CONTENTS OF MINERAL VEINS.

Having described the veins of igneous rock, and the cracks, fissures, and faults which affect all rocks in different places, we are now in a position to re-examine the subject of mineral veins, with a view especially to their contents.

In veins or dykes of igneous rock, we have seen that they are either *veins of segregation* with or without fissures, or *veins of injection*, liquid matter having been forced into fissures, either previously existing or formed at the time of injection. There is commonly in such veins no farther dislocation of the adjacent rocks than will allow of the intrusion of the igneous matter.

We have also seen that in "faults" the fissure will probably be closed in soft and easily compressible rocks, while in hard ones it will often stand open, either wholly or in part, the walls or sides of the fissure being kept asunder

by the knobs and protuberances which result from the irregularities of its form.

Geology.

It is of course quite possible that molten matter may gain access to such a fissure, and fill it up with a dyke or vein of igneous rock. If, however, it be not so filled up, it will be ultimately more or less completely filled with other kinds of mineral matter, and in a different way.

Blocks and fragments of the adjacent rocks may fall into such a fissure, and such blocks are often found in mineral veins. If it have anywhere any open communication with the surface, different matters may be swept into it by floods or springs. Branches of trees, gravel, sand, and clay, and other surface matters, have accordingly been found in mineral veins.

Besides these matters, however, thus introduced by mechanical causes, many minerals have been chemically deposited in fissures, and it is to these chemically-deposited substances that we look as the true contents of a *mineral vein*.

The number of minerals found in such veins is far greater than that of the minerals forming the principal constituents of rocks. Silica or quartz, however, among the earthy minerals, maintains an equally abundant presence in veins as in rocks. In addition to the earthy minerals, however, such as quartz, fluor spar, baryta, calcite, strontia, &c., mineral veins are the principal repositories of the metallic minerals, the ores of copper, lead, tin, zinc, mercury, antimony, silver, gold, platina, &c. &c.

It is to these metallic minerals that the miner of course chiefly looks, and he generally speaks of the earthy minerals as the gangue, matrix, or vein stuff of the "vein" or "lode."

The mineral contents of a vein is sometimes confusedly dispersed through it, the "vein stuff" being either crystalline or amorphous, and the ore occurring either as disseminated crystals or nests, or as "strings" or ribs." Sometimes there appears a regular arrangement of the various substances, the "cheeks" or "walls" of the "lode" being lined with a layer of crystals of one kind of substance, with their points or apices directed inwards, each of these layers being covered by a crystalline layer of another substance impressed by the crystals of the first, and therefore evidently deposited upon it, and after two or three such alternations a rib of ore is found in the centre.

In other instances the vein will be filled with only one kind of substance, sometimes the "vein stuff," sometimes the ore.

Such structures as that in fig. 74 seem necessarily to

- c. Coating of first mineral, or of a third, say sulphate of baryta.
- d. Rib of ore, as copper or lead.
- w, w. Walls of the lode.

involve the idea of successive depositions of the different

Geology. coatings or linings of the vein, the central rib of ore being the last or newest.

Assuming, however, the vein to have been filled with a liquid solution of these minerals, it is not absolutely necessary to suppose them to have been successively introduced, since all the substances may have been in solution together, and circumstances having been favourable at one time to the deposition of one substance and to that of another at another time.

In some veins it appears that after being filled up, subsequent movements have taken place, causing fresh openings, and new deposits of crystals formed in these openings. These subsequent movements have often produced shining striated surfaces, the effect of enormous friction, which are known as "slickensides;" but these are not confined to veins, since they are found in "faults," and in broken or contorted and fractured rocks of all kinds, where a grinding motion has been communicated to different parts of the rock.

Where "lodes" and "cross courses" occur together in a district, their contents are often different, one kind of minerals being found in one and another in the other. Where the date of the "cross course" is newer than that of the "lode," which is often the case, it is easy to understand the difference in their contents. When, however, the two veins are contemporaneous, as sometimes happens, it is not so easy.

Sometimes the cross courses contain no ores themselves, but the parts of the right lodes near the cross courses are found to be more than usually rich. By "right lodes" are meant those mineral veins which run parallel to each other with a certain magnetic bearing over a given district of country, and by "cross courses" those which cross these more or less nearly at right angles. Both in the north and west of England the "right lodes" run nearly east and west, the "cross courses" nearly north and south.

Of the various hypotheses proposed to account for the origin of the contents of mineral veins, none perhaps are altogether satisfactory. Mr Wre Fox called attention to the fact of currents of electricity traversing veins; and there appears no difficulty in supposing that if veins are filled with water more or less acidulated and impregnated with mineral solutions, a great natural "electro-plating" process may be set up, by which different minerals may be deposited at different times or in different parts of the walls of the lodes. Where the minerals, however, and especially the metallic ores, are derived from, is another question, whether directly from original repositories below, or indirectly by segregation in minute particles from the adjacent rocks. That the fissure should remain open for a great and indefinite period of time, and that its sides should be hard rock, seem the two essential conditions, though perhaps the latter may only be necessary to ensure the former.

The mineral contents of veins seem to be by no means permanent, even when complete, since crystals of minerals are often found that have not their true form, but the form of some other mineral; the originally deposited crystal having decomposed and been removed, and the newer one deposited in its place. Vast periods of time must have elapsed for such processes to have taken place.

If the mineral contents of veins have not been deposited from aqueous solutions either filling the veins or trickling down their sides, the only other alternative appears to be to suppose them the result of sublimation. This supposition seems to have lately lost the favour with which it was once received, it having been objected to it, that the temperature of the walls of the vein must necessarily be too low for sublimation to take place, or for minerals to continue in a state of vapour in any but the lower and more deeply-seated parts of veins. To this objection, however, it might be replied that the mineral veins, now near the surface, were

probably deep-seated, and covered with vast thicknesses of other rock, at the time the minerals were formed in them, and therefore their walls may have had then a very high temperature. Moreover, it may be doubted how far it is impossible for minerals to be brought into them in a state of vapour even now. With respect to lead, at all events, we recollect to have been shown a chimney a mile long, built along the side of a hill, proceeding from some lead works in the county of Northumberland, with chambers in it at intervals, and to have been told that its expense was repaid in a few years by the quantity of lead deposited in these chambers, which would otherwise have been dissipated in the state of vapour into the atmosphere. It was the noxious action of these mineral vapours on the surrounding crops which first necessitated the erection of the chimney.¹

It appears then, that, provided it be possible for mineral vapours to be generated and gain access to fissures in rocks, it is not impossible for some of them at least to be condensed and deposited on the sides of lodes in the way in which we now find them, even close to the present surface.

This method of formation, however, would not account for the strings of ore that are often found leading from lodes into the minute cracks of the walls, frequently horizontal, and often more or less completely blending with the rock itself; nor would it account for the detached nests and concretionary lumps of ore frequently found, entirely inclosed in rock, both in the neighbourhood of mineral veins and elsewhere.

In the rounded concretionary blocks of ironstone, for instance, found in the clays of the coal measures, crystals of galena and of blende are often found together with those of iron pyrites, carbonate of lime, and others. In the Carboniferous limestone and Old red sandstone rocks of the south of Ireland and elsewhere, small cavities are found, not so large as the fist, filled up with crystalline concretions of galena and of specular iron ore.

Any explanation of the formation of the contents of mineral veins must include that also of the deposit of these detached and isolated nests of minerals, as well as the formation of quartz veins in general, and all other veins, and strings, and nests, and cavities that have been more or less completely filled by any crystallized mineral substances of whatever kind.

If we take the crystalline stalactites and stalagmites forming in caverns as the basis of our reasoning on this subject, and suppose all other cavities to have been either filled or to be in process of filling by crystalline minerals

¹ As this was a recollection of twenty years ago, we wrote to Mr Sopwith, the eminent manager of Mr Beaumont's mines, respecting it, and in answer we were informed by him that formerly "large quantities of lead were carried off in the state of vapour and deposited on the surrounding land, where vegetation was destroyed, and the health of both men and animals seriously affected. This led to various extensions of the horizontal or slightly inclined galleries in use at Mr Beaumont's mines, and the quantity of lead extracted rapidly repaid the cost of construction. The latest addition of this kind was made at Allen Mill, and it completed a length of 8789 yards (nearly five miles) of stone gallery (or chimney) from that mill alone. This gallery is eight feet high and six feet wide, and is in two divisions widely separated, one being in use during such times as the *fume* or deposit (a black oxide of lead) is taken out of the other. There are also upwards of four miles of gallery for the same purpose connected with other mills belonging to Mr Beaumont in the same district and in Durham, and further extensions are contemplated. The value of the lead thus saved from being totally dissipated and dispersed, and obtained from what might be called *chimney scrapings*, considerably exceeds ten thousand pounds sterling annually. It should be observed, however, that the mines of which these chimneys or flues are an appendage, are the largest lead mines in the world, and that the royalties or freehold rights of mining belonging to Mr Beaumont, in the county of Northumberland alone, extend over more than a hundred square miles, in addition to extensive leasehold mines in the county of Durham."

Geology. in a similar way, we shall probably not be far from the truth.

We may not be so well acquainted with the exact nature of the process by which other minerals are dissolved in one place and redeposited in another, as we are in the case of carbonate of lime; but we may feel pretty well assured that water is the principal medium through which other agents act in the one case, as carbonic acid does in the other.

The association of different minerals in different veins may possibly some day throw some light on the nature of these processes. Werner, for instance, says that galena or lead glance, copper pyrites, blende, and calamine, frequently occur together; as also cobalt, copper, nickel, and native bismuth; tin, wolfram, tungsten, molybdena, and arsenical pyrites, &c. It appears that magnetic iron (the emery of the gold diggers) generally occurs with gold. Silver also is commonly found in lead ore. Recent experiments of Dr Percy show that minute quantities of gold occur in almost all lead ores, as well as in all copper and iron pyrites.

The relation between the contents of mineral veins and the nature of the rock which they traverse is also important.

The lead veins of the north of England traverse limestones, sandstones, and shales, and their contents vary according to the nature of the substances which form the walls of different parts of the "lodes." It is even said that the "lodes" vary in contents in different beds of limestone, but it does not appear that the richness of a lode is constant for any beds of limestone. When one or both walls consist of shale, the lode is always poorest, but this may be the result simply of the greater contraction of the fissure and more unstable condition of its walls when soft than when they are hard.

The supposed relation between mineral veins and the age of the rocks they traverse is probably an accidental one only. Mineral veins may be expected in all highly-indurated and greatly-fractured rocks, whatever may be their geological date. Neither does the connection between mineral veins and the occurrence of igneous rocks appear to be better founded, than on the probability that igneous rocks will be most likely to be found in the same indurated and fractured districts which we have seen to be essential for the production of mineral veins.

Geology.

PART II.—PALÆONTOLOGY.

(The treatment of this part of the subject is deferred to a separate article under that head.)

PART III.—HISTORY OF THE FORMATION OF THE SERIES OF STRATIFIED ROCKS.

CHAPTER I.

PRELIMINARY OBSERVATIONS.

We have hitherto been dealing with general principles, examining structures which are common to all rocks, and referring the production of those structures to their several causes. We have had occasion to remark frequently on the vast lapse of time required for the formation of these rocks, and it remains now to classify and arrange the results of the operations that have been taking place during this vast lapse of time, and to give, as far as possible, a connected history of the events which have been concerned in the production of that external portion or crust of the earth which alone is open to our examination.

The way in which this order is to be discovered will, I think, be sufficiently obvious from what has been said before. In a former chapter we saw, that after having acquired a knowledge of the number and nature of a series of beds, by examining a cliff on a sea-shore, or other "section" where they were well exhibited, any little natural or artificial excavation in the interior of the country which enabled us to identify one of these beds assured us of the presence of all the rest above and below it. By searching out places where such "sections" were to be seen, and then following them by different indications across countries, and joining them on one to another, verifying them now and again by the discovery of other sections where they were again to be seen in more or less detail, and performing the same process for the sets of beds that successively cover them, we eventually survey great tracts of country, and arrive at a knowledge of the order and succession of subterranean groups of rock, to a much greater depth under certain localities than it would be possible to reach to by any process of mining or direct excavation.

The history of the formation of the whole crust of the globe, then, is to be learned by piecing together our know-

ledge of different parts of it, as they rise to the surface one from under the other, over different tracts of ground.

We might give this history in either of two ways, namely, by investigating or *tracing* it backwards from the present to the past, or by *narrating* it as nearly as possible in the order in which it occurred. We prefer the last method as the shorter and more intelligible, since it is hoped that the previous parts of this article will have sufficiently prepared the student to understand it.

As, however, to narrate this history in full, even so far as it is already known, would require a library rather than a book, what will be here given must be taken as a mere abstract,—a chronological table rather than a history,—by means of which the student will be able to refer to its proper period any more detailed account, which he may either read or observe for himself, of its different portions.

Even this abstract is a very imperfect, broken, and fragmentary one. Comparatively few parts of the earth's surface have as yet had their structure even sketched out; still fewer have been accurately surveyed, and had their details thoroughly unravelled, and placed in their proper and regular order. Many of the events, therefore, which are now supposed to have occurred contemporaneously in different places may in reality have occurred in succession; many which are supposed to have directly succeeded each other may have been separated in reality by great spaces of time, of which there are no records as yet discovered, or of which none may ever be found. It is obvious that all future discoveries may add to the time we know to have elapsed, but cannot diminish it.

As the structure of the British Islands is better known than that of any other part of the globe of equal dimensions, and contains a more complete series of rocks in a small space than any other district, we shall take that as our principal authority, as it were, for our history, pointing out the several groups of rock which were produced in this part of the globe during the several periods, and then give some of

Geology. those other well-known typical groups of rock which are believed, or are known, to have been deposited contemporaneously with them in other parts of the earth. Where a group of rocks is known of which we have no contemporary representative in the British Islands, it will of course be best to describe it from its best known locality. Our history, therefore, will be chiefly that of the formation of the Celtic or British province, as we may call it, with occasional reference to the history of other provinces.

Chronological Nomenclature.—One difficulty meets us at the outset as to our nomenclature; that is, as to the names we are to give to the different periods of past time. This difficulty must at present be evaded, since the time is not yet come; that is to say, our knowledge is not yet complete enough to enable us to overcome it.

The early geological observers described certain kinds of rock, to which particular names were given. These names were in the first instance lithological, or descriptive of the kind of stone, of which Chalk, Oolite, Granite, are instances. In other cases they were petrological, such as Trap, Mountain Limestone, Coal Measures, &c. Others again were geographical, of which Wealden, Neocomian, Silurian, Oxford Clay, are examples; while others were local terms adopted by geologists, such as Lias, Cornbrash, Gault, &c. Such terms as Old and New Red Sandstone were combined lithological and geological terms, referring at once to the kind of rock of which they were composed and their relative place in the series.

Gradually, as extended observation showed that all the aqueous rocks occurred in a certain order, and formed a series or succession of beds regularly and invariably superimposed one upon the other, a chronological sense began to be extended to these terms, having reference to this order of occurrence or corresponding relative date of formation. Thus the Oolite and the Chalk came to mean not only the rocks to which those names were first and truly applied as descriptive of their lithological character, but also all other kinds of rocks which, having been formed about the same period as these, occupied the same relative place in the general series, and contained the same fossils. Used in this sense, Cretaceous or Chalk rocks might be made either of white chalk, of black marble, of brown sandstone, or blue slate; "cretaceous rocks" meaning in reality only rocks of *the same age* as the chalk. Silurian rocks, in like manner, mean those of *the same age* as the rocks of Siluria; and so of the rest. This double signification of words is almost unavoidable, and the student will find himself naturally and inevitably falling into it in the course of his geological pursuits. It may, however, conduce to the more ready understanding of the classification of the great series of stratified rocks, and the history of their formation, if we confine our attention to the chronological signification only of the principal terms, speaking of them as periods of time during which such and such beds were deposited. I shall not attempt to invent new terms for these periods, but shall take those most ordinarily used and accepted. When, then, we speak of Silurian, or Carboniferous, or Oolitic, or Cretaceous *periods* of time, the reader must pardon the apparent contradiction in the terms, and look on the names as *names only*, and not as descriptive designations.¹

We may, again, group the great periods of geological time into still larger epochs, to which it is usual to apply the simple terms Primary, Secondary, and Tertiary. As synonyms of these, the words Palæozoic, Mesozoic, and Kainozoic, proposed by Professor Phillips, have been pretty

generally adopted, signifying the periods of ancient, middle, and modern life. Geological time, then, may be thus arranged:—

3. TERTIARY OR KAINOZOIC EPOCH.

- n. Human, Historical, or Recent period.
- m. Pleistocene period.
- l. Pliocene period.
- k. Miocene period.
- j. Eocene period.

2. SECONDARY OR MESOZOIC EPOCH.

- i. Cretaceous period.
- h. Oolitic period.
- g. Triassic period.

1. PRIMARY OR PALÆOZOIC EPOCH.

- f. Permian period.
- e. Carboniferous period.
- d. Devonian period.
- c. Upper (or True) Silurian period.
- b. Lower (or Cambro-) Silurian period.
- a. Cambrian period.

It will be advisable, perhaps, to say a few preliminary words as to the commencements of each of these great epochs.

The commencement of the Primary epoch has been already spoken of; and it was shown that by the very nature of the case this must be lost in the dark uncertainty of the remote past, with no clear and definite starting-point to be determined. The earliest formations of all must necessarily have been all long ago destroyed by the erosive action of water, or re-absorbed by the melting agency of internal heat; and even of those later, but still very early rocks, some of which do yet remain in a recognisable state, most of the contemporaries must have been destroyed or so metamorphosed as to be no longer recognisable. The commencement, then, of the Primary epoch must necessarily be uncertain, doubtful, and irregular.¹

The commencement of the Secondary epoch is a marked one, depending on a great change having taken place in the character of animal and vegetable life in the interval between the formation of the last of the Primary or Palæozoic rocks, and the first of the Secondary ones. This change was coincident with the occurrence of great disturbances and great denudations in the parts of the world now occupied by Europe, and perhaps some other parts. It is probable, however, that the greater break, both in the position of the rocks and the character of the fossils, here than elsewhere in the series, is more apparent than real, and is owing to a great chasm in our documents, and the absence of a vast number of beds which may yet be discovered in other parts of the earth.² However that may be, there is a decided line to be drawn between Primary and Secondary rocks and fossils.

The commencement of the Tertiary epoch is more arbitrary, though it is marked also by a decided change in the

¹ We may dismiss all reference to the derivation of the terms just as readily here as in many other cases. When using the term "sycophant," we rarely think of a "false fig merchant;" nor do the words "bishop" and "overseer" convey to us the same ideas, although really identical in meaning.

² The term "primary" was formerly attached to granitic and highly metamorphosed rocks only; and another term, namely, "transition," was used to designate many of those which are now called "primary." In consequence of this uncertainty as to the meaning of "primary," it is more usual now to speak of this epoch as Palæozoic. It is undoubtedly true that much of the granite we know is of primary or palæozoic age, and that many metamorphic rocks were formed during the same epoch. As, however, some granites are secondary or tertiary, and some secondary and tertiary rocks are just as much metamorphosed as any primary ones, the old use of those terms is now properly abandoned.

³ This was written while we had but a very faint knowledge of the nature of the St Cassian beds. The publication of Sir C. Lyell's Supplement makes English readers acquainted with the existence in the Austrian Alps of a large mass of beds of the very character here anticipated, namely, the St Cassian or Hallstatt beds, and others associated with them, having fossils of an intermediate character between those found in palæozoic and those in mesozoic rocks.

Geology. rocks and fossils, and a probable absence of a number of beds. The most marked character of the Tertiary rocks is derived from the fact that a few of the animals which came into existence at the commencement of the Tertiary epoch are still living on the globe. It would follow, then, that if these few species were now to die out and become extinct, the boundary between Secondary and Tertiary rocks would have to be shifted, or else it would be left with a still more arbitrary character than now. There is no essential difference between Secondary and Tertiary fossils. The genera are mostly the same, though the species are all different, and often not very widely different. It was for this reason that the late Professor Edward Forbes proposed to do away with the distinction between them, and to group the whole of the great series of stratified rocks, or, in other words, to divide the whole lapse of past geologic time into two great epochs only, namely, Palæozoic and Neozoic.

In drawing up the following summary, it will be best to give under each period a brief description of the groups of rocks that may be taken as typical of those formed during the period in different parts of the earth, with their maximum thickness,¹ as the measure of the time elapsed, and the possible importance of the group.

Reference will be made chiefly to the Celtic province, or British area, in these statements.

PRIMARY OR PALÆOZOIC EPOCH.

CAMBRIAN PERIOD.

(*Lower Cambrian of Professor Sedgwick.*)

TYPICAL ROCKS.—Wales.—A great series of gritstones, or sandstones, and slates, generally of purple and green colours, the sandstones sometimes becoming conglomeritic, and containing fragments of still older slates and grits. In the Longmynd (Salop) there is an apparent thickness of 26,000 feet of these rocks; but this enormous thickness may perhaps be due to concealed folds or reduplication of the beds. In Anglesea these rocks are largely metamorphosed into chloritic and micaceous schists and gneiss, the metamorphism having apparently taken place at a very early period.

Ireland.—A great series of grits and slates, generally of purple and green, or brown and liver-coloured hues, often interstratified with large beds of yellowish quartz rock, which are most abundant in what appears to be the upper portion of the group. In this upper portion the fossils also are found.

Cumberland.—The Skiddaw slate of Professor Sedgwick is probably of nearly the same age as the rocks above mentioned.

None of the Cambrian rocks of Wicklow and Wexford are known to be metamorphosed, though it is possible that much of the mica schist and gneiss, with altered limestone of the north of Ireland, and of Scotland, and other parts of the world, are the metamorphosed clays, sands, and limestones of this period.

Bohemia.—Probably stage A (crystalline schist) and stage B (slate and conglomerate) of M. Barrande. No fossils known.

Scandinavia.—Regio 1. Fucoidarum of M. Angelia almost certainly is of this period.

America.—Sir W. Logan described rocks, apparently of

this period, below the Potsdam sandstone in Canada. No fossils. **Geology.**

Much of the metamorphic series of America,—as of Europe the great masses of gneiss and mica schist,—are doubtless altered Cambrian, or else still more ancient rocks, the unaltered members of which may never be known to us.¹

LOWER OR CAMBRO-SILURIAN PERIOD.

(*Upper Cambrian of Professor Sedgwick.*)

TYPICAL GROUPS OF ROCK.—Wales and the Border Counties.—

	Feet.
1. Lingula flags ²	5000?
2. Llandeilo flags	5000?
3. Caradoc Sandstone and Bala beds ...	9000
4. Lower Llandovery beds	1000

1. The Lingula flags.—Dark brown and blue flags and slates, interstratified in their lower beds with sandstones, and seeming to pass down by insensible gradations into the gritstones and slates of the Cambrian rocks below, to which they are quite conformable. Thickness several thousand feet.

2. Llandeilo flags.—Brown, fine-grained, rather sandy flags, and black earthy rotten slates. Thick beds of contemporaneous traps and ashes in some places. Thickness several thousand feet independent of the traps.

3. Caradoc Sandstone and Bala beds.—In Shropshire these are chiefly thick brown and yellow sandstones, often calcareous. In Merioneth, &c., they are gray grits and sandy slates, sometimes black slates with beds of sandstone. Near Bala they have a band of concretionary limestone 20 or 30 feet thick about their middle portion, called the Bala Limestone, and another smaller occasional band near the top called the Hirnant Limestone. Great masses of contemporaneous traps and ashes are interstratified with the slates and grits in some places. Thickness, without trap, about 9000 feet.

4. Lower Llandovery beds.—Gray and brown grits and conglomerates, with dark shales. Thickness several thou-

¹ Although few traces of life have hitherto been found in the Cambrian rocks, and no unaltered rocks below them are at present known, yet the conclusion that life now first began upon the globe is one that is anything but satisfactory to our mind. Even on the supposition that no more fossils should ever be found in Cambrian or still earlier rocks, the possibility of the existence of full assemblages of earlier life remains the same. Had general metamorphic action spread a few stages higher than it has, and the Silurian and Devonian rocks of Europe and America, and other parts of the globe, been affected by it, so as to have their organic remains obliterated and become generally converted into crystalline schists, it would have been argued that the carboniferous period was that in which life commenced upon the globe; and had large parts of the south-west of Ireland and South Wales been left unaffected by metamorphism, great formations of sandstones and slates of Devonian age, many thousand feet in thickness, might have been appealed to as utterly destitute of a single trace of organic existence, and therefore a proof that, during their deposition, life did not exist upon the globe. In Ireland, as in Wales, calcareous bands (cornstones, &c.) might be shown without a trace of a fossil for miles and miles, and ranging through a thickness of 10,000 or 12,000 feet of rock at the least. The present known districts where unaltered Cambrian rocks are visible may be just the parallels of such a case; and their metamorphosed contemporaries and still earlier formations may once have been crowded with organic forms, none of which we shall ever see. We do not assert that it was so, but merely that we have not yet arrived at *any proof* that it was not, nor has the accumulation of negative evidence been yet of any thing like sufficient extent to preclude even its probability.

² Sir C. Lyell, in his Manual, draws the boundary between Cambrian and Silurian at the top of the Lingula flags, and, palæontologically, such a boundary seems well founded. It is, however, impossible to draw any physical boundary in North Wales between 1 and 2, since they are both similar dark-coloured slates and flags, and there is conformity of position throughout.

¹ It is evident that the maximum thickness must be taken as the true measure of time, or rather as the nearest approximation to it. Any less thickness at other localities merely shows that a greater portion of the period elapsed without any deposition taking place there. Much time may pass without leaving any record of its passage, but proof that time elapsed in any one locality proves that it elapsed everywhere.

Geology. sand feet, occupying all Cardiganshire, great part of Glamorgan and Radnor—the Plynlimon rocks.

Ireland.—The Lingula Flags are not yet known in Ireland. Their discovery would be of interest, as it would be of importance to know whether they would be conformable to the Cambrian or to the Lower Silurian rocks, or would, as in Wales, introduce conformity throughout the series.

The Lower or Cambro-Silurian rocks of Wicklow, Wexford, and Waterford, are of the Bala and Caradoc sandstone age, as shown by their fossils, with unfossiliferous beds below them that may or may not belong to the Llandeilo flags. They consist of dark blue or black and gray flags, slates and grits, sometimes, as in Wales, becoming purple, green, olive, &c. They contain many contemporaneous beds of trap and ash (felstone, &c.) like those of Wales, and one or two calcareous bands (very like the Bala limestone), near Courtown, and at Tramore. Their thickness must be many thousand feet, but there are no good continuous sections sufficient to determine it exactly.

They repose on the Cambrian rocks below, quite unconformably, stretching directly across the ends of the beds, and coming into contact with different portions of the lower rocks.

The fossils are found only in the upper part of the series in the neighbourhood of the traps¹ and calcareous bands, and the exact relations of the lower beds are accordingly unknown.

Another great tract of apparently similar beds stretches from the centre of Ireland (Cavan, &c.) to the coast of Down. It contains a bed of anthracite, which is worked and locally used for coal, and this is said to reappear in one or two spots in Tipperary, &c.

On the flanks of the Dublin and Wicklow granites the Lower Silurian slates and grits are greatly metamorphosed into mica and other schists, and occasionally into gneiss, full of crystals of andalusite, staurolite, schorl, feldspar, and other minerals.

Other metamorphic tracts in the north of Ireland may be also composed of metamorphosed Lower Silurian rocks.

Cumberland.—The Coniston group of Professor Sedgwick is doubtless the equivalent of the Caradoc sandstone and Bala group. Whether the group below (his chloritic slate and porphyry) ought to be placed with the Llandeilo flag or the Lingula flag, is difficult to decide in the absence of fossil evidence. The latter is perhaps the more likely of the two, and seems to be the belief of Professor Sedgwick himself.

Scotland.—The rocks of the border Highlands from Dumfries to the Lammermuir Hills belong to this period, probably both to the Llandeilo flags and the Caradoc sandstone.

Bohemia.—Stage C, argillaceous schist, and stage D, quartzites, &c., of Barrande, are of this period. Stage C probably corresponds to the Lingula flags, but is more fossiliferous, containing twenty-seven species of trilobites alone. Stage D will then answer either to the Llandeilo flags or the Caradoc sandstones, or both.

Scandinavia.—M. Angelin's Regio A, Olenorium, and Regio B, Conocorypharum, consisting of aluminous schists and limestone, approximately=stage C of Barrande, and therefore approximately=Lingula flags.

Angelin's Regions.—BC, Ceratopygarum (aluminous schist and black limestone); C, Asaphorum (gray and reddish impure limestones); and D, Trinucleorum (marly schists with calcareous concretions) are together approximately=stage D of Barrande.

North America.—According to Professor H. D. Rogers, **Geology.** the following is the series of the Lower Silurian rocks of North America:—

		Feet.	
HUDSON GROUP.	{ 11. Lorraine shale and sandstones.....	2000	
	{ 10. Utica slate.....		
	{ 9. Trenton limestone.....		
BLACK RIVER GROUP.	{ 8. Black River limestone.....	2500	
	{ 7. Bird's-eye limestone.....		
	{ 6. Chazy limestone.....		
	{ 5. Calcareous sandstone.....		100
	{ 4. Upper Primal slate.....		700
POTSDAM GROUP.	{ 3. Potsdam sandstone.....	700	
	{ 2. Lower Primal slate.....	1200	
	{ 1. Conglomerate, with quartzose, feldspathic, and slaty pebbles.....	150	

The beds described by Mr Dale Owen are an extension and development of the Potsdam sandstone, in the country west of Lake Michigan. They are probably of the age of the Lingula flags, or may be still older.

At the close of this period, or immediately after it, very considerable movements of elevation and disturbance took place over the area now occupied by the British Islands, and some parts of Western Europe. Denudation consequently occurred, removing large portions of the upper rocks, and exposing the surfaces of those below. The rocks of the next period, therefore, are very frequently unconformable to those of this and the preceding period, resting now on one and now on another portion of them. This unconformity always involves the supposition of a vast lapse of time to allow of the slow action of elevating and denuding forces to produce the effect. Wherever unconformity is noted in future, the student will be careful to apply these remarks.

UPPER SILURIAN PERIOD.

TYPICAL GROUPS OF ROCKS.—*England.*—*Siluria; the Border Counties of England and Wales.*—

10. Tilestone..... 800
 9. Upper Ludlow rock..... 650
 8. Aymestrey limestone..... 100
 7. Lower Ludlow rock..... 1000
 6. Wenlock limestone..... 300
 5. Wenlock shale..... 1500
 4. Woolhope limestone..... 50
 3. Denbighshire sandstone..... 2000
 2. Tarannon shales..... 1000
 1. Upper Pentamerus beds, or May Hill sandstone, or Upper Llandovery beds..... 1000

The sandstones of the May-Hill group were at one time confounded by the geological survey with the true Caradoc sandstone, which they often greatly resemble in lithological character. Professor Sedgwick first pointed out their difference; and the officers of the Geological Survey afterwards traced the boundary between the two, and showed that the sandstones of the Upper Silurian period rested unconformably on those of the Lower. The first mistake unfortunately had a bad influence on the survey of North Wales, where a thick sandstone formation, lithologically resembling the true Caradoc formation of Shropshire, was taken for it, and therefore the Bala beds were presumed to be below the Caradoc, while in reality they were themselves its true representative. (*Ramsay MS.*) This thick sandstone formation of North Wales, then, described first by Mr Bowman (British Association), and then by Professor Sedgwick, under the name of *Denbighshire grits*, together with the other beds associated with it, requires to be admitted as a new, and, locally, a very important member of the Upper Silurian series. It has other beds underneath, more or less intimately associated with it; and the group forms the true base of the Upper Silurian series, reposing

¹ The eruption of igneous rocks at the bottom of the sea, though doubtless occasionally destructive of animal life at the moment, seems generally favourable to its development during the period. Contemporaneous trap rocks have often highly fossiliferous beds intimately associated with them.

Geology. almost invariably, in an unconformable position,¹ on the perfectly distinct Lower or Cambro-Silurian rocks below. (See Professor Ramsay's forthcoming *Memoir on North Wales*.)

1. Upper Llandovery sandstone, or Pentamerus beds, or May-Hill sandstone.—Gray and brown sandstones and conglomerates, with (in Shropshire) very calcareous bands, almost limestones. Thickness, 800 to 1000 feet.

2. Tarannon shales.—Generally pale gray, nearly white shales or slates, very fine grained (spoken of by Professor Sedgwick as "paste rock"), sometimes becoming of a bright-red colour. Thickness, 500 or 800 feet.

3. Denbighshire sandstones and flags.—Generally thick-bedded yellowish or brownish sandstone, largely made up of angular grains of white feldspar, with grains of quartz occasionally as large as peas, and passing into conglomerate. These are interstratified with beds of brown slaty shale, and occasionally dark, nearly black slate, overlaid by hard brown and blue flags. Thickness at least 2000 feet.

4. Woolhope limestone.—A locally occurring group of beds of gray, argillaceous, nodular, concretionary limestone, interstratified with gray shales, occasionally attaining a thickness of 100 feet.

5. Wenlock shale.—Generally dark-gray, sometimes black shale, with occasional calcareous concretions, capped by

6. Wenlock limestone.—An irregularly-occurring set of concretionary limestones, sometimes thin and flaggy, sometimes massive, highly crystalline bosses of carbonate of lime; sometimes in one, sometimes in two or three sets of beds, with interstratified shales, forming a thickness of 100 to 300 feet.

7. Lower Ludlow rock of Shropshire is generally a brown or gray sandy flag, or argillaceous sandstone, locally called mudstone.

8. Aymestrey limestone.—A nodular concretionary limestone, sometimes pure and crystalline, at others argillaceous and impure; like the Wenlock, but more local in its occurrence.

9. Upper Ludlow of Shropshire, &c.—A gray argillaceous sandstone, often calcareous, and containing calcareous nodules passing up into shales with sandstones, which gradually acquire a red colour.

10. Tilestone.—Red, shaly, and flaggy sandstones. At the base, near the junction of the Ludlow and tilestone beds, are one or two little thin but very widely extended bands, called "bone beds," full of the teeth and bones of small fish. Wherever these widely-extended but very thin beds full of peculiar fossils (the inhabitants generally of a clear sea) are met with, it may be expected that there is a great gap in the series, and that many intermediate beds, perhaps a formation or so, will be found elsewhere.

Cumberland, &c.—According to Professor Sedgwick, the following are the typical groups of rocks deposited during the Upper Silurian period in the north of England:—

- 3. Kendal group = Ludlow rocks.
- 2. Ireleth slates = Wenlock rocks.
- 1. Coniston grits = May-Hill sandstone.

1. The Coniston grits have few fossils, and their identity with the May-Hill sandstone is therefore doubtful, although very probable.

2. The Ireleth slate group is divided into four stages: *a.* Lower Ireleth slate; *b.* Ireleth limestone; *c.* Upper Ireleth slate; *d.* Coarse slate and grit. Fossils are rare, but generally of the Wenlock type.

3. The Kendal group is divided into three stages: (*a.*) A great group of flags and grits; fossils abundant and of the

Lower Ludlow type. (*b.*) Thick grit and flagstone, with bands of coarse slate; fossils locally abundant, and of Upper Ludlow type. (*c.*) Tilestones, resembling those of Shropshire, &c. (Sedgwick, *Synopsis of Classification, &c.*)

Scotland.—Not much has hitherto been known as to the existence of Upper Silurian rocks in Scotland. The representatives of the tilestones, however, and probably the lower groups, have lately been discovered by Mr Slimon of Lesmahago, and described by Sir R. Murchison. (*Geological Journal*.) These are dark-gray schistose rocks, with lighter and more siliceous stony bands, and other schists containing calcareous concretions.

Ireland.—No detailed descriptions of the Upper Silurian rocks of Ireland have yet been published. The labours of Mr Griffith, however, and more recently of the Geological Survey, have shown the existence of rocks of this age on the western side of the island. The Dingle promontory contains the representatives of both the Ludlow and Wenlock rocks, and possibly of part of the May-Hill sandstone group also. Abundance of most of the characteristic fossils, and some not found in England, though occurring in the Upper Silurian rocks either of Scandinavia or of North America, have been found.

In Galway, as shown by Mr Griffith, and confirmed by Sir R. I. Murchison and others, there is a vast series of gray grits and slates reposing unconformably on mica schist, &c., and having frequently red sandstones at its base, and sometimes great beds of conglomerate in its upper part, containing perfectly-rounded pebbles and boulders of quartz rock and syenite up to 18 inches in diameter.¹ Abundance of fossils have been found near the base of this series, comprising all the characteristic species of the May-Hill sandstone or Pentamerus beds, and in other parts an assemblage of corals like those found in the Wenlock rocks. This great group of rocks in Galway must have a thickness of several thousand feet at least, but its details have yet to be worked out.

Somewhat similar rocks form a small range of high land at Ughool, near Ballaghaderreen in Mayo, from which a great series of Wenlock corals and other Upper Silurian fossils had been collected by Mr Griffith, and also last year by Mr Kelly and ourselves.

One feels inclined to speculate from these facts on the former existence of a range of mountains rising where the Irish Sea now flows, and composed of an axis of Cambrian and Lower Silurian rocks, with Upper Silurian on their flanks sloping down into the border country of England and Wales on the one side, and to the west coast of Ireland on the other.

Bohemia.—The rocks deposited during the Upper Silurian period in what is now Bohemia are divided by M. Barrande into—Stage E, Calcaire inferieur. Stage F, Calcaire moyen. Stage G, Calcaire superieur. Stage H, Schists culminaux.

Scandinavia.—M. Angelin similarly divides the Upper Silurian rocks of this district into his Regio D, E, Harparum—shales and white limestones; and Regio E, Cryptonomorum—limestones resting on sandstones and shales.

Of these, Stage E of Barrande and Regio E of M. Angelin certainly equal very nearly the Wenlock rocks of Sir R. Murchison, there being 18 species of Brachiopoda, besides corals and other fossils common to this group of rocks in the three countries. Sir R.

¹ So long as the Denbighshire grits were supposed to be the same as the Caradoc sandstone, the unconformity of the Upper on the Lower Silurian, which in Derbyshire and Merionethshire is not, very striking, was entirely overlooked.

¹ In an excursion last summer with Mr John Kelly, we measured some of the smooth round boulders of syenite embedded in these Silurian rocks, and found them frequently a foot, and sometimes, though rarely, eighteen inches in diameter. Other almost equally massive conglomerates occur in the Silurian rocks of Lisbellaw, south of Enniskillen. In Galway, on the northern side of the beautiful promontory of Kilbride, on the shores of Lough Mask, a magnificent assemblage of fossils is to be seen in the rocks of the beach.

Geology. Murchison gave in 1847 a list of 74 species found in the rocks of Gothland (Regio E), 47 of which occur in Britain, 13 in Ludlow rocks, and 14 in the Wenlock, the 20 others being found in both. The Regio D. E. of M. Angelin is not represented in Bohemia. It may possibly be equal to May-Hill sandstone. The stages F, G, H of Barrande are not recognisable in Scandinavia.¹

North America.—The rocks of this region of the age of the Upper Silurian period are—

	a. Soft brown argillaceous sandstone, and red shale	600
	1. Gray sandstone, with thick beds of siliceous conglomerate, containing fragments of the lower rocks.....	400

According to Professor Rogers (Johnston's *Physical Atlas*, 2d ed.), not only does the Medina group contain a conglomerate made of pebbles of the lower rocks, but the whole Upper Silurian rocks are distinctly unconformable to the Lower, as they are in Wales and other parts of the world.

DEVONIAN PERIOD.

TYPICAL GROUPS OF ROCK.—There has long hung much obscurity over the classification of the rocks which belong to this period. This has chiefly been owing to the fact that we have in the British Islands two distinct types of rock which never come into close contiguity with each other, and do not contain any fossils in common, but are yet undoubtedly intermediate in age between the Silurian and Carboniferous periods. One of these types has long been known to British geologists as the Old Red Sandstone; the other, confined to Devon and Cornwall, was not classed with the former till Mr Lonsdale, and Professor Sedgwick, and Sir R. I. Murchison worked it out. The Old Red Sandstone type is not known on the Continent; but the rocks and fossils of Devon re-appear in the Eifel and other parts of the Continent. The Old Red Sandstone was formerly placed as the lowest rock of the Carboniferous series by some authors (Professor Phillips and others); while a part of what was formerly called Old Red Sandstone by others (Tilestone) is now placed as the upper part of the Silurian series. Recent researches by the Geological Survey in Kerry and Cork induce us to believe that what has hitherto been called Old Red Sandstone, and treated as one great group, must in reality be separated into two—the upper part, or Old Red Sandstone proper, being really the base of the Carboniferous; while the

lower portion must be separated from the rest under **Geology.** another designation, and looked upon as more closely allied to the Silurian system. In the Dingle promontory there are good representatives of Wenlock and Ludlow rocks, the latter containing abundance of *Pentamerus Knightii* and other Ludlow fossils, surmounted quite conformably by two great groups of purple and green gritstones and conglomerates; while over all these, widely and utterly unconformable to them and to the Silurian rocks, there sweep red sandstones and conglomerates 3000 or 4000 feet thick, which pass up conformably into the base of the Carboniferous series. This upper group of red sandstones and conglomerates also contains fossils (plants in Ireland, plants and fish in Scotland) that place it in more close connection with the Carboniferous than with any formation.

We shall also separate from the rocks of this period those which are called Upper Devonian in Devonshire (the Marwood, Pilton, and Petherwin beds), and treat them as belonging to the Carboniferous period.

There remains some little doubt, perhaps, whether the middle and lower Devonian groups of Devonshire be strictly contemporaneous with the middle and lower Old Red Sandstone. The latter contain fish and a few plants only, while the former have neither fish nor plants in them—in the British Islands at all events. We shall therefore describe them separately as belonging to this period, but without attempting to draw them more closely together. In Russia, indeed, the fish of the one are found with the fossils of the other, as shown by Sir R. I. Murchison; but questions of geographical distribution arise to complicate any deductions as to exact synchronism in two such distant localities.

Devon and Cornwall.—A great series of slates, sandstones and conglomerates, and limestones, of various textures and colours, brown, blue, and red. According to Professor Sedgwick, they may be classed as follows:—

3. DARTMOUTH SLATE GROUP.—Coarse roofing-slates and quartzites, ending upwards with beds of red, green, and variegated sandstone.
2. PLYMOUTH GROUP.
 - c. Coarse red sandstone and flagstone.
 - b. Calcareous slates.
 - a. Great Devon limestone.
1. LISKEARD OR ASHBURTON GROUP.

Belgium and the Rhine.—A series of rocks of a similar type, and with similar fossils to those just mentioned, are found in this district. They are divided by M. Dumont into—

3. EIFEL GROUP.
 - c. Eifel limestone.
 - b. Gray shales, occasionally calcareous.
 - a. Red sandstone and conglomerate.
2. AHRIAN GROUP.—Bluish-gray grits, sandstones, and shales.
1. COBLENTZ GROUP.—Green and gray grits, sandstones, and shales.

Sir R. I. Murchison, in his *Siluria*, gives a slightly different classification into Lower, Middle, and Upper Devonian; the Upper containing some beds above the Eifel limestone, as follows:—

3. UPPER.
 - b. Clymenia and Cypridina schists.
 - a. Goniatites retrorsus schists.
2. MIDDLE.
 - b. Eifel or Stringocephalus limestone.
 - a. Calceola schists = Ahrian group.
1. LOWER.
 - b. Wissenbach slates.
 - a. Coblenz or Spirifer sandstone.

The upper division, however, is clearly the same as that which we have thought it best to transfer to the Carboniferous period.

Rocks and fossils like those of Devon and Cornwall not being known in any other part of the British Islands, we must speak of those now to be described as Devonian, with a certain reserve as to the exact propriety of the name. They have hitherto all been described as Old Red Sandstone, which has been taken as synonymous with Devonian.

Scotland.—The labours of the late lamented Hugh Mil-

¹ We have perhaps dwelt at a little greater length on these facts relating to the Silurian period than the relative importance of the rocks of that period might warrant, because they bring before the reader's notice principles which are equally applicable to the rocks of all other periods.

Geology. ler on the so-called Old Red Sandstone of Scotland have made that district classic ground. According to his classification, as given by Professor Sedgwick in his Synopsis, the series of rocks are the following :—

UPPER.	7. Yellow siliceous sandstone.
	6. Impure concretionary limestone.
	5. Red sandstone and conglomerate.
MIDDLE.	4. Gray sandstone and earthy slate.
LOWER.	3. Red and variegated sandstone.
	2. Bituminous schists.
	1. Great conglomerate and red sandstone.

The upper division we should now relegate to the base of the Carboniferous series; and Miller, in his *Testimony of the Rocks*, throws some doubt on the superposition of No. 4 above 3 and 2. It appears that they nowhere come actually into contact, and that it is possible that No. 4 may be a fresh-water deposit, more or less contemporaneous with the marine beds 3 and 2. The balance of evidence, however, both in Miller's opinion and that of Professor Sedgwick, recently confirmed to ourselves, is in favour of the order given above.

Herefordshire and South Wales.—The Old Red Sandstone of this large district is composed of the following groups :—

	Feet.
2. Red and yellow sandstone marls and conglomerate.....	3000 or 4000
1. Cornstone group.....	5000 or 6000

Of these we believe No. 1 only properly to belong to the Devonian period, and shall describe No. 2 in the Lower Carboniferous period.

1. The Cornstone group consists of a great series of red and white sandstones and red and green marls and shales, with frequent partial bands of impure concretionary limestone, locally known as "cornstone." It graduates down quite conformably and insensibly into the tilestone of the Upper Silurian period.

Ireland: Kerry and Cork.—In the Dingle promontory we have the following groups lying conformably on the Ludlow rocks :—

	Feet.
3. Dingle beds.....	4000
2. Glengariff grits.....	6000
1. Red slates and sandstones.....	1000

1. The red slates and sandstones lying conformably over the rocks containing *Pentamerus Knightii* and other Ludlow fossils, may possibly be the representatives of the Tilestone group; but as it contains no fossils in Kerry it is impossible to determine this satisfactorily.

2. The Glengariff grits consist of very thick-bedded massive green or purple sandstones or gritstones, of a very peculiar lithological aspect, interstratified with beds of red or green slate. Sometimes the sandstones, sometimes the slates, are calcareous, forming concretionary beds not unlike debased cornstones. Steady sections of 5000 or 6000 feet may not unfrequently be seen in these rocks in the promontories of Dingle, Iveragh (between Killarney and Valentia), and those lying between the bays of Kenmare, Bantry, Dunmanus, and Roaring Water.

3. Dingle beds.—These consist of red sandstones and slates, with beds of conglomerate, which in the Dingle promontory are thick and prominent, containing angular and subangular fragments of red jasper, hornstone, felstone, and other rocks, together with pebbles of Silurian limestone or calcareous sandstone containing *Pentamerus oblongus* and other fossils of the May-Hill sandstone group.

Over the upturned and denuded edges of all these beds, as well as across the edges of the Silurian beds below, sweep the thick beds of red sandstone and conglomerate which form the Old Red Sandstone. This is the case throughout the Dingle promontory; but in that of Iveragh, on the

Geology. south side of Dingle Bay, and over all the rest of the country, this unconformity is no longer perceptible, and the conglomerates also rapidly die out to the south, so that we get only the Glengariff grits covered by red and purple slates and sandstones, with no very obvious boundary between them and the Dingle beds, nor between the latter and the Old Red Sandstone.

North America.

	Feet.
9. Catskill group, red shales and red and gray sandstones, with a few white quartz pebbles.....	5000
8. Chemung group, gray, blue, and olive-coloured shales, and gray and brown sandstones.....	3200
7. Portage group, fine-grained gray flagstone, with blue shale partings.....	1700
6. Genesee slate, brownish-black and bluish-gray slate.....	300
5. Hamilton group, bluish-gray, brownish and olive shale, with thin dark-gray sandstones.....	600
4. Marcellus shales, black and bituminous, with thin argillaceous limestone at base.....	300
3. Upper Helderburg or Corniferous limestone, straw-coloured, light-gray or bluish, with chert nodules.....	350
2. Caudagalli grit, argillaceous, calcareous, thin-bedded sandstone.....	300
1. Oriskany sandstone, coarse yellowish calcareous sandstone.....	200

The Oriskany sandstone is considered by its fossils to be undoubtedly contemporaneous with the Lower Devonian group of the Rhine. The others represent the superior parts of that formation, and it is possible that some of them are rather Lower Carboniferous than Devonian.

Formations possibly belonging to the Devonian period are largely developed in Australia; and characteristic fossils have been brought from China, where they are used as medicines.

The Cape of Good Hope, too, has large formations, believed to belong to the Devonian period, of which we may shortly hope to hear more from the labours of Mr Andrew Wyley.

CARBONIFEROUS PERIOD.

Preliminary Observations.—In the account of the deposits of the preceding period it will be seen that we have ventured to detach from it the rocks called Upper Old Red in Scotland and Upper Devonian in Devonshire; and by parity of reasoning, the Upper or Old Red Sandstone proper of the south of Ireland and of South Wales; and to consider the rocks so detached as forming the base of the Carboniferous system of rocks. This conclusion has been forced upon us rather unwillingly, and against our previous belief, by the examination of the structure of the south of Ireland. It has always been the opinion of the Irish geologists, especially of Mr Griffith and Mr John Kelly, of whom the latter has published this opinion in a paper in the *Journal of the Geological Society of Dublin*. The correctness of their view on this point, however, was obscured by the endeavour to identify all below the Old Red Sandstone proper with Silurian rocks, and altogether to obliterate the Devonian period. Admitting the existence of a Devonian period as intermediate between the Silurian and Carboniferous, and placing in it the rocks and fossils just described as belonging to it, we may retain the Old Red Sandstone proper, that which stretches round the Carboniferous rocks of the south-east of Ireland and those of South Wales and the border counties, and the thin skirts and patches of Old Red in North Wales and North England, and the upper part of that of Scotland, as forming the true commencement of the Carboniferous period. There is in many places a perfect blending of the Old Red into the Lower Carboniferous rocks, or into beds which contain fossils having commonly a generic and often a specific identity with undoubted Carboniferous forms. Still there are a sufficient number of peculiar species, both of plants and shells in these lower rocks, to warrant the separation of the Carboniferous sys-

Geology. tem of the British Islands into an upper and a lower series, the general terms of which may be stated as follows:—

- UPPER. { 4. Coal measures.
3. Carboniferous limestone.
2. Carboniferous slate, or Lower Limestone shale, with
Lower. { Coomhola grits and yellow sandstones.
1. Old Red Sandstone, passing up into Yellow Sandstone.

TYPICAL GROUPS OF ROCK.—*Ireland*.—We have already said, that in the Dingle promontory there is a mass of 3000 or 4000 feet of red Sandstones and conglomerates, the true Old Red Sandstone, utterly unconformable to the Devonian and Upper Silurian rocks below, but conformable to the Carboniferous rocks above. The junction, however, of the Old Red and Carboniferous is not very well seen there, but is admirably shown when the rocks are traced round to the neighbourhood of Glengariff, at the head of Bantry Bay. In this district the Glengariff grits are the lowest rocks seen, having the characters before described, and being surmounted by a great series of purple, and red, and green sandstones and slates which must represent both the Dingle beds and the Old Red Sandstone, all lying apparently conformably, and without any marked boundary between them.

The upper part of this red series alternates with many green and gray coloured beds, and some liver-coloured slates, and in these fragments of plants are found. A little higher the red colour disappears, and we have grits and slates of various shades of green, yellow, or gray, eventually interstratified with black shales or slates. These black beds rapidly increase in thickness as we ascend, still interstratified at first with numerous sets of beds of thick massive gritstone; but above these black shales or slates alone occur, eventually becoming calcareous, and containing thin beds of impure concretionary limestone.

The fossils of these calcareous bands, which are the highest beds seen in Bantry Bay, are all Carboniferous fossils such as are found in the Lower Limestone shale of South Wales and elsewhere. Carboniferous species, shells, and encrinites, likewise occur in the shales, interstratified with the grits below, and also in the grits themselves; but there are here also other fossils which are not found in the higher part of the series. Together with these fossils are some plants similar to, but not exactly identical with, the plants usually found in the Carboniferous series, and these plants extend down into the green and gray shales interstratified with the red beds, where, however, they are not accompanied by marine species. We would group these beds, then, as follows:—

	Feet.
CARBONIFEROUS SLATE.	5. Lower Limestone shale with calcareous bands..... 150
	4. Dark-gray and black slates and shales 2000
	3. Coomhola grit series 2500
OLD RED SANDSTONE.	2. Yellow Sandstone series..... 1000
	1. Red Sandstone and slate 2000

1. The Red or purple Sandstone and slate contains a few green or gray beds, but no fossils. It stretches continuously from the extreme west of Cork and Kerry into Waterford and Tipperary, where it reposes unconformably on the Lower Silurian rocks, having a conglomerate at its base, partly made of the fragments of the rocks it rests on, partly of well-rounded quartz pebbles. It still retains a thickness of 2000 or 3000 feet, till it dies away rapidly towards Wexford in one direction, and towards Carlow in the other, reappearing afterwards merely as little local patches here and there in the hollows of the lower rocks.

2. The Yellow Sandstone series can only be separated from No. 1 by the greater abundance of greenish, grayish, and yellowish beds among the red ones, and by the occurrence of remains of plants in the former. It is continuous with No. 1 over all the south of Ireland, and probably extends

Geology. a little further than it, since the thinning out of the Old Red Sandstone seems to take place from below upwards, higher and higher beds extending further and further, showing gradual depression to have been taking place during the period.

3. The Coomhola grit series can only be separated from the yellow sandstone by the shales between the grits being dark-gray or black, and the occurrence of some marine species in some few of the beds together with the plants.

4. The dark-gray shales and slates are perfectly well marked by the absence of grit beds, but they contain few or no fossils in Bantry Bay.

5. The Lower Limestone shale cannot be separated from the shales and slates below, except by the occasional appearance of calcareous bands together with an abundance of some Carboniferous fossils. The latter rocks, Nos. 3, 4, and 5, preserve the characters and the thickness first assigned to them over all the country from Bantry Bay to the Old Head of Kinsale and the mouth of Cork Harbour, the only variation being a diminution in the number and thickness of the gritstones in the Coomhola grit series, and a corresponding increase in the dark-gray slates above. They likewise preserve their character and thickness northwards as far as Sneem on the north side of Kenmare Bay. But when we proceed to the head of this bay about Kenmare itself we find a remarkable change to have occurred. The Carboniferous limestone there makes its appearance in its ordinary form, having under it a thickness of about 50 feet of the beds first described as Lower Limestone shale, precisely similar to the shales with calcareous courses in Bantry Bay, and containing the same fossils. But at Kenmare these beds rest directly on red slates and sandstones, forming the upper part of the Old Red Sandstone; the great mass of the Carboniferous slate series, with all the Coomhola grit group that is so strongly developed 10 or 15 miles to the westward and southward, being entirely absent at Kenmare. Neither does this absence of a group of beds nearly 5000 feet thick produce any apparent unconformity, though, as all the beds are at very high angles, and a good deal contorted, it is impossible to decide whether they were originally conformable or not. North and east of Kenmare, over all the rest of the south of Ireland to Tralee, Ballybunnion, and Limerick on the north, and to Cork, Youghal, and Wexford on the east, this latter type prevails, the whole of the Carboniferous slate group being absent except the small portion of it called here the Lower Limestone shale.

We believe, then, that all the beds mentioned above as lying below the Lower Limestone shale form in reality a Lower Carboniferous series, which is only locally developed in its true proportions,—introducing when it is so developed a perfect apparent continuity and blending from the base of the true Old Red Sandstone, or perhaps in some places even from the Devonian rocks themselves, up into the highest of the Carboniferous series.

Devon and Cornwall.—The Petherwin slates, the Pilton beds, the Marwood sandstones, and others belonging to the same period as the Carboniferous slate and Coomhola grits of Ireland.

South Wales.—The Old Red Sandstone surrounding the South Welsh coal-field has a base of conglomerate reposing on the Devonian cornstones, over which are red sandstones and marls, which in their upper parts have yellow sandstones interstratified with them, containing fragments of plants, and appearing to graduate upwards into the black shales and sandstones of the Lower Limestone shale, which in its upper part is interstratified with beds of limestone, passing thus into the base of the Carboniferous limestone.

Scotland.—In accordance with the classification here adopted, we must place in the Lower Carboniferous series the beds called Upper Old Red Sandstone of Scotland, which, if our present views be correct, should be called Old

Geology. Red Sandstone only; the so-called Middle and Lower Old Red Sandstone being termed Devonian.

They consist of red sandstones and conglomerates, having in their upper part yellow sandstones, in which plants and fish remains are found, and these are believed to be connected more or less with the base of the Upper Carboniferous rocks, through the group called Calciferous sandstone by Mr Maclaren, which is possibly of about the same age as the Coomhola grits of the south-west of Ireland.

The Rhine.—If the views here given as to classification be correct, we must place as Lower Carboniferous the rocks called Upper Devonian in the Rhenish provinces, which are subdivided by F. Roemer into

4. Schists with *Rhynchonella cuboides* and *Producta subaculeata*.
3. Schists with many *Clymenia*, *Goniatites*, and *Cypridina*.
2. Limestone with *Goniatites auris*, &c.
1. Schists with *Receptaculites Neptuni*.

No. 1 may possibly be a Devonian rock, as the undetermined fossil called *Receptaculites Neptuni* occurs in Ludlow rocks at Ludlow; but the other three groups are identified with the so-called Upper Devonian of Devon, especially by the presence of the little *Cypridina serratostrata* in great abundance. (Murchison, *Siluria*, p. 372.)

UPPER CARBONIFEROUS ROCKS.

Taking the Old Red Sandstone proper as the true base of the great Carboniferous system of Britain, and understanding that the great mass of the Carboniferous slate group above it is found only in the south-western corners of Ireland and England, dying out everywhere rapidly to the north and east, except a few of the upper beds, known as the Lower Limestone shale, which seems also to die out towards the north and east in England, though they spread over all Ireland; and taking into account that the Old Red Sandstone proper appears to be entirely wanting in Devon and Cornwall, where the Carboniferous slate rests on true Devonian rocks,—we have now to trace the range of the upper part of the Carboniferous system through the British Islands. In doing this we will again commence with the south-west portions of—

Ireland—Kerry, Cork, and Waterford.

2. Coal Measures	Feet. + 2000
1. Carboniferous limestone	1500
Old Red Sandstone.	

No. 1. Over this district the Carboniferous limestone forms a nearly unbroken series of beds of gray limestone, sometimes compact, sometimes crystalline, generally in very highly-inclined positions, and often so traversed by slaty cleavage as to have its stratification entirely obscured. It occurs only in the plains and bottoms of the valleys.

No. 2. Directly on the upper beds of the limestone occur black indurated shales, likewise traversed by slaty cleavage, but never making good roofing-slate; higher up, these alternate with greenish or olive-coloured fine-grained grits and flags; and among these, or above them, occur two or three thin bands of coal, together with abundance of coal plants. The shales have often curiously concretionary globular forms, of one or two feet in diameter, appearing in them, piled one over the other; a single spheroid sometimes embracing parts of two or more beds. Except weathering into these singular spheroidal forms, the shales do not appear different from those which are not concretionary. These Coal Measures are commonly highly-inclined and contorted, and often inverted, and the coals are not only changed into anthracite, but squeezed and crushed so as to be only got in small dice-like fragments. The regularity of the beds is also interfered with, so that beds of which the original thickness was probably a couple of feet or so, have now for many yards only one or two inches, and then sud-

denly expand into large pockets of coal 20 or 30 feet in thickness. Coal-mining here is conducted like vein-mining.

Clare, Limerick, Tipperary, Kilkenny, &c.

	Feet.	Feet.
5. Coal Measures		+ 2000
4. Upper Limestone	250 to 1000	
3. Calp or Middle Limestone	400 to 1000	
2. Lower Limestone	1000	
1. Lower Limestone shale	50 to 150	
Old Red Sandstone.		

No. 1 is everywhere the same as before described.

No. 2 is a series of thick gray limestones, generally light-coloured, sometimes crystalline, sometimes compact; large parts of it are magnesian, sometimes becoming a true dolomite. In some parts of the district some of the beds become as Oolitic as the Bath stone, still, however, retaining their gray colour. In some places, especially in Limerick, contemporaneous traps and trappean breccias are interstratified with these beds and with the upper or yellow part of the Old Red Sandstone below them.

No. 3. Black limestones, sometimes very earthy, interstratified with black shales, that become in some places more important than the limestones. The limestones of this group are usually unfit for burning into lime. Chert bands and nodules are very abundant in the Calp.

No. 4. Thick and thin bedded crystalline and compact limestones of various colours, but usually light-coloured. Chert bands and nodules are also abundant occasionally.

No. 5. The Coal Measures are exactly the same as those previously described in Kerry and Cork, except that they are little contorted, lying generally horizontal or nearly so, and the coal beds retain their thickness apparently unaltered,—this thickness, however, being rather inconstant between 6 inches and 2 or 3 feet. The fossils found in the lower part of these coal shales are marine—*Goniatites*, *Bellerophon*, and *Pecten papyraceus*. Coal plants, however, are abundant in the higher part near the beds of coal. It is possible that these Coal Measures may be of the same age as the millstone grit of central and northern England.

North of Ireland.—As we trace the Carboniferous series from the central to the northern districts of Ireland, a still further change takes place always in the same direction; that is, always becoming more complicated and subdivided as we proceed from south to north. The typical rocks then become—

7. Coal Measures.
6. Millstone grit.
5. Upper Limestone.
4. Calp { Upper Calp shale.
Calp sandstone.
Lower Calp shale.
3. Lower Limestone.
2. Lower Limestone shale.
1. Yellow Sandstone and Old Red Sandstone.

1. The Yellow Sandstone of Dr Griffith, as shown in the north of Ireland, is interstratified with dark shales and gray limestones, containing common Carboniferous fossils in great abundance. It has also red beds of shale interstratified with it, but may perhaps be a rather different group from the yellow sandstones forming the top of the true Old Red Sandstone in the south of Ireland.

2. This group does not appear to differ in any respect from the Lower Limestone shale of the south of Ireland.

3. The Lower Limestone is also apparently just like that of the south.

4. The Calp becomes more purely an earthy deposit, and the shales are split up by a considerable group of sandstone beds in its middle portion, sometimes containing traces and thin seams of coal.

5. The Upper Limestone is probably the same as the Great Scaur Limestone of the north of England.

Geology

6 and 7. These also are similar to the corresponding beds in Derbyshire and Yorkshire, shortly to be described.

Let us now turn to England, and trace in like measure the Carboniferous series from south to north.

South Wales and the Border Counties.—The rocks of the Carboniferous period may here be grouped as follows:—

	Feet.
4. Coal Measures.....	12,000
3. Millstone grit, or Farewell rock	1,000
2. Carboniferous limestone	2,000
1. Lower Limestone shale	500
Old Red Sandstone.	

1. The Lower Limestone shale consists of dark earthy shales, occasionally interstratified with yellowish sandstones below, and always with thin flaggy limestones in its upper part. It seems therefore to graduate downwards into the top of the Old Red Sandstone, as well as upwards into the Carboniferous limestone.

2. Carboniferous limestone.—A great series of compact limestones, thick and thin bedded, of various shades of gray and red, interstratified with brown, gray, and red shales below, and with shales and sandstones (often red) in the upper portion.¹ Thickness, 1800 to 2000 feet.

3. Millstone grit or Farewell rock.—A series of sandstones, hard, quartzose, white or gray, and near Bristol, red. Maximum thickness about 1000 feet.

4. Coal Measures.—An enormous series of alternations of many hundred beds of shales, sandstones, and coals, the latter varying from 1 inch to 7 or 8 feet in thickness. The total thickness of the whole group is not less than 7000 feet, and is believed in some places to be even as much as 12,000 feet.²

Near Bristol it is thinner, and is divisible into three sub-groups, having a central band of hard sandstones called Pennant.

	Feet.
c. Upper Coal Measures	1800
b. Pennant series	1725
a. Lower Coal Measures	1665

This central band of sandstones is traceable also in South Wales by means of a hard quartzose sandstone called Cockshort rock.

In the Forest of Dean coal-field the thicknesses given above are diminished to about one-third, or—

	Feet.
Coal Measures.....	
Millstone grit.....	270
Carboniferous limestone	480
Lower Limestone shale.....	165

(*Mem. Geol. Survey*, vol. i., p. 129.)

Derbyshire, &c.—The base of the formation is not here seen, but we have the following groups:—

	Feet.
4. Coal Measures, more than	2700
3. Millstone grit	1600
2. Upper Limestone shale	400
1. Carboniferous limestone, more than	600

1. The Carboniferous limestone is a series of pure pale-gray, thick-bedded limestones, with scarcely a trace of clay or shale interstratified with them, over large areas, and through a thickness of several hundred feet. On the southwest, however, towards Staffordshire, shales alternate with its upper portion. Over the centre and north of Derbyshire two contemporaneous beds of greenstone, called toadstone, are interstratified with the limestones. The thickness of

these toadstones is sometimes as much as 100 feet, but generally 20 or 30.

2. Upper Limestone shale.—This is a series of beds of black shale, without either limestone or sandstone in all the central part of the district, and about 500 feet thick.

It is not recognised as an independent group in the South Welsh district.

It is generally devoid of fossils.

3. Millstone grit.—Thick, yellow, white or brown sandstones, sometimes fine-grained, sometimes very coarse, containing quartz grains as large as peas. Separated into four groups of sandstones by three little intervening coal-seams and their associated shales.

4. Coal Measures.—Alternations of sandstones and shales, with interstratified beds of coal generally resting upon fire-clay. The Lower Coal Measures in Derbyshire and Yorkshire contain many beds of hard sandstone called "ganister," and it is difficult to draw any decided boundary line between them and the Millstone grit.

Proceeding northwards from Derbyshire, we find a gradual change taking place in the arrangement and grouping of the beds mentioned above. The Coal Measures retain their characters, but the Millstone grit first becomes more separated by beds of shale and coal, while the Upper Limestone shale becomes split up by beds of sandstone above and of limestone below, and eventually likewise contains beds of coal; and, lastly, the limestone itself has its beds separated by shales and sandstones, which finally, as we go farther north, include beds of coal; so that the whole series becomes a great series of Coal Measures containing interstratified limestones in its lower part only. This change is perceptible by examining the rocks of *North Yorkshire and Durham*. (Phillips.)

	Feet.
4. Coal Measures, more than	2000
3. Millstone grit	414
2. Yoredale series.....	540
1. Great or Scaur Limestone group, more than	1119

1. The Great or Scaur Limestone, as described by Foster in Teesdale (Phillips' *Manual*, p. 163), consists of ten sets of beds of limestone from 7 feet to 130 feet in thickness, separated by as many sets of shale and sandstone varying from 12 to 240 feet thick, the total thickness of the whole being 1119 feet, with the bottom not seen.

2. The Yoredale series contains nine sets of limestone from 2 to 30 feet thick, with as many alternations of shales and sandstone from 17 to 70 feet thick, with occasional beds of coal, the whole being 544 feet thick.

3. The Millstone grit here contains one central band of limestone, called Feltpit lime, between alternations of sandstone, shale with ironstone, and coal, having a total of 414 ft.

4. The Coal Measures of the Tyne district (Newcastle, &c.) are about 2000 feet in thickness, containing about 600 separate beds (or measures), and a total of about 60 feet of coal. The coal lies in many beds, two of which are 6 feet in thickness, and three others 3 feet and more. The Lancashire coal-field, containing higher beds than are to be seen on the Tyne, is more than double this thickness, or about 5000 feet, including 75 beds of coal over a foot thick (some being 6 feet), and a total thickness of 150 feet of coal.

Scotland.—The Carboniferous rocks of the country between Edinburgh and Glasgow may be judged of from the following section, of which the upper 600 feet is taken from the Monkland district, and the rest from that of Carluke:—

	Feet.
Red Sandstone (Carboniferous)	
Alternations of sandstones and shales with coal and ironstone.....	130.0
Limestone.....	1.0
Alternations, &c., five beds of coal 4 feet thick, many others less.....	1635.0
Forward.....	1766.0

¹ Section near Bristol (*Mem. of Geol. Survey*, vol. i., p. 113). Along South Wales the group is more purely limestone, and much thinner, especially to the northward and westward.

² It was in the examination of the South Welsh coal-field, while on the geological survey of the United Kingdom, that Sir W. Logan was first struck with the invariable position of the beds of coal upon an "under-clay," crowded with stigmata (roots of *Sigillaria*, &c.), which he inferred was the old soil on which the plants grew that formed the coal.

Devon and Cornwall.—This district contains beds belonging to the Upper as well as the Lower Carboniferous series, but they are very anomalous and scarcely comparable with any degree of certainty with those of the rest of Britain. They consist of—

2. Culm Measures.

1. Shales and limestones, probably the Lower Limestone shale.

1. The shales, &c., over the Marwood sandstone group resemble more or less the Lower Limestone shales of South Wales, except that they are traversed by slaty cleavage, and have in their upper parts a dark-coloured limestone that may be a debased representative of the Carboniferous limestone.

2. The Culm Measures are a great series of alternations of shales (sometimes cleaved into slates), sandstones, and fine conglomerates, into a few beds of earthy anthracite or culm. Whether they are of the same age as the true Coal Measures is doubtful. They may perhaps have been deposited contemporaneously with part of the Carboniferous limestone, but under different conditions, and probably in water (fresh or salt) altogether separated from the seas of the north. Or if we suppose with Sir R. I. Murchison that the black limestone of group 1 represents the whole of the Carboniferous limestone, then the Culm Measures may be of the age of millstone grit, and possibly that of the coal-bearing rocks of the Kilkenny and the Kerry coal-field.

Midland Counties.—The Carboniferous rocks of the midland counties of England are by no means typical groups. They consist generally of the upper portion or Coal Measures only, resting unconformably on Silurian or still older formations. It is probable that during the time of the deposition of the Carboniferous limestone there was land existing where the midland counties of England now are, which land only became covered with water in consequence of a gradual depression taking place in the latter part of the Carboniferous period.

Belgium.—According to M. Dumont—

SYSTEME { 4. Alternations of "ampelite" (sandstone) shale, and
HOULLIER. { coal.

Geology. { 3. Crinoidal limestone, dolomite, Productus limestone, with chert and anthracite.
SYSTEME { 2. Gray sandstone, soft sandstone, and anthracite.
CONDUR- { 1. Gray shales, calcareous shales, dark limestone, and
SIEN. { pisolitic iron ore (oligiste).

Carboniferous rocks occur in small detached localities in many other parts of Europe, but do not admit of description as *typical* rocks of the period. The fossils contained in them agree with those already mentioned, with just that amount of difference that might be expected to arise from the laws of geographical distribution.

North America: Nova Scotia.—According to Mr Dawson—

UPPER { 3. Grayish and reddish sandstones and shales, with
GROUP. { beds of conglomerate, and a few thin beds of
limestone and coal. 3000 feet and more.
MIDDLE OR { 2. Gray and dark-coloured sandstones and shales,
GOOD COAL { with red and brown beds, coal, ironstone, and
GROUP. { bituminous limestone. 4000 feet and more.
LOWER or { 1. Red and gray sandstones and conglomerates,
GYPSIFEROUS { and red and green marls and shales, with
GROUP. { thick beds of gypsum and limestone. 6000
feet and more.

Altogether there is a thickness of more than 14,000 feet, without reaching any exact base, or arriving apparently at the very highest beds of the series. There are seventy-six beds of coal, of which, however, most are only 1 or 2 inches thick, and the thickest not more than 4 feet. (Dawson's *Acadian Geology*.)

Some of the beds of group 1, consisting of sandstones with variegated marls and gypsum, and a few beds of coal, were seen formerly by ourselves in Newfoundland, on the south shore of St George's Bay, and at the northern extremity of the Grand Pond. (*Report on Geology of Newfoundland*.)

United States.—According to Professor Rogers—

3. UPPER { Coal Measures, alternations of sandstones,
CARBONIFEROUS { shales, and coals, like groups 2 and 3 of
or COAL MEASURE { the Nova Scotia district, but thinning out
GROUP. { westward, so as to be only 3000 feet in

CARBONIFEROUS { ing with coarse siliceous conglomerates and
GROUP. { dark-blue and olive-coloured slates. In
some places contains black carbonaceous
slate, and a bed or two of coal. 2000 feet
thick in Pennsylvania, thinning out to
nothing in the north-west.

Australia: New South Wales.

5. Dark-brown shales, with impressions of plants, 300 feet and more.
4. Sydney sandstone, thick white or light-yellow sandstone, with quartz pebbles occasionally, and partings of shale, 700 feet.
3. Alternations of shales and sandstones, 400 feet.
2. Shales containing two or three good beds of workable coal 6 feet thick, 200 to 300 feet.
1. Wollongong sandstones, thick dark-gray reddish-brown, often calcareous, with large calcareous concretions, 400 feet and more.

¹ The light-blue limestone mentioned above thickens toward the south-west and dies away to the north-east in Pennsylvania.

Geology. This is only a part of the series, as there may be beds below No. 1, and others above No. 5.

Victoria.—The same formations as New South Wales. We may expect shortly to receive more definite information respecting them from Mr A. N. C. Selwyn and the geological survey under his direction.

In Tasmania similar rocks occur, similarly associated with a thin group of shales, containing one or two good beds of coal.

India.—We may shortly expect more definite information than we yet possess, from the labours of Professor Oldham and his staff, on the geological survey of that country.

PERMIAN PERIOD.

TYPICAL GROUPS OF ROCKS.—*Durham, &c.*—According to Professor Sedgwick—

	Feet.
6. Red gypseous marls.....	100
5. Thin-bedded gray limestone.....	80
4. Red gypseous marls, slightly saliferous.....	100
3. Magnesian limestone.....	500
2. Marl slate.....	60
1. Lower Red Sandstone.....	200

1. Is a coarse pale-red sandstone, resting unconformably on the Coal Measures, often containing large fragments of coal plants, that *may* have been drifted out of the Coal Measures, and sometimes fragments of coal.

2. Marl slate, a brown indurated fissile shale, with occasional beds of thin compact limestone.

3. Magnesian Limestone.—A singularly diversified mass of limestones, sometimes compact, at others crystalline, brecciated, earthy, globular, oolitic, cellular, &c.; some beds like piles of cannon or musket balls, others like bunches of grapes, &c.; some very hard, some quite friable, some thin and flexible. General colour, shades of yellow, sometimes red and brown.

Nos. 4, 5, and 6, are sufficiently described already; they are destitute of fossils, except a few traces of bivalves in No. 5.

Midland Counties of England.—A great series of red and variegated sandstones and conglomerates, with breccias containing angular fragments of trap and of Silurian and Carboniferous rocks, together with thick dark-red marls, and in some places mottled calcareous bands, like the cornstones of the Old Red Sandstone. The total thickness in many places exceeds 1000 feet.

Ireland and Scotland.—The red sandstones of Roan Hill, near Dungannon, containing abundance of *Palæoniscus catopterus*, are probably Permian. Yellow magnesian limestones, exactly like those of Durham, and with many of the characteristic fossils previously mentioned, occur in patches at Artree,¹ county Tyrone, and at Cultra, near Belfast.

The red sandstones of Dumfries, with tracks of reptiles so beautifully figured by Sir W. Jardine in his *Ichnology of Annandale*, may also possibly belong either wholly or in part to the Permian rather than the Triassic period.

South of Russia: Government of Perm.—According to Sir R. I. Murchison, the district of Perm exhibits so great a development of the rocks of this period as to induce him to select that name for it. These beds are said to be very various, but in one locality they have the following type:—

- c. Conglomerate and sandstone.
- b. Red sands and copper beds.
- a. Sandstones, limestones, gypsum, and grit beds.

The limestones are often numerous, and contain fossils like those of the magnesian limestone of England and the

Zechstein of Germany, while other beds contain Thecodontosauria and fishes.

In Thuringia so great is the accordance with the British series, both in the rock groups and their included fossils, that Professor King in his monograph places them side by side as follows:—

THURINGIA.	NORTH OF ENGLAND.
Stinkstein.....	Crystalline limestone.
Rauchwacke.....	Brecciated limestone.
Dolomit.....	Fossiliferous limestone.
Zechstein.....	Compact limestone.
Mergel, or Kupfer schiefer.....	Marl-slate.
Rothe todle liegende.....	Lower Red Sandstone.

Professor Sedgwick long ago pointed out the remarkable similarity of the fish in the "Mergel schiefer" and his Marl slate. (See Sedgwick's paper on *Mag. L. Trans. Geol. Society.*)

During the Permian period, and at its close, the part of the earth now occupied by Western Europe seems to have been more than usually affected by movements of elevation and disturbance, attended with consequent large denudation of the previously existing rocks. We are obliged, therefore, to look to other parts of the globe, where tranquillity reigned during the portion of time that elapsed at the close of the Primary and the commencement of the Secondary epochs, for the typical deposits during this part of the earth's history. Future research will probably be prolific of future discovery of records now unknown to us belonging to the Permian and Triassic periods. Some of these discoveries are even now being made, but many others will doubtless follow. As a consequence of this disturbance and denudation, the Permian rocks are frequently unconformable to the Carboniferous, and the Triassic to the Permian.

CHAP. II.—SECONDARY OR MESOZOIC EPOCH.

TRIASSIC PERIOD.

TYPICAL GROUPS OF ROCK.—*Germany.*—

	Feet.
3. Keuper.....	1000
2. Muschelkalk.....	600
1. Bunter Sandstein.....	1500

1. The Bunter Sandstein, or "variegated sandstone," is a red and white sandstone interstratified with red marls and thin bands of limestone, sometimes oolitic, sometimes magnesian. This is the "Gres bigarré" of the French.

2. *Muschelkalk.*—A compact reddish-gray or yellowish limestone, rarely oolitic, but in some places magnesian, especially in the lower beds, which include beds of gypsum and rock-salt. It might accordingly be divided into two sub-groups:—

- b. Upper Muschelkalk, regularly-bedded limestone, more than 300 feet thick.
- a. Alternations of limestone, dolomite, marl, and gypsum or anhydrite, and rock-salt, 280 feet.

3. *Keuper.*—"Marnes irisées" of the French. Principally red and green marl, but is locally divisible into three sub-groups, namely:—

- c. Keuper sandstone, of a yellowish-white, sometimes green and reddish colour, containing calamites and other plants.
- b. Keuper marls, with gypsum and dolomite, containing coprolites, fish, and saurian bones, scales, and teeth.
- a. Lettenkölle (clay-coal) group, a dark-gray shale or gray sandstone, containing small irregular beds of impure earthy coal, with remains of *Mastodonsaurus* (*Labyrinthodon*), *Gervillia*, *Posidonomya*, and *Lingula*.

This latter group rests directly on the Muschelkalk, and

¹ See Professor King's paper (*Dublin Nat. Hist. Review*, No. x.), or *Journal of the Geological Society*, Dublin, vol. vii.

Geology.

seems, from its animal remains, to belong to it, but its plants are those of the Keuper.

Near Stuttgart, and in other parts of Germany, the Keuper sandstone is capped by a layer of sandstone breccia, full of the remains of saurians and fish in fragments, exactly like that known in England as the "bone bed." It is still doubtful whether this belongs more properly to the Trias or the Lias. Like the bone bed at the top of the Ludlow, it may perhaps be taken as an indication of a great gap in the series of beds.

In the *Supplement* of Sir C. Lyell before mentioned we have the latest intelligence regarding a set of beds which fill up the gap indicated by these "bone beds;" and, moreover, give us the true marine fossiliferous equivalents of the elsewhere fresh-water or unfossiliferous Keuper, and possibly also of part of the Bunter.

Near Hallstatt (south-east of Salzburg), on the north side of the Austrian Alps, and at St Cassian, on the south side, are a set of beds composed of red, pink, and white marble, from 800 to 1000 feet in thickness, and containing more than 800 species of fossils.

Underneath the Hallstatt and St Cassian beds are others called the Guttenstein and Werfen beds. They consist of—

	Feet.
b. Guttenstein beds, black and gray limestone, alternating with red and green shale.....	150
a. Werfen beds, red and green shale and sandstone, with gypsum and rock-salt.....	

It is yet doubtful whether these are only a lower portion of the St Cassian beds, or are to be considered as equivalents of the British or Lower Trias

Over the St Cassian beds again come 2000 feet of white or grayish limestone, known as the Dachstein beds, and above these 50 feet of gray and black limestone with calcareous marls, called the Kœssen beds. Each of these groups contain a peculiar set of fossils of a character which renders it uncertain whether they should be classed as Upper Triassic or as Lower Liassic groups.

We would press upon the reader's attention that we have in these beds one or two of the missing links that are to reward the researches of future geologists, and fill up the many gaps in our geological history.

England.—The Triassic rocks of England are anything but typical, notwithstanding that they occupy a greater surface than perhaps any other formation. The important central division, the Muschelkalk of Germany, is entirely wanting, as are the still more important Hallstatt and St Cassian beds. The labours of the Geological Survey of the last few years have shown the following to be the groups in the midland counties, where the formation is best developed:—

3. Red and variegated marls.
2. White sandstone.
1. Red and mottled sandstone.

1. The Red and Mottled Sandstone has a base of "brick-red" sandstone, very fine grained and thick-bedded. Over this come reddish-brown sandstones, or red and white sandstones, with beds of marl, and thick, rather irregular bands of partially consolidated conglomerate, called "pebble-beds." Mottled calcareous concretionary sandstones, not unlike some varieties of "cornstone," occur occasionally in this "brown" division, often associated with the marls. The whole group seems to be locally represented by a dolomitic conglomerate, unless that should be referred rather to the Permian period.

2. The White Sandstone is a very persistent and well-marked group over a very wide area, forming the hill on which Beeston Castle (Cheshire) stands, and spreading through a great part of the midland counties of England. It is generally white, sometimes mottled with red, and is

often used as a building stone, for which purpose it is occasionally sufficiently well adapted.

3. The Red and Variegated Marls contain irregular beds of sandstone, and almost invariably beds and veins and strings of gypsum, and frequently thick masses of rock-salt. In Cheshire, near Northwich, the following section shows a part of the thickness of these beds:—

	Feet.
Upper strata (marl, &c.).....	127
1st bed of rock salt.....	85
Indurated marl (locally called "stone").....	30
2d bed of rock salt.....	106
Indurated marls, with thin beds of salt.....	151
	499

Over this thickness of 500 feet are other beds of marl, &c., before we reach the base of the Lias, and under them others before we should attain the top of the whistone, so that the entire depth of the group must be 700 feet with, or 500 without, the salt.

An occasional set of beds of a pale-coloured sandstone, called by ourselves formerly the "Dove-coloured Sandstone," in the upper part of this group, contains fossil plants and fragments of reptiles, enabling us to identify this group, No. 3, with the Keuper of Germany. No. 1 is almost certainly the same as the German Bunter Sandstein, and the French "Gres Bigarré."

Ireland.—In the north, near Belfast, a considerable mass of red sandstones belong either to the Bunter sandstone or the Permian. Over them is a group of red and variegated marls, which, near Carrickfergus, contains beds of gypsum and rock-salt, of which the following is a section:—

	Feet.
Red marls, with gypsum.....	510
Red salt.....	22
Marl and salt.....	26
Pure rock-salt.....	84
Mixed rock-salt.....	14
Pure rock-salt.....	39
Blue bands and freestone, &c.....	25
	700

These have other beds of red marl above them, about 100 or 150 feet thick, over which is the base of the Lias. They in all probability therefore belong to group No. 3, and = Keuper of Germany.

THE OOLITIC OR JURASSIC PERIOD.

TYPICAL GROUPS OF ROCK.—*England.*—If we arrange the whole series of the rocks of this period in their order of occurrence, in slightly different but neighbouring localities, we shall have the following list:—

	Feet.	
D. PORTLAND, OR UPPER OOLITE.	12. Purbeck beds..... 150	{ a. Upper.
		{ b. Middle.
		{ a. Lower.

Geology.

Geology.

	Feet.	
A. LIAS.	3. Upper Lias.....	300
	2. Marlstone.....	200
		600
	1. Lower Lias.....	600

A. The Lias.—Essentially a great clay deposit, with occasional bands of a peculiar compact argillaceous limestone near the bottom, and an argillaceous sandstone near the middle, with a loose sandy deposit at top connecting it with the group above.

1. Lower Lias.—At the top of the red marls of the Triassic Keuper group below is a little layer of hard sandstone full of fragments of bones and teeth of reptiles and fish. In some places bones of Keuper reptiles have been seen in it, and the layer therefore referred to the Trias; in other places it is full of undoubted Lias fossils. It is probable that there is in reality more than one bone bed, the diminutive representative of the great passage beds between the Trias and the Lias, 2000 feet and more in thickness, which are found at Dachstatt and Kœssen.

In some places the black shales of the Lower Lias rest on the red marls without any bone bed and without any limestone, while in others a group of limestones, interstratified with clays, having a thickness of 20 to 50 feet, is seen. Over these limestones occur the ordinary blue clay of which the Lower Lias is generally composed.

2. The Marlstone is a well-marked division of the Lias, being more arenaceous, though still fine-grained, and often bound by calcareous or ferruginous cement into a hard stone. In Gloucestershire it is divisible into the hard "rock bed" above, and the sands, often rather argillaceous, below.

3. Upper Lias.—This consists of a great thickness of blue clay, over which are some brown and yellow sands, hitherto classed with the Inferior Oolite, but separated from it on good palæontological evidence by Dr Wright of Cheltenham, and called by him Upper Lias sands, capped by a particular band called the "Cephalopoda bed," from the abundance of those fossils which it contained.

The lithological type and the characteristic assemblages of fossils are applicable to the Lias throughout England from Lyme Regis to Whitby, if we allow for some variations in thickness and in the character of the minor groups of rock, and for a local distribution in the fossils.

B. The Lower or Bath Oolite, composed of the four groups called,—4. The Inferior; 5. Fuller's earth; 6. The Great Oolite, and 7. The Cornbrash.

4. The Inferior Oolite near Cheltenham, where it contains its greatest development, consists of—*a.* The Pea grit, a pisolitic limestone, made up of flattened oval concretions rather larger than peas, sometimes 40 feet thick; *b.* The Freestone, a fine pale-coloured oolitic or shelly limestone, 164 feet thick, containing a bed of marl 7 feet thick near the top; *c.* The Ragstone, a brown sandy limestone, sometimes hard, sometimes incoherent, 38 feet thick.

In the Cheltenham district even the subdivisions of the Inferior Oolite mentioned above have their lists of peculiar and characteristic fossils. (*Memoirs of the Geological Survey*, 1857; Mr Hull *On the Geology of Cheltenham*.)

5. Above the Inferior Oolite comes in the Gloucestershire district, a series of blue and yellow shales, clays, and marls, some of which are of the peculiar kind of clay called Fuller's earth, the name assigned to the group. Interstratified with these are occasional bands of limestone.

The maximum thickness is about 150 feet, rather rapidly diminishing in all directions.

6. Great Oolite.—This, like all the other oolitic groups, except the clays, has a very variable lithological character. Mr Lycett says that near Minchinhampton it is made up of

weatherstones, sandstones, and limestones; the weatherstones, shelly calcareous sandstones, being always at the base of the group, but passing laterally into sandstones, which are commonly covered by limestones, while the weatherstones have never any of the limestones above them. (*Jour. Geol. Soc.*, vol. iv.; and *Palæontolog. Soc.*, 1850.) Mr Hull divides the Great Oolite near Cheltenham into two zones,—*a.* The Under zone, a variable series of sandy flags, "slates," and blue limestones, with white oolitic freestones, showing much oblique lamination. The flaggy limestones, and sometimes the thick-bedded ones, split in some places into very thin slabs, which are called, though erroneously, "slates."¹ The Stonesfield slate, so celebrated for its terrestrial reptiles and mammalian remains, belongs to these beds, and it might therefore give its name to the zone. The Collyweston slate belongs to this group; thickness, 35 feet. *b.* The Upper zone is well marked in Gloucestershire by the occurrence of a bed of marl at its base, and a band of hard white limestone at its summit, the intermediate beds being oolitic limestones, sandstone, or sandy limestone, greatly marked by oblique lamination; thickness, 100 feet. (*Memoirs of the Geological Survey*, 1857.)

7. Cornbrash group.—This is a very variously composed set of clays, sands, and limestones, containing local divisions, such as the Bradford clay, the Forest marble, and the Cornbrash itself.

The Bradford clay is a blue unctuous clay occurring at Bradford, and extending for a few miles around it; it is never more than 40 or 50 feet in thickness; locally full of *Apicrinites Parkinsoni* (*rotundus*). The Forest marble (so named from Wychwood Forest) is composed of coarse fissile oolite, with much oblique lamination, hard shelly limestones, blue marls and shales, yellow siliceous sand, with large spheroidal blocks of limestone, and fine oolitic freestone. It is rarely more than 40, never more than 80, feet thick. The Cornbrash is generally a rubbly cream-coloured limestone in thin beds, always nodular and concretionary, each fragment having a deep red coating. Not more than 15 feet thick.

The foregoing description of the Bath Oolite is applicable, with more or less accuracy, to all the country south of the Humber. Proceeding into Yorkshire, however, a very remarkable change takes place both in the rocks and the fossils.

The little insignificant-looking band of the Cornbrash continues lithologically and palæontologically the same; below this, however, instead of limestones, there is a great mass of shale and sandstone, with a band of shelly oolite in the centre, and, underneath all, ferruginous sands and calcareous sandstones that may either represent the Inferior Oolite or the Upper Lias sands.

Professor Phillips gives the following as a condensed account of this Yorkshire type:—

	Feet.
5. Shelly Cornbrash limestone of Gristhorpe and Scarborough.....	10
4. Sandstones, shales, ironstones, and coals of Gristhorpe, Scarborough, and Scalby, inclosing some calcareous shelly bands.....	200
3. Shelly oolite, and clays of Cloughton and West Nab.....	60
2. Sandstones, shales, ironstones, and workable coal of the Peak, Stainton Dale, and Haiburn Wyllie.....	500
1. Irony sandstone and subcalcareous beds, with bands of shells and plants.....	60

Some Equisetites are found erect in these beds, and everything tends to show that we have in this type a true secondary coal formation of the Oolitic period, in addition

¹ We have formerly pointed out the advisability of confining the term "slate" to those rocks of which the thin plates are the result of "cleavage," not of deposition.

Geology. to that primary coal formation formed in that which is distinctively called the Carboniferous period.

C. The Oxford or Middle Oolite consists of two principal groups—the Oxford Clay and the Coral Rag.

8. The Oxford Clay is generally a dark blue clay, sometimes dark gray, approaching to black. In its lower portion it has some beds of tough calcareous sandstone, with brown sands called Kelloway rock, from a place in Wiltshire. This Kelloway rock appears to be wanting in the midland counties, but reappears in Yorkshire with the same characters and fossils. The maximum thickness of the Kelloway rock is 80 feet. That of the whole Oxford clay, including it, cannot be less in some places than 600 feet.

9. The Coralline Oolite or Coral Rag.—Like all the other calcareous or arenaceous groups of the Oolite, this is very irregular, and subject to great variations in character and thickness. There is a pretty close general resemblance in the Yorkshire and Wiltshire types, while in the intermediate district the whole group seems to disappear. It may be divided into three sub-groups,—

	Feet.
c. Upper Calcareous grit, maximum thickness	60
b. Coralline oolite, „	50
a. Lower Calcareous grit, „	80

a. The lower beds in Yorkshire are a series of gray marly sandstones, 70 feet thick, passing up into cherty limestone, covered by sands full of great calcareous concretions, capped by strong calcareous sandstones.

b. A variable group of irregular masses of nodules made of corals compacted together, often earthy, and connected by blue clay, passing into blue crystalline limestone; alternations of hard shelly oolite, and soft perishable limestone, and in Wiltshire a rubbly nodular oolite, sometimes pisolitic.

c. The upper group obscurely indicated in the south is, in the north, like group a, but more ferruginous and less cherty, passing up by intercalation into the Kimmeridge clay above. (Phillips.)

D. The Portland or Upper Oolite is composed of three principal groups, each capable of subdivision into two or three sets of beds.

10. The Kimmeridge Clay is in some places a dark gray shaly clay, in others brownish or yellowish, and containing bands of sand, or of calcareous grit, or ferruginous oolite, and layers of nodules of septaria. In some places, especially in the district about the Isle of Purbeck, it becomes very bituminous, and the bituminous shale sometimes passes into layers of “brown shaly coal.” Layers of a particular kind of oyster, called the *Ostræa deltoidea*, occur abundantly in some places, always appearing “in broad continuous floors, parallel to the planes of stratification, the valves usually together, with young ones occasionally adherent to them, and entirely embedded in clay, without nodules or stones of any kind, and without any other organic remains in the layers.” (Phillips.)

11. The Portland beds.—These, like most of the other members of the Oolitic series, have a variable composition, consisting of sands and sandstones below, becoming calcareous and passing into oolitic limestone above. They are therefore divisible into

	Feet.
b. Portland stone, consisting of white oolite and beds locally termed “stonebrash” and “roche,” &c., interstratified with clays, and containing layers of flint, about.....	90 to 100
a. Portland sands, consisting of brown or yellow sands and sandstones, full of green grains, like those afterwards to be described in the Greensands, about.....	80

12. The Purbeck beds are remarkably distinguished from the Portland, on which they rest, by being chiefly of fresh-water origin. They contain, however, some marine

species, which are allied to Oolitic more closely than to any other types. Edward Forbes therefore detached them from the base of the succeeding formations, and placed them at the top of the Oolitic series. They are also distinguished from most other aqueous rocks by containing one or two beds of “vegetable soil,” called by the quarrymen “dirt beds,” with the stems of trees and cycadoid plants still erect, and the trunks of trees prostrate alongside of them. This clearly points to a tranquil and gradual elevation of the surface of the rock into dry land, the growth of a forest through hundreds or thousands of years, and its as tranquil and gentle submergence beneath some stagnant water without sufficient current to disturb the soil or carry off the buried plants.

Edward Forbes divides the Purbecks of Dorsetshire into three groups, each characterized by a peculiar assemblage of organic remains, without any other very marked distinction between them, and with no sign of any physical disturbance or denudation.

a. The lowest division, 70 or 80 feet thick, consists of calcareous flags, marls, and limestones, with cypridiferous shales and some siliceous bands, with one large and two or three smaller “dirt beds” near its lower portion. These are all either fresh-water or aerial, except 20 feet in the centre of the group, which are brackish water deposits, containing *Rissoæ* (*Hydrobia*), *Protocardium*, and *Serpulæ*.

b. The Middle Purbecks, 40 or 50 feet thick, consist first of shales and limestones with thick bands of cherty stone, having impressions of leaves and many fresh-water shells; then the conspicuous “cinder bed,” a great heap of small shells of *Ostræa distorta*, over which are other limestones and shales, some fresh-water, some brackish, and some purely marine, containing yet undescribed species of *Pecten*, *Modiola*, *Avicula*, and *Thracia*, together with a *Protocardium* distinct from that in the lower beds. Many fish—*Lepidotus* and *Microdon radiatus*—and reptiles of the genus *Macrorhynchus* also occur. It is in a little band not more than 6 inches thick, about 20 feet below the “cinder bed,” that the very remarkable discoveries of a number of remains of mammalian animals belonging to several genera and species have been made. (Lyell's *Supplement*.)

c. The Upper Purbecks, 20 or 30 feet thick, are another series of beds full of fresh-water shells, distinct from those below, and new forms of fish. The fresh-water snail-shells are sometimes so abundant as to form a hard limestone, much used formerly as Purbeck marble.

It is remarkable that the fresh-water shells have a much closer resemblance to those living at other and more recent periods, or those now existing, than the marine species have. The three changes of life in this small group of Purbecks appear to be due solely to lapse of time, and to those slow and gradual changes in the physical geography of the district which took place, and not to any sudden or violent revolutions or disturbances of which there is no trace.¹

Ireland.—The Oolitic series is represented in Ireland by a few thin beds of Lias only, not exceeding thirty feet in thickness, resting on the summit of the red saliferous marls of the Trias of the county of Antrim. It contains, however, a considerable abundance of characteristic Lias shells.

Scotland.—On the west coast, opposite the north-east of Ireland, Lias is found also in Scotland, together with Oxford clay, and other representatives of the Oolitic series;

¹ Professor E. Forbes mentions one set of beds as curiously dislocated and disturbed, apparently by causes not affecting the beds below; but this band of local disturbance is included in the lower division, and is not accompanied by any change in the species, while, on the other hand, the great changes in the species take place at certain lines where there is no lithological or petrological boundary whatever. (*Report of British Association*, 1850.)

Geology. while on the east coast at Brora, &c., representatives of the Yorkshire oolites are found, containing also impure coal.

The series of rocks deposited in the British Islands during the Oolitic period is so complete, both petrologically and palæontologically, that they serve as a type for those known all over the world. In Europe, the term Jurassic is commonly used instead of Oolitic; the Jura mountain being principally composed of rocks belonging to this period. In tracing the rocks across Europe, differences, both lithological and palæontological, occur, as might be naturally expected; but on the whole a wonderful similarity in both characters extends over very large areas.

It will perhaps be most useful to give a few of the foreign synonyms of the different rock groups adopted by different Continental geologists.

- A 1. LOWER LIAS.—Terrain sinémurien, grès du Luxembourg, calcaire de Valognes, grès de Lincksfield, Gryphiten kalk. Lower black Jura.
- A 2. MARLSTONE.—Terrain liasien, marnes de Balingen, amaltheen thon, mumismalen mergel. Middle black Jura.
- A 3. UPPER LIAS.—Terrain toarcien, schistes de Boll, Posidonomya schiefer, Jurensis mergel, Apalinus thon. Upper black Jura and Lower brown Jura.
- B 4. INFERIOR OOLITE.—Terrain Bajocien, calcaire Lædonien, calcaire à polybien, marnes vésuliennes, Eisen-Rogenstein discoidien mergel. Middle brown Jura.
- B 5. FULLERS' EARTH; 6. GREAT OOLITE; and 7. CORNBRASE.—Terrain Bathonien, calcaire de Caen et Ranville, Parkinsoni Bank. Part of brown Jura.
- C 8 a. KELLOWAY ROCK.—Terrain Callovien, Oxfordien inferieur. Part of brown Jura.
- C 8. OXFORD CLAY.—Terrain Oxfordien, terrain argovien, terrain à chailles, ornaten thon, Impressa kalke, Spongiten layer. Part of brown Jura and Lower white Jura.
- C 9. CORAL RAG.—Terrain corallien, schistes de Nattheim, calcaire à nérinées. Middle white Jura. (The lithographic flags of Solenhofen are believed to be in this group.)
- D 10. KIMMERIDGE CLAY.—Terrain Kimméridgien, argiles noirs de Honfleur, marnes du Banné, calcaire à astartes. Part of the terrain portlandien of the geologists of the Swiss Jura, who call the lower part Terrain Séquanien; part of Upper white Jura.
- D 11. PORTLAND BEDS.—Terrain portlandien, Upper white Jura, calcaire à tortues de Soleure.
- D 12. PURBECK BEDS.—These do not receive any exact synonym either in Pictet or in Vogt, the only two authorities accessible to me.

In other parts of the world the rocks of the Oolitic (or Jurassic) period appear chiefly in their Yorkshire type—that is to say, as sandstones and shales with beds of coal and ironstone, or as Oolitic Coal Measures. Sir Charles Lyell gives a brief description of the Oolitic coal-field of Richmond in Virginia, which has one bed of coal forty feet thick. In India also coal occurs in beds, some of which contain ammonites, shells, and plants very similar to those found in the Oolitic rocks of Britain.

One of the most remarkable localities for rocks of the Oolitic period to occur in, with fossils very closely allied to those of Europe, is the Arctic regions. Captain M'Clinck brought home several fossils from the Arctic regions, consisting of ammonites and other shells, closely analogous to Oolitic species; and Captain Sir E. Belcher brought part of the remains of an ichthyosaurus from the same regions.

The questions thus raised as to the climate of the globe, when cephalopods and reptiles, such as we should expect to find only in warm or temperate seas, could live in such high latitudes, are not very easy to answer.

CRETACEOUS PERIOD.

It is perhaps doubtful whether it would not be more advisable to divide the Oolitic period into two, calling the first portion *Liassic*, and treating it by itself. It is still more doubtful whether it would not be advisable to do the same with that on which we are now commencing, and

treat the early part of the period as a distinct one, under the name of the *Neocomian*, or some other designation. For the present, however, it will be best to follow the classification adopted by Sir C. Lyell and others, calling the whole *Cretaceous*, but dividing the series of rocks into two strongly-marked divisions, called Lower and Upper, or the period of time into Earlier and Later Cretaceous.

TYPICAL GROUPS OF ROCK.—S.E. England, N.W. France, Belgium, &c.—The following is the entire series of rocks deposited during the great Cretaceous period in this area:—

	Feet.
UPPER CRETACEOUS.	
8. Maestricht and Faoes beds, Pisolitic chalk	100
7. White chalk, with flints.....	500
6. White chalk, without flints.....	600
5. Chalk marl.....	100
4. Upper Greensand.....	100
3. Gault.....	150
LOWER CRETACEOUS.	
2. Lower Greensand.....	850
2 a. Speeton clay ¹	60
OR NEOCOMIAN. 1. Wealdon beds.....	1300

This classification is derived from the study of different parts of the area lying between Yorkshire and Orleans, and Dorsetshire and Denmark. As happens in other cases, there is no place where the whole series is present at once, and some of the members are very local and inconstant. The middle part of the Upper Cretaceous series is the most constant and best-marked part of the group, giving us generally an easily recognisable geological horizon or band of demarcation between the beds below and above it.

We saw that at the close of the Oolitic period fresh-water deposits began to prevail within the area we principally contemplate. This involves the existence of large spaces of dry land in the neighbourhood, some of the surfaces of which have even their "soils" still preserved. It appears that a very large portion of the earth's surface must have been converted into dry land at this time in the neighbourhood of our area, for we have, in the commencement of this period, evidence of the existence of a great river, and the earliest deposit of this period appears to have been formed by the matter thrown down at the mouth of this river, and to be in fact a *fossil delta* as large as that of the Ganges or Mississippi. As, however, marine depositions must have been taking place in some other localities, it is to these that we should look if we wish to carry on our history with equipollent data; and it is believed that certain marine rocks, known as Neocomian, from their occurring at Neuchâtel (*Neocomiensis*) in Switzerland, are those which were the contemporaries of our fresh-water beds.

We will, however, first describe the beds of our own area, and take separately the *Lower Cretaceous* or *Neocomian* beds to begin with.

1. The Wealden beds, so called from their now forming a district known as the Weald of Kent and Sussex, consist of a great series of sandstones and shales, with a few beds of limestone and ironstone occasionally, often full of large fragments of drift-wood, and of the remains of fresh-water shells, and of some fresh-water and some land animals (reptiles). In general appearance the Wealden rocks not unfrequently resemble some of the Coal Measures of the true Carboniferous period.

The Wealden rocks are commonly divided into two groups:—

	Feet.
b. The Weald clay.....	280
a. The Hastings sand.....	1000

These distinctions, however, seem hardly to be carried

¹ The exact position of the Speeton clay is a little uncertain. Professor E. Forbes, in Johnston's *Physical Atlas*, placed it at or below the base of the Lower Greensand on palæontological evidence alone.

Geology. out by any precise line of demarcation. The lower beds are more arenaceous, and the upper more argillaceous; but great beds of clay occur interstratified with the sandstones of the Hastings sands, and beds of sandstone with the clays of the Weald clay. It is probable that these beds change their character laterally as well as vertically, great banks of sand and large deposits of mud having been formed side by side. The sandstones are sometimes impregnated with carbonate of lime, so as to become calciferous grits; and small beds of limestone, forming Petworth or Sussex marble, chiefly consisting of fresh-water snail shells (*Paludina*), occur here and there. Local names are given to the different parts of the Wealden series in different places, as Ashburnham beds, Worth sands, Tilgate beds, Horsham beds, &c. (Phillips.)

2. The Lower Greensand was formerly considered the base of the Cretaceous series, separated only by the occasional bed of clay called Gault from the Upper Greensand. When the Gault is absent, and the Upper rests on the Lower Greensand, it is difficult to separate them by any lithological distinctions, but when they are separated they are found to be very distinct palæontologically.

Where best shown (as at Atherfield, Isle of Wight, and Hythe, Kent; Fitton, Forbes, and Ibbetson, *Jour. of G. S.*, vols. i. and iii.), the Lower Greensand is found to be a great series of alternations of sands, sandstones, and clays, with occasional calcareous bands. The calcareous sandstones form hard bands, known as Kentish rag; the clays are sometimes excellent fullers' earth, 60 feet in thickness, and are most abundant in the lower part of the formation, the upper being almost entirely sands. The general colour is dark-brown, sometimes red, and the sands are often bound together by an abundance of oxide of iron, from which the formation was formerly called Ironsand. It derives its name of Greensand from the occurrence of a number of little dark green specks (silicate of iron), which are sometimes so abundant as to give a greenish tinge to some of the beds; but the term "green" is generally quite inapplicable as a *description*, though it still remains as a commonly received *name*. The whole formation in Britain is very various in character. Its maximum thickness is 843 feet.

The beds immediately above the Wealden show sometimes a sort of passage lithologically, as if partly made up of those below, while the fossils are quite distinct, being entirely marine. It appears that a depression had taken place and allowed the sea to flow over the area which had been previously covered with fresh water. The change may thus be one of conditions rather than one of great lapse of time—a supposition strengthened by the fact of the bones of the *Iguanodon Mantelli* being found in the Lower Greensand, showing that that great reptile still lived on some neighbouring land, and that an occasional carcass of it was swept out to sea.

2 a. The Speeton clay of Yorkshire, a local band of dark clay, is almost certainly of the same age as the Lower Greensand, if not, as thought by Professor Forbes, a little older than it.

Switzerland.—The rocks of Neuchâtel in Switzerland, which are looked upon as one of the best continental types of the beds deposited during this part of the Cretaceous period, are the following:—

	Feet:
5. Yellow limestone, at least	130
4. Yellow limestone, with siliceous masses	43
3. Yellow limestone, in broken beds	22
2. Blue marl	32
1. Lower yellow limestone	22

These beds rest *unconformably* on the beds of the Portland Oolite. (*D'Archiac*, vol. iv., p. 556.)

France.—*D'Archiac* gives the following as the type of the rocks of this period in the basin of the Seine:—

- Geology.**
- C. { 6. Green and ferruginous sand.
 - 5. Clay, with *Plicatula* and *Exogyra sinuata*.
 - B. { 4. Variegated sands and sandy clays, with iron ore.
 - 3. Clays, with oyster shells, &c.
 - A. { 2. Neocomian limestone and blue marl.
 - 1. White sand and ferruginous sand, with iron geodes.

He says that these groups overlap each other from east to west, but that the upper group (C) also spreads much more widely than the rest from north to south.

The following continental names for groups of rock belong to this part of the period, being more or less nearly contemporary with Lower Greensand:—Hils clay and Hils conglomerat; Biancone; Spatangus and *Exogyra* limestone; Marls of Hautrive; Terrain Urgonien, or "premier zone de rudistes;" and Terrain Aptien,¹ or argile à plicatules of D'Orbigny; the Hippurite limestone, &c.

Upper Cretaceous Beds.—We may now proceed to the examination of the Upper Cretaceous beds of our original area.

3. Gault.—This is a stiff dark-gray, blue, or brown clay, often used for brick-making. It can be seen very well at Cambridge and at Folkestone, but is by no means invariably present. The shells in it are often beautifully preserved, having been well packed and protected from atmospheric or other influences.

Mr Sharpe was inclined to the opinion that the sands of Blackdown were of the same age as the Gault, being the littoral deposits of the same sea, in the deeper parts of which the clay was deposited.

4. Upper Greensand.—This set of beds often resembles the Lower Greensand in lithological character, but the same caution is to be used in taking its designation for a *name* only, and not for a *description*. The sands are by no means always green, and other sands, especially some Tertiary sands, are to be found quite as green, or greener, than those which have received the name of Greensand. Beds and concretionary masses of calcareous grit occur in it, sometimes called firestone, sometimes malm rock. Concretions, probably coprolitic, containing phosphate of lime, also occur, and are valuable to the agriculturist. It has been surmised that the Upper Greensand may be in part a shore deposit, and therefore contemporaneous with, rather than preceding, the lowest beds of the chalk, but wherever the two are together, we always find the Upper Greensand underneath the Chalk Marl.

5. Chalk Marl.—The top of the Upper Greensand becomes argillaceous, and passes upwards into a pale buff-coloured marl or argillaceous limestone, sometimes of sufficient consistency to be used as a building stone. This in its higher portion begins to lose the argillaceous character, and gradually passes into the soft white pulverulent limestone familiar to every one as chalk.

6. White Chalk without flints.—This is a great mass of soft and often pulverulent limestone, thick-bedded, the stratification often obscure, partly by the obliteration of the bedding planes, partly by the abundance of quadrangular and diagonal joints, the surfaces of which are often weather-stained, dirty-green, or yellow. Nodular balls of iron pyrites, radiated internally, are frequent in it, and produce rusty stains about the rock.

¹ M. Renevier, after a detailed comparison of the British and continental rocks, determined that the Lower Greensand of England was strictly contemporaneous with the Aptian beds, and therefore not according to him Neocomian, of which he says the Urgonian is the upper part. We should be inclined, however, to give a wider sense to the term Neocomian (in default of a better), and to include in it all beds of an age intermediate between the Purbecks and the Gault. If M. Renevier be right, it is probable that the Urgonian and other Neocomian beds of Switzerland, &c., are the exact marine representatives of the fresh-water Wealden series.

Geology.

7. White Chalk with flints.—There are no lithological distinctions between the Lower and Upper Chalk, except the occurrence in the latter of rows of nodules of black flint, and occasionally of seams and layers of the same substance. These occur either along the planes of stratification or parallel to them, so that they point out clearly the original bedding of the rock.

It is rare to find, either in the Upper or Lower Chalk, anything but pure limestone or pure flint. Little pebbles, however, sometimes occur in it, probably carried by the roots of plants; and in a cliff a little east of Dieppe, we once observed in the heart of the Upper Chalk a little band about 8 inches thick and 20 feet long of brown clay or marl, perfectly interstratified with the chalk. This was quite distinct from the seams and irregular patches of sand which may now and then be seen in the chalk, having been washed in subsequently from the drift on the surface, along the open joints and fissures, which are formed in it, as in all limestones, by the action of acidulous water along the original joints of the rock.

Although the Chalk and the Carboniferous limestone are so different in texture and induration, there is yet a certain resemblance in the forms of the country they produce. Their hills have equally broad undulating grassy downs, the escarpments of which are quite smooth in the chalk, while they are notched into steps in the mountain limestone. Their valleys are equally marked by scaurs, and tors and pinnacles, as any one may see by comparing the forms of the rocks on the sides of the valley of the Seine with those in the valleys of Derbyshire. The forms are, of course, bolder, larger, and more durable in the latter than the former.

8. Maestricht or Pisolitic Chalk.—At Mendon and Laresines, and in other parts of the north of France, there occur curious banks of a white Pisolitic limestone, resting apparently in hollows of the Chalk, not always on exactly the upper portion of it, and being therefore apparently slightly unconformable to it. It occurs also sometimes on the same level as the lower beds of the Tertiary rocks about it. The fossils are rather peculiar, but some of them are Cretaceous, while none I believe are Tertiary.

Near Maestricht in Holland, also, the Chalk with flints (No. 7) is covered by a kind of chalky rock with gray flints, over which are some loose yellowish limestones, without flints, and being sometimes almost made up of fossils.

Similar beds containing some of the same fossils occur also at Faxoe in Denmark.

North of Ireland.—The Chalk of the north of Ireland is generally a rather hard compact stone, and usually goes by the name of "the White Limestone." It contains flints and a large assemblage of the characteristic fossils. Its thickness, however, rarely if ever exceeds 150 feet. Underneath it occur occasionally some beds of a whitish sandstone speckled with green, very much resembling some of the beds of greensand in the S.E. of England. Professor E. Forbes, however, once remarked to us that he thought it was more nearly of the age of the gault from its fossils. It is called in the country "Mulatto stone." Its thickness is rarely more than 15 or 20 feet.

CHAP. III.—TERTIARY EPOCH.

Preliminary Observations.

The nomenclature of the Tertiary periods proposed by Sir C. Lyell, and now all but universally adopted, is more systematic than that of the Primary or Secondary periods. It is based on the gradual increase of recent (*i.e.*, living) species in the newer rocks. The earliest of the periods is termed Eocene, from the Greek words *ἦως* and *καινός*,

Geology.

signifying the dawn of the recent; the second, Miocene, from *μείων*, the minority; the third, Pliocene, from *πλείων*, the plurality of recent species; and the next, Pleistocene, which expresses the recentness of the great majority of the species.

To these we may add the present period itself, which we may perhaps most conveniently designate as the Recent or the Human Period.

The adoption of this principle of classification was rendered more necessary in the case of the Tertiary than the preceding epochs, from the nature of the physical conditions of Western Europe, on the structure of which our classification is chiefly based.

In the primary and secondary epochs, the part now occupied by Western Europe seems to have always contained more sea than land, and the rocks deposited are accordingly so widely spread as frequently to overlies and rest one upon the other. We can therefore often determine their order of superposition by their geognostic relations only; that is, by actually tracing each group of beds till we find it plunging under the superior group on the one side, or till the inferior group rises up to the surface from underneath on the other. When, however, we come to examine the Tertiary rocks of the same area, we find them more isolated and occurring in smaller and more detached patches, each patch ending before it comes in contact with the rest, so that their order of superposition can rarely be determined by simple inspection. To take a conspicuous instance at once:—The Chalk of the S.E. of England is continuous with that of France¹ and Belgium, and no mistake could possibly be made as to the relative position of the beds above and below it. The Oolites below the Chalk are even still more extensive, and can be traced both geognostically and palæontologically. The Tertiary beds above the Chalk, however, form isolated districts in the hollows of the Chalk, one being called the Hampshire basin, another the London, and a third the Paris basin; and if we wish to determine whether the beds of these three districts are of the same age, or whether one be older than another, it is obvious that we can no longer employ the positive evidence of an inspection of their superposition, but must have recourse either to the petrographical evidence of their being made exactly of the same kinds of rock occurring in the same order, or to the palæontological evidence of their containing the same assemblages of fossils occurring in the same order; or if neither rocks nor fossils were the same, then we should have to fall back on the general rule or principle just spoken of, and see which contained an assemblage of fossils having the greatest approximation to living forms, and this in the case of Tertiary rocks is most easily determined by the relative percentage of actually existing species.

The Lower Eocene Group.

The surface of the chalk on which the Eocene beds rest is generally eroded into hollows and undulations, showing a marked but not a very wide unconformity, as when the Chalk is greatly tilted, the Lower Eocene beds partake of the disturbance to an equal amount.

1. Thanet Sands.—Light-coloured quartzose sand, mixed in the lower beds with much argillaceous matter, but never passing into actual clay; containing occasionally dark-green grains like those mentioned before in the Greensands. It rests almost invariably on a stratum of Chalk flints, from which the chalk seems to have been washed away without wearing or fracturing the flints, and these are of a bright olive colour externally, by which they may be recognised in other beds (Tertiary or drift) to which they may have been subsequently carried. The Thanet sands are very constant in character from the Isle of Thanet throughout the London basin, but thin out to the westward, till a little north of Windsor they are only 4 feet thick, shortly beyond which they disappear entirely. (Prestwich, *Geological Journal*, 1852, p. 235.)

2. The Plastic Clay, or the Woolwich and Reading series of Prestwich.—This group is more variable in character than that of the Thanet sands, and also more widely extended, becoming thicker from east to west, or in the opposite direction to the Thanet sands.

On the east, near Herne Bay, we have in it—

	Feet.
a. Argillaceous green sand.....	12
b. Dark-gray argillaceous sand with nodules of iron pyrites.....	7
a. Light ash-green and yellow sands.....	9
	28

At Black Heath it consists of—

	Feet.
a. Pebble beds.....	12
d. Brownish sand.....	2
c. Comminuted shells in light-coloured clay with pebbles.....	6
b. Light-green sandy clays.....	7
a. Light-green sands with pebbles.....	6
	33

¹ The total thickness of the fluvi-marine strata of the Isle of Wight, reckoning from the base of the Headon series, will be about 540 feet.

Near Reading the beds are—

	Feet.
e. Mottled red and light bluish-gray clay	20
d. Laminated yellow sands.....	2
c. Light-gray and greenish sandy clay.....	4
b. Fine yellow sand.....	8
a. Green sand with <i>Ostræa Bellovacina</i>	2
	36

But these beds are more than 50 feet thick in other parts of the district.

At New Haven, an outlier of the Hampshire district—

	Feet.
i. Gray clay and dark-yellow sand.....	12
h. Round flint pebbles in gray clay and yellow sand.....	1
g. Laminated gray clay with seams of yellow sand.....	8
f. Concreted oyster rock (<i>O. Bellovacina</i>)	2
e. Comminuted shells in yellow sand and gray clay	6
d. Yellow, brown, and red sand in layers	5
c. Dark-gray clays with ironstone	20
b. White, ochreous, and green sand.....	25
a. Green and ferruginous coated flints in sand.,	2
	81

In Alum Bay, Isle of Wight, these beds are from 90 to 140 feet thick, consisting of bright-coloured tenacious mottled clays, the prevailing colour being blood-red, but having mixtures of light bluish-gray and yellow, light and dark slate colour, lavender, puce, yellow, and brown, almost free from any admixture of sand.¹ (Prestwich, *Geol. Jour.*, 1854, vol. x., p. 75.)

The Druid Sandstones, Gray Weathers, Sarsenstones, and Puddingstones, scattered in loose blocks over many of the Chalk downs around the London basin, are believed by Mr Prestwich to be consolidated portions of the sands and gravels of the Plastic clay series.

3. The London Clay.—In the London basin this consists of—

- b. Dark-gray and brown clay, with layers of septaria or cement-stones, varying from 200 feet on the west to 480 on the east about Sheppey Island.
- a. Basement bed, yellow, green, and ferruginous sands, and occasionally clays with layers of rounded flint pebbles, having a total thickness of about 5 feet, and resting on slightly eroded surface of beds below.

In the Hampshire basin we have—

- b. Dark-blue clays and sands, containing nodules of argillaceous ironstone with bands of gray clayey sands and dark-greenish sands, sometimes compacted into hard stone called Bognor rock, having a total thickness varying from 193 to 363 feet.
- a. Basement bed of sand and clay, with a conglomerate of round flint pebbles and partly rounded fragments of chalk and of the mottled clays below, 4 to 5 feet.

The Middle Eocene Groups.

4. The Bagshot series, which takes its name from Bagshot Heath, but is best seen in the Isle of Wight. These consist of four groups, namely:—

- 4 a. The Lower Bagshot beds, composed of alternations of sand and clay; the sands generally pale yellow or gray, but sometimes dark and ferruginous, at others fawn-coloured or rose-coloured; the clays are white pipe-clay, or gray or chocolate-coloured clay. Thickness, 660 feet.
- 4 b. The Bracklesham beds (so called from Bracklesham in Sussex).—Dark chocolate-coloured marls and carbonaceous clays below, over which are whitish marly clay and white sands capped by a band of conglomerate of flint pebbles. Thickness, 110 feet.

¹ I have given these beds in a little more detail than their relative importance deserves, as a good example of the variable character of some of the Tertiary beds of Western Europe.

Geology.

- 4 c. The Barton beds.—Greenish-gray sandy clay below, passing up into bluish green and brown clay, interstratified occasionally with beds of sand and loam. Thickness, 300 feet. This was formerly supposed to be the London clay.
- 4 d. Upper Bagshot beds.—Yellow and white sands with ferruginous stains. Occasionally 120 feet.
- (Mr Bristow's section in *Mems. Geol. Survey*, 1856; Forbes' *Isle of Wight Mem.*)

The arrangement is different from that given by Mr Prestwich in his papers in the *Geological Journal*. It appears that No. 16 of Mr Bristow's section, p. 157, is the same as No. 24 of Mr Prestwich's in *Geological Journal*, vol. ii., p. 258. All below that Mr Bristow called Lower Bagshot, while Mr Prestwich includes many of the sands below in his Bracklesham series. (*Geological Journal*, vol. xiii., p. 99.)

5. The Headon series.—All the beds hitherto described, except part of the Plastic Clay series, are of marine origin. With the commencement of the Headon series, however, we meet with indications of fresh water having prevailed over what is now the Hampshire area, as well as at the corresponding period of the Paris Tertiaries. In the London area no beds higher than the Bagshots are known.

- 5 a. The Lower Headon beds consist of clays and marls in Whitecliff Bay, while at Headon Hill and Colwell Bay they contain thick limestones; and they are still more varied at Hordwell on the opposite coast. They are the "Lower Fresh-water formation" of Webster.
- 5 b. The Middle Headon beds consist principally of sands, showing at Headon Hill brackish water conditions, but containing beds of oysters; while at Colwell Bay and Hordwell, and still more strongly at Whitecliff Bay, the beds have a purely marine character. Webster called them the "Upper Marine formation."
- 5 c. The Upper Headon beds contain the strongest limestones of Headon Hill, which, however, thin out rapidly towards the north. They are represented by a few very thin and inconspicuous sandy concretionary bands in Whitecliff Bay. The uppermost beds of the group are marls. Webster gave the name of "Upper Fresh-water formation" to this group.
6. Osborne (or St Helen's) series.—This is divisible into two groups, of which the first or lowest is—
- 6 a. The Nettleson grits, consisting of hard rag and shelly sandstone below, capped by marl and bright-yellow limestone. The whole about 20 feet in thickness.
- 6 b. The uppermost has an alternation of white, and green, and yellow sands, with blue, white, and yellowish clays and marls, having a total thickness of about 50 feet.

The Upper Eocene Groups.

The fluviomarine conditions are still continued in the Isle of Wight district, without any very marked line of distinction, between the top of the middle and the base of the Upper Eocene groups.

7. The Bembridge series, of which the first or lowest division is—

- 7 a. The Bembridge limestone, a pale yellow or cream-coloured limestone, interstratified with clay or crumbling marl—the limestone full of cavities, and often quite tufaceous and concretionary, and sometimes conglomeritic, sometimes a true travertine; contains siliceous or cherty bands in some places. Thickness, 20 to 25 feet.
- 7 b. The oyster bed, a few feet of greenish sands containing oysters (*Ostrea Vectensis*) in great abundance, capped by a band of hard septarian stone, which is constant over a large area. About 10 feet altogether.
- 7 c. Unfossiliferous mottled clays, alternating with fossiliferous laminated clays and marls. Containing *Cyrena pulchra*.
- 7 d. Marls and laminated gray clays, containing *Melania turritissima*; capped by the *Black Band* forming the base of the Hempstead series.

8. The Hempstead series—the three lower divisions of fresh-water and estuary origin.

- 8 a. The lowest bed of this group is a firm carbonaceous laminated clay, highly fossiliferous, about two feet thick, known as the *Black Band*, over which are pale-bluish and yellow shaly

marls, with ironstone concretions. The whole about 40 feet thick.

- 8 b. The base of this group, called the White Band, is a bed of mingled broken and entire shells, more or less consolidated, often very ferruginous, from 6 inches to 2 feet thick; over which are mottled, yellow, and pale-green marls, capped by shaly clays and dark marls, and blue-green ferruginous clays, with ironstone concretions. Total thickness about 50 feet.
- 8 c. Variegated red and green marls and gray clays, covered by greenish clay, passing up into pale and dark gray or lead-coloured clays. Thickness about 40 feet.
- 8 d. Clays with septaria, and gray and bluish clays with concretions containing abundance of *Corbula*; marine. About 25 feet thick.

France and Belgium.—The labours of Mr Prestwich, continued so long and assiduously, have gradually made plain to us the correlation of the English and French Eocene beds, and joined with those of Sir C. Lyell and M. Dumont, have also taught us the relation of these with those of Belgium. The following table exhibits these relations as they are now believed to be, taking Mr Prestwich's classification for all below the Upper Bagshot sands, and Professor Edward Forbes' for these and all above them:—

ENGLAND.	BELGIUM.	FRANCE.
11. Hempstead.	Rupelian.	Calcaire de la Beauce. Grès de Fontainebleau. Sables et bancs de coquilles, marnes marines.
10. Bembridge.	Tongrien.	Calcaire siliceux, calcaire lacustre moyenne, Gypseous series of Montmartre, &c.
9. Osborne. } 8. Headon. }	Laeckenien, part of?	Calcaire marin et Grès de Beauchamp.
7. Upper Bagshot.	{ Système Laeckenien supérieur ?	Sables moyennes, upper zone.
6. Barton clay.	{ Système Laeckenien inférieur.	Sables moyennes, lower zone.
5. Bracklesham.	{ Système Bruxellien.	Calcaire grossier, ¹ and Glauconie grossière.
4. Lower Bagshot.	{ Système Ypresien supérieur ?	Lits coquillières, and Glauconie moyenne.
3. London clay.	{ Système Ypresien inférieur ?	Wanting. ²
2. Woolwich and Reading.	{ Système Landenien supérieur.	Grès de Poulungues, Lignites et Argile Plastique, Glauconie inférieur.
1. Thanet sands.	{ Système Landenien inférieur.	Wanting.

According to Mr Prestwich, the London Tertiaries were

¹ Mr Prestwich gives (*Geol. Jour.*, vol. xiii., p. 99) the following detailed description of the Calcaire grossier:—

	Feet.
4. Compact white marls, passing down into alternations of greenish marls and thin yellow limestones, with seams of chert.....	20
3. Thin-bedded fissile calcareous flags and sandstones, alternating with white marls and limestones	15
2. Thick main mass of soft, light yellow calcareous freestone (the building stone of Paris got by mining or subterranean quarrying), passing sometimes into calcareous sands	40
1. Variable, more or less calcareous greensands, sometimes concreted, flint pebbles often at base.....	25

100

² Some part of it, however, formerly extended into Normandy, as some clay at the top of the cliff of Ailly, near Dieppe, is believed to be London clay. (Prestwich, *Geol. Jour.*, vol. xi., p. 230.)

Geology.

Geology.

deposited in a sea open to the north, spreading at least over South-East England, Belgium, and north of France, whilst to the south of that area, dry land prevailed over the great part of the Paris Tertiary district and still further south. Gradual depression then took place, extending the limits of the sea over the Paris area, leading to the introduction of Nummulites and more southern forms of marine life than had hitherto prevailed. Dry land was still in the immediate neighbourhood, as shown by the occasional presence of terrestrial forms, and alternations of elevation and depression doubtless took place, modifying here and there the physical geography of the district. The Barton Clay, for instance, seems to have been deposited in a sea of a more northern character than that in which the Bracklesham Clays and sand were formed. Fresh-water conditions finally became prevalent, large estuaries opened into the seas over the British and north of France areas, while large lakes existed in the centre and south of France, where, soon after, volcanic eruptions commenced to break forth, and continued for many thousand years in subsequent periods. Edward Forbes pointed out that the upper part of the Bembridge series was probably of the same age as the Molasse of Fronsadais and the associated beds, and also as the Calcaire à Astéries of the S.W. of France. Part of the Tertiary beds of Malta, Corsica, Greece, Crete, Cerigo, S. of Spain and Portugal, Azores, and North Africa, are also believed to be contemporaneous with these beds. Contemporaneous with the Hempstead also were the Molasse ossifere and the Faluns jaunes of Dax, the lower division of the Vienna Tertiaries; and the marine beds, the Cerithium kalk and Upper Brown Coal of Mayence. (*Mems. Geol. Soc.* 1856, p. 100.)

Sir C. Lyell, however, in his *Supplement*, thinks that it would be more convenient to retain a nomenclature common on the Continent, and to class the Hempstead series and its contemporaneous beds as Lower Miocene, taking the beds from the Barton Clay to the Bembridge series inclusive as Upper Eocene, and the Bracklesham and Lower Bagshot beds only as Middle Eocene. He remarks, however, that we must in this case look on the boundary between Eocene and Miocene as an arbitrary and purely conventional line.

Certainly, as far as England (Isle of Wight) is concerned, the Hempstead beds are linked to those below by a greater number of species than they have peculiar to themselves.

The Alps, the Borders of the Mediterranean, Egypt, India.—Through these countries, from the Alps to the Himalayas, occurring at intervals through 25° of latitude and near 100° of longitude, are found great masses of rock, sometimes even thousands of feet in thickness, crowded with Nummulites, and sometimes almost made up of them. These are of Middle Eocene age. Associated with these are still higher beds called Flysch and Macigno in the north of Italy, and the black slates or shales of Glarus containing quantities of fossil fish, &c. The Monte Bolca fish-beds are also of about this age. (Murchison, *Geol. Jour.*, vol. v., p. 157, &c.)

North America.—Sir C. Lyell places the Claiborne and Alabama beds among the productions of the Middle Eocene period.

THE MIOCENE PERIOD.

The proportion of living to extinct species is taken at about 25 per cent. If we include the Hempstead series in the deposits of the Eocene period, we have no stratified rocks in the British Islands representative of the formations of the Miocene period, unless it be the "ash" beds and lignites associated with the basalts of the north of Ireland and west of Scotland. Edward Forbes thought that the

Geology.

fossil leaves found by the Duke of Argyll in the Isle of Mull more nearly resembled Miocene forms than any other, and were certainly not the same with those of any known Eocene forms.

If we adopt the classification usual on the Continent, and consider the Hempstead beds and their equivalents the earliest of Miocene beds, then the Bembridge series of the Isle of Wight, and the Gypseous series of Montmartre, will be the uppermost or newest of the Eocene period. There is, it appears, a palæontological reason for this arrangement on the Continent, inasmuch as if we draw the line at the top of the Montmartre beds, and at the base of the Calcaire lacustre superior (or Calcaire de la Beauce), certain generic and even specific forms of Mammalia are kept wholly within the Miocene groups which otherwise would be made common to the Eocene and Miocene periods. The genera *Dorcatherium*, *Cainotherium*, *Anchitherium*, and *Titano-mys*, and the species *Rhinoceros incisivus*, and others, are examples. (M. Lartet, in Lyell's *Supplement*.)

We shall then have the following as

TYPICAL GROUPS OF ROCKS OF THE MIOCENE PERIOD.

—*Belgium and France.*—Limburg beds, Rupelian of Dumont, the Bolderburg beds, the Fuluns of Touraine and Bourdeaux, the principal part of the lacustrine strata of Auvergne and Central France. Associated with the latter were the earliest beds of lava and volcanic breccias, which began now to be poured forth in the districts of Auvergne,¹ Velay, and Cantal, and continued to break forth at intervals to far later times.

Germany and Switzerland.—The Mayence basin, the principal part of the Vienna basin, part of the Molasse of Switzerland, containing the "nagel-flue," a conglomerate 6000 or 8000 feet thick.

Italy.—Part of the beds in the hill of Superga, near Turin.

North America.—The sands of Richmond, and the James River in Virginia.

India.—The Sewalik formations, which compose the sub-Himalayan range of hills. (Lyell's *Manual*.)

PLIOCENE PERIOD.

TYPICAL GROUPS OF ROCKS.—

	Feet.
2. Red Crag	50
1. Coralline Crag	40

1. The Coralline Crag is composed chiefly of soft marly sands of a white colour, sometimes speckled with green, containing occasionally thin bands of flaggy limestone. It is generally about 20 feet, but sometimes as much as 50 feet in thickness. Near Ipswich it has been denuded, and the Red Crag is seen to lie in the hollows that have been eroded in it, which is the only direct evidence of the superposition of the Red Crag on the Coralline; otherwise they lie side by side, the Coralline² Crag being confined to a strip of country 20 miles long by 3 or 4 wide, stretching through Ipswich from the Stour River to the Alde River.

2. The Red Crag consists of beds of red quartzose sands and gravel, with accumulations of rolled shells. It is very variable in character, sometimes regularly stratified, sometimes more confused.

¹ It is, however, most probable that the great volcanoes of the Mont Dor and the Cantal, &c., are of a still earlier period, as may be surmised from their more ruined and eroded character, the obliteration of their craters, and the great valleys worn deep into the flanks of their wide-spread mounds.

² It appears that this term of Coralline is a mistake, inasmuch as true corals are rare in both the divisions of Crag, while the coral-like bodies which are common in the Lower Crag are Polyzoa, and are also found, though not so abundantly, in the Red Crag. (Edward and Haime, *Palæontographology*, vol. i.)

Geology.

Both groups resemble the deposits which we may now suppose to be taking place in the shallow bed of the German Ocean.

Antwerp.—Sir C. Lyell (*Manual*, p. 174) describes strata around Antwerp, and on the banks of the Scheldt below that city, containing 200 species of shells, of which two-thirds are the same as those of the Crag of Suffolk. More than half are living species, principally belonging to the Celtic, though containing some Lusitanian (Mediterranean) species.

Normandy.—The same authority mentions a patch of Crag near Valognes in Normandy, and at other places, extending to a little south of Carentace, but none farther.

Italy.—The sub-Appennines or low hills intervening between the Appennines and the sea, on each side of Italy, are made of Tertiary strata, of which part are of Miocene, part of Pliocene, and part of a still more recent period. The beds of Asti and Parma, and the blue marl of Sienna, which near Parma is 2000 feet thick, over which are yellow sands and conglomerates formed on the shallowing of the sea, belong to this period, as do the Tertiary marine beds forming the base of the seven hills of Rome.

South Russia.—Sir R. Murchison and M. de Verneuil describe limestone and sands, rising occasionally to the height of several hundred feet above the sea around the coasts of the Caspian and Aral Seas, and the north-western parts of the Black Sea, as belonging to this period. They call them the Aralo-Caspian formation. The fossils are partly fresh-water, partly marine.

PLEISTOCENE PERIOD.

Without attempting to draw any very nice or accurate distinction between the deposits of this and the preceding period, we may take, as a rough definition of the Pleistocene deposits, "those in which more than three-fourths of the fossils are of existing species."

We know of no remarkable living generic forms, with the exception only of man, that may not have been in existence during this period. The horse, the ox, the dog, and all the variety of terrestrial Mammalia, seem now to have been disseminated over the earth, each species in its own province, very much as they are now distributed. The species of Mammalia were almost always, and in some cases even the genera were, different from those now occupying the province, while the species of Mollusca, &c., were nearly the same.

TYPICAL GROUPS OF ROCKS.—*Britain.*—The assemblage of sands and gravels about the county of Norfolk, known as the Mammaliferous or Norfolk Crag, containing both marine and fresh-water shells, and the bones of mammoths, together with those of the horse, dog, pig, deer, &c.,—deposits of Brentford (Middlesex), of Gray's (Essex), and of Maidstone (Kent), containing the bones of the mammoth or woolly elephant (*Elephas primigenius*); the extinct woolly rhinoceros (*Rhinoceros tichorhinus*), a monkey (*Macacus pliocenus*), and fresh-water shells, which, though not extinct entirely, are no longer inhabitants of Britain; one of them, for instance (*Cyrena consobrina*), being now only found in the Nile; the elephant bed near Happisburgh (Norfolk), underlying "the drift" there, and stretching under the sea, from which, according to Woodward, 2000 mammoths' grinders were dredged up by the fishermen in thirteen years; the clay deposit at Chillesford, Suffolk, described by Prestwich. (*Jour. Geol. Soc.*, vol. v., p. 345.)

Other similar partial superficial patches of clays, sands, and gravels, some of the gravels being widely spread over high ground, and known as the "high-level gravels," having the present river valleys excavated through them, others occupying these valleys and the lower grounds, and known as the "low-level" gravels. Some of these deposits are

older, and some newer than the Glacial beds to be mentioned presently.

Geology.

It was about this time, perhaps, unless it were still later after the close of the Glacial period, that the caves of the British Islands were inhabited by large hyænas and bears (*Hyæna spelæus* and *Ursus spelæus* and *priscus*). Into these dens many bones of other animals then inhabiting the neighbourhood were dragged by them. These remains are generally found in mud, under a layer of stalagmite.

The *Glacial Deposits* are chiefly clays, sands, and gravels, sometimes stratified, sometimes rudely piled together, and containing great blocks of rock, which also sometimes occur scattered loosely over the surface. They are variously called by the terms of "Great Northern Drift," "Till" (in Scotland), a brown clay with boulders; "Marls" in Wexford and Wicklow, where fossiliferous marl is interstratified with sand and gravel; "Limestone Gravel" in Central Ireland, chiefly consisting of pebbles of Carboniferous limestone, heaped sometimes into narrow ridges 40 or 50 feet high, and from 1 to 20 miles long, which are called "Escars;" "the Boulder Clay" in Northern and Central England, &c.; and "Drift" almost universally. The "Erratic Block group" of Delabeche is likewise a well-known name for these deposits.

The fossils of the Coralline Crag have a southern, while those of the Red Crag have a more northern aspect; those which are found at Gray's, &c., still point to a climate more like that of the south of Europe than our own, though as far as the woolly elephant and woolly rhinoceros are concerned, they might well have inhabited Britain at the present day, or even countries with a still severer climate.

A change, however, now took place, of a kind different from any we have yet met with, unless Professor Ramsay's ideas as to the glacial origin of the Permian and other old conglomerates be well founded. Simultaneously with a gradual, but eventually a great and wide-spread, depression of land, amounting in many places to 2000 or 2500 feet, there was a refrigeration of the climate of our own latitudes, so that the glens of our present mountains were encumbered with glaciers, even where their valleys were penetrated by the sea, and our low lands were entirely submerged. By the action of these glaciers, the rocks were scored and rounded, polished and grooved, and masses of rock carried down and heaped into moraines, while great blocks of rock were transported on fragments of those glaciers which dipped into the sea, and formed icebergs, being often carried far over the shallow seas, and dropped many miles from their parent sites,¹ sometimes resting on hill-tops, which were then banks and shallows in the sea, and so arrested the icebergs in their course. Alternations of elevation and depression doubtless took place, and the ordinary action of the breakers along the beach was aided by the quantity of detritus poured into it by the glaciers, and modified by that of the shore ice which formed along it in the winter seasons.

The Escars of Ireland were probably formed in the eddies at the margins of opposing and conflicting currents, the materials being piled up from each side.

These Glacial deposits are not confined to the British Islands, but extend over all the north of Europe and North America, down to a certain curved boundary, which in

¹ The largest boulder I know in the British Islands is near the head of the Devil's Glen in county Wicklow. It is 27 feet long, by 18 wide, and 15 high. It is of granite, resting on Cambrian grits and slates, six or eight miles from the nearest granite *in situ*, with a wide shallow valley between the hill on which it now stands and the granite district. At the recent meeting of the British Association at Dublin, Mr Godwin Austen described a large boulder of granite (apparently Scandinavian) found in the chalk near Croydon, showing that occasional icebergs wandered southwards even in the Cretaceous period.

Geology. Europe, according to Sir R. I. Murchison, only stretches so far S. as Lat. 50° in one part of its course, namely, near Cracow. Great blocks of Swedish or Norwegian rocks, as large as cottages, lie scattered over the plains of North Germany.

Towards the close of the Glacial period, or after it, our present low lands seem to have been again above water, and to have been more extensive than they now are, the British Islands being probably united to each other, and to the Continent, by plains which have since been widely eroded, and the shallow seas formed out of them that now separate our present lands. On these plains the Irish elk, the reindeer, the musk-ox, and other animals roamed, sometimes becoming drowned in the lakes or mired in the swamps, and leaving their skeletons as records of their former existence.

During the prevalence of the cold climate of the Glacial period many species of Molluscs which previously inhabited the British seas, and are found fossil in the Crag, retired southwards, and occur fossil in the Mediterranean Pleistocene deposits; but at the close of the Glacial periods they again came northwards, and are now inhabitants of our seas for the second time, while some of them no longer live in the Mediterranean.

Dr Falconer has recently shown that a similar history might be told with respect to the Mammalia. The *Elephas primigenius* has, according to him, never been found south of the Alps, where an allied species, *E. antiquus*, has left its remains (Lyell's *Supplement*); that species having previously roamed much farther north, and left its remains in the earlier Pleistocene deposits of Britain. Mr Godwin Austen informs us that Dr Falconer believes that the relative ages of the different drifts or superficial deposits may ultimately be worked out by paying attention to the different species of elephant found in them. (Austen "On Newer Tertiary Deposits of Sussex Coast,"—*Geological Journal*, vol. xiii., part. i.,—in which Mr Austen now would write *E. antiquus* for *E. primigenius*, on p. 50, line 18, and p. 55, line 8 from bottom, on Dr Falconer's authority.)

In like manner the Arctic or Boreal fauna and flora which prevailed over our islands and shores during the Glacial period, have receded towards the north again, but have left some traces of their former existence in the Arctic or Boreal plants which are found near the summits of our mountains, and the Boreal shells which may be dredged from certain deep hollows in our sea. Edward Forbes showed that the present fauna and flora of the British Islands is derived from five sources.

1. The remnant of a Spanish (Lusitanian) flora in the W. of Ireland, probably dating from the Miocene period.

2. A Gallican or Norman flora in the S.W. of England and S.E. of Ireland, with a remnant of a corresponding fauna.

3. A Kentish or north of France flora, and corresponding fauna, extending over the S.E. of England. These two may both perhaps be of Pliocene date.

4. The Arctic flora and fauna just spoken of, diminishing in numbers from the N. of Scotland towards the S. of England.

5. The great Germanic flora and terrestrial fauna, occupying all the central and northern parts of England and Ireland and south of Scotland, and spreading through the other districts in co-tenancy with the rest, dating from the time when the British Islands were united by the great plain to each other and the Continent.

The Celtic marine fauna comes in with this; its peculiar species being apparently created to occupy the shallow seas formed by the erosion of this great plain, and inhabiting them together with the Arctic or Boreal species that remained about the coasts and spread into the new sea, and such of the southern species as returned to it from the

Lusitanian province. One or two Arctic or Boreal outliers occur in deep cold hollows of the British seas, containing species not found elsewhere till we go much farther north, just in the same way that the tops of our loftiest mountains have plants not found on our lower grounds and plains, but occurring down to the waters' edge in Scandinavia.

It appears that just as the present surface of all land is formed by the outcrop of a number of beds of different ages, the newest being generally the most widely spread, and concealing the others, except in some particular localities where they rise up to view; so the population of animals and plants—the fauna and flora—of many countries, may be made up of different assemblages of different dates and different origins,—the newest perhaps spreading over, and more or less concealing, the others, the oldest only perhaps becoming apparent in one or two separated and isolated localities.

Besides the "Great Northern Drift," consisting of far-travelled boulders and fragments, there is also a much more generally diffused local drift, the materials of which are always derived from the immediate neighbourhood. This may be either contemporaneous with, or of earlier or later date than, the Glacial period, but is most probably later, and much of it perhaps of subærial origin. It is occasionally of very considerable thickness and importance in the British Islands, and similar "drifts" are found in other parts of the world in all latitudes, and not confined, like that of the Glacial period, to high northern or southern regions.

Raised Beaches and Submarine Forests.—Neither is our history brought to a close after the formation of all our present deposits, and the coming into existence of all our present species. Changes of level have since taken place, as shown by the occurrence of raised beaches, in the shape of banks of sand and shingle with shells, above high-water mark, round our coasts, containing just such species as occur in the beaches below them; and in the fact of peat bogs, containing the stumps and roots of oak, and fir, and other common trees, to be seen at dead low water, passing under the sea. In many of the bays along the south coast of Ireland peat is dug from such situations at low water of spring tides, and dried and used as fuel.

These facts show us that some of our peat bogs, at all events, may date back from a considerable antiquity. Beds of peat, indeed, sometimes occur beneath the clay and gravel of the Glacial deposits, or interstratified with such deposits.

Soil and Subsoil, Vegetable Mould, &c.—As long as the geologist is engaged only with the local facts, as to the formation of regularly stratified rocks or of large masses of earthy matter, whether regularly or irregularly accumulated, he proceeds with pretty confident steps towards his conclusions. Those conclusions are general ones, and often of a sufficiently sweeping character. Certain districts, now high dry land, were formerly deep sea, in which certain beds were deposited, including the remains of creatures that lived in the sea. The time when these things took place was a very remote one, and the interval occupied by them a long one,—hundreds, thousands, or millions of years, as the case may be. We are not compelled to be more definite, nor have we any inducement to be so. In proportion, however, as we approach the recent or human period, our steps necessarily become more cautious, since we have more of a personal interest in ascertaining precisely the nature of the processes and the period of their occurrence.

We are naturally anxious to know, if possible, the actual date, in years, of the last elevation of the lands we inhabit out of the sea in which they have been so often immersed, and what has taken place upon them between that last emergence and the historic times. Indications, then, which

Geology.

Geology. would be at other times overlooked, become now of importance; but in proportion to the interest attached to the investigation becomes its difficulty, since observations now are required to be more accurate and minute, as well as more widely spread, and more strictly checked and compared, than when larger generalities are dealt with. Hence it arises that we have not yet arrived at any satisfactory union of the history of the pre-human and the human periods, and possibly no very satisfactory union may ever be arrived at.

One strictly geological subject has yet scarcely been commenced upon, and that is the formation of soil. The natural formation of soil is certainly not always a rapid one. On many coral islets, crowded with birds and covered with vegetation, some even having considerable trees, there is little that could be called soil. The loose coral fragments and coral sand are slightly discoloured, and from their interstices small particles of "mould" could be picked up with the finger and thumb, but there is no layer of pure soil. Neither does soil always follow vegetation, however long continued. The great gum-tree forests of Australia rise from wide tracts of bare ironstone gravel or bare sandstone rock, slightly covered with an inch or two of rubble, without anything that could be called soil for scores of miles at a stretch. The ground looks like a great untidy gravel walk, from which a few straggling blades of grass spring up here and there between the trees. Neither are even calcareous rocks always covered with vegetation. In Galway and Mayo considerable flats of low ground may sometimes be seen formed of horizontal sheets of Carboniferous limestone, perfectly bare except in the crevices of the joints, where a short sweet grass springs up. On some of the fine corn land of the Cotteswold Hills, too, on the Oolitic limestones, the soil is not half an inch in thickness, and is composed principally of the rubble of the rock below, just such a soil as that of a coral islet would be if ploughed.

On some of the downs of the Carboniferous limestone, as also on Chalk downs, the soil consists of about an inch of close green turf, that may be cut with a knife and peeled off¹ the rock below in great rolls. I am not aware of any experiments for determining how long such bared spots would require to be reclothed with turf by unassisted nature.

Mr Darwin, in a paper in the *Trans. Geol. Soc.*, vol. v., attributes the formation of "mould" to the digestive action of worms, who swallow finely-divided soil, and eject it after extracting the nutritive matter therefrom, and thus improve the nature of the soil.

Foreign Pleistocene Deposits.

It has been said that, during the Glacial period, many of the Molluscs which previously inhabited the British seas retired southwards, and that their remains are to be found fossil in the Pleistocene deposits of the Mediterranean, while they do not now live on that sea, but have returned to their original province. In Sicily, especially, there are two if not more groups of rock, the Lower argillaceous and the Upper calcareous, consisting of thick beds of hard limestone, having an aggregate thickness of 700 or 800 feet. These beds cover half the island, and rise to a height of 3000 feet, the lower portions having as much as 30 per cent. of extinct species, while the upper parts contain shells mostly identical with species now living in the Mediterranean. (Lyell's *Manual*, chap. xii.) Some of these beds appear to be interstratified with lavas, part of the early outflows of the volcanic focus of *Ætna*.

Geology. These thick deposits, which are found in Sicily and the Grecian Archipelago, and some of which may exist in Spain and Portugal, were shown by Edward Forbes to be the contemporaries of the Glacial deposits, or northern "drift" of the higher latitudes, by the evidences already described.

It is perhaps to a later part of this period that we must assign the formation of the "loess" or "lehm" of the valley of the Rhine and its tributaries. This, as described by Sir C. Lyell in his *Manual*, p. 122, is a deposit of fine loam, of a yellowish-gray colour, occasionally laminated, but never separated into distinct beds, although it is often 200 or 300 feet thick, and rises occasionally to a height of 1200 feet above the sea. It seems to have been formed in consequence of the gradual depression of the whole country, after it had assumed its present external shape and "mould," and the filling up of a great part of the Rhine valley and its tributaries with matter brought down by the floods of the upper parts of the rivers. These materials being then spread from side to side of the valleys, would again be greatly eroded on the gradual re-elevation of the country, when every stream would cut down through the soft loess and re-occupy its old bed. Land and fresh-water shells of the same species that now inhabit the country are found in the loess; and in some places near the extinct volcanoes layers of pumice and lapilli are found, seeming at first sight as if ejected during an eruption, but perhaps merely washed away from the old previously existing cones. One crater, indeed,—that of the Roderberg, near Bonn,—is partly filled by the loess. Bones of the mammoth and other contemporaneous mammals have been found in it.

A similar deposit is described by Sir C. Lyell as found in the valley of the Mississippi, and forming the cliffs called the "Bluffs," which often rise to a height of 200 feet above the present alluvial plain of the river.

It is also to the Pleistocene period that we must assign the deposits of clay and sand which spread over the plains called the Pampas in South America, in which the bones of the Megatherium, Mylodon, and Glyptodon have been found. Similar superficial deposits are found in most countries; and either in these or in the bottoms of caverns, mostly buried under stalagmite, are found more or less of the remains of the extinct animals that preceded the existing races in their occupation of the globe.

There are two remarkable agencies now at work in various parts of the world which are probably more or less intimately connected with the period we are now considering, or perhaps with still earlier periods. Many of our present coral reefs, and many of our active volcanic mountains are of an incalculable antiquity, if we measure them by mere years or centuries, and not by geological periods.

Coral Reefs.—In a former part of this article these most singular, and at first sight most mysterious phenomena, were alluded to as illustrations of the method of formation of marine Calcareous rocks. Mr Darwin, however, has shown them to be also proofs of movements in the crust of the earth, and of great depression having taken place in the bed of the ocean where they prevail. He showed that since reef-making corals could not live at a greater depth than 15 or 20 fathoms (Forbes' *Circumlittoral Zone*), and since vast reefs (Atolls and Barriers) now rise with steep wall-like sides from profound depths in the great Pacific and Indian Oceans, just to the level of low water, their existence is only to be accounted for on the supposition, that when these reefs commenced to grow, the water was shallow enough for the animals to live in it near enough to the surface to enjoy that amount of light, heat, and play of the waves which is necessary for their existence. After the reef was thus commenced and built up to the level of low water (but how long after we cannot say), a slow and gradual motion of depression must have set in,

¹ Excellent fossils may often be procured from the surface of the Carboniferous limestone by this process of stripping it.

Geology.

either gentle and continuous, or acting by little fits and starts, never producing during any interval of time an amount of depression so great as to prevent the polyps continuing to raise the reef towards the surface, by the growth and multiplication of the calcareous framework of their own bodies. In this way the ocean bed that was once only fifty or sixty feet, is now hundreds and thousands of feet below the sea-level; and vast masses of calcareous rock are thus erected, as distant barriers encircling islands, some of whose loftiest summits still rise above the water, or as great massive tombs utterly enveloping and burying in their secret recesses the bodies of lands and islands, once rising high into the air, and now lying enveloped in coral rock deep beneath the sea.

It may well be that in some, if not many, of these instances the first movement took place in Pleistocene, Pliocene, or still earlier periods: it is possible even that some of these enormous submarine masses of coral limestone may be based upon corals of species different from those that form their summits—species that have died out in the lapse of time.

VOLCANOES.—When we study the structure of a volcanic district such as *Ætna*, *Teneriffe*, and many others, and find that the lower parts of the volcanic rocks that are open to our observation are interstratified with marine limestones, or sandstones full of sea-shells, we perceive at once that great changes have taken place in the district since the first commencement of volcanic activity. In many instances, such as in the Andes, in Java (see Horsburg's Map), and perhaps, if they were worked out, in every large volcanic district now at work upon the globe, we are enabled to trace back this commencement of volcanic action to some Tertiary, sometimes, perhaps, to a rather early Tertiary, period. One other result which we should arrive at is, that volcanic districts are, as pointed out by Darwin in his volume on *Coral Reefs*, districts of elevation, and that these in some parts of the world alternate with the districts of depression occupied by coral reefs. Volcanic districts never have atolls and barrier reefs in them.

But even if we dismiss from consideration all the aqueous rocks with which volcanoes are connected, and look solely at the igneous products themselves, we are in most instances compelled to assign an age to the volcano far greater than that of the human race.

Even so small an example as *Ætna* forms, compared with the gigantic volcanoes of Asia and America, will enable us to prove this. This mountain has a base of some 30 miles in diameter, and a height of about 11,000 feet. It has been built up by the ejection of ashes, dust, lapilli, and other fragmentary matter from the interior of the earth, and an occasional outpouring of streams of molten rock. It is made up of an indefinite number of conical heaps of such materials, arranged variously around one central and dominant mound, from which the greatest quantity of matter has been ejected. Some of these external cones are fully shown; some are half buried by the ejectamenta from other cones, or from the central one; and many others are doubtless altogether concealed under the great piles of materials heaped over the central parts of the mountain. On one side a huge ravine, 3000 feet deep and 5 miles long, has either been scooped out of the mountain by erosion or formed by subsidence.

Now the sensible additions made to this great mass of materials during the last 2000 or 2500 years bear a very trifling and insignificant proportion to the whole mass; and yet nothing we know of the structure of *Ætna*, or of volcanic action in any other parts of the globe, warrant us in concluding that it has been built up by a process much more rapid in its action than the one that has been going

on during the last 2500 years. Even if we make allowance for a considerably more energetic action during the earliest periods of its activity (which, however, nothing that we know of volcanic action would compel us to do), and suppose that it did not assume its present slow rate of growth till it became as large as *Vesuvius*, for instance, still the additional matter added to the bulk of *Ætna* since it attained that size must be so great that, judging from our experience of the rate of volcanic action all over the world, we could not allow a less period than one or two hundred thousand years for the process.

The mention, however, of such a period as a hundred thousand years is only introduced here to show the long period of time necessary; a million may have been nearer the truth for all anybody can show to the contrary; and if once even so much as 20,000 or 30,000 years be allowed as possible, no one would, I suppose, be inclined to insist upon further limitation from any considerations relative to human history.

But if such conclusions may fairly be drawn from the consideration of the structure of the comparatively small hill of *Ætna*, what period of time are we to allow for the slow and gradual piling up of the lofty cones of *Chimborazo*, *Cotopaxi*, *Aconcagua*, and others of the Andes, rising to twice the height of *Ætna*, spreading their bases over a width equal to the whole island of Sicily, and running through hundreds and even thousands of miles in length. We cannot conceive all the vast chain of the Andes ever to have had all its fiery vents in fierce activity at once. We know that in all volcanic chains eruptions take place successively, now from one, now from another; their very number therefore increases the time we must allow for the gradual accumulation of each, especially when we have to intercalate vast periods, during which they may have been all quiescent together. And yet these are most recent geological events; their operation is most obviously continued into our own times, and directly link our own history with the far receding past.

These are not unnecessary or superfluous speculations, but considerations requisite to enable us the better to understand and appreciate the geological facts of our own islands. When we see that hundreds of thousands, or even millions, of years have probably elapsed, during which other countries have stood pretty much as we now see them, except that the grand monuments that rise from them have been slowly elaborated, we can make proper allowance for the great spaces of time which have elapsed during the process of the comparatively insignificant changes that have taken place in our own lands. We learn to look upon the Glacial period, for instance, as separated from our own days by the lapse probably of millions of years, and we begin to understand how it is that physical causes, acting with infinitesimal slowness, have so changed the climate and the physical geography of our own part of the world, as to have caused the gradual extinction of whole races of large animals that once flourished in it.

Large, indeed, as the demands of the geologist may have been thought upon the bank of time, they probably fall far short of the capital stored up there for his future use. Some of the more recent of geological events are probably in reality of an antiquity as great as we have been accustomed to assign in our imaginations to the most remote. The Pleistocene period is probably really as far separated from us in past time as we have hitherto been accustomed to consider the Silurian or Cambrian periods removed from us. Geologists themselves have perhaps hardly formed adequate conceptions on this subject; and yet without those conceptions, difficulties are perpetually rising in the science which with them would disappear.

(J. B. J.)

Geology.

Minerva
||
Mines and
Mining.

MINERVA, in ancient mythology, was a goddess worshipped by the Romans under that name, and by the Greeks under that of Athene, or Pallas Athene. According to the earliest traditions among the Greeks, Athene was the daughter of Zeus. Homer says nothing of the mode of her birth; but Hesiod and other authorities say that she sprung from the head of Zeus after that god had swallowed his wife Metis. Various other legends concerning the origin of Athene were afterwards current, which arose, in all probability, from local traditions, or from the identification of the Greek Athene with similar deities of foreign nations. In the Greek religion Athene seemed to represent the union of power and wisdom. Thus she appears in Homer as the patroness and protectress of all those heroes who were distinguished for wisdom or courage, such as Achilles, Ulysses, Diomedes, and others. She is likewise represented as the deity of agriculture, and the giver of the olive to the citizens of Athens, the city called after her name; as the inventress of all sorts of arts and contrivances; as the protectress of cities and states; and the upholder of law and order. Although a warlike deity, she was not regarded, like Ares, as bloodthirsty and delighting in war for its own sake; but rather as succouring and en-

Minerva
||
Mines and
Mining.

couraging the defenders of the righteous cause, and as resisting and checking the mere brute strength of the god of war. The Roman goddess Minerva, who was identified with the Greek Athene, was represented as possessed of the same attributes. Her name seems to be derived from the same root as *mens* and *monere*. Minerva accordingly appears as the impersonation of wisdom, learning, and mental power. In Rome she was worshipped as one of the three Capitoline deities, and a festival was celebrated in her honour on the 19th of March, called *Quinquatrus* or *Quinquatria*, on account of its taking place on the 5th day after the Ides of that month. Minerva was also believed to have been the inventress of numbers; and a nail was annually driven into the wall of her temple to mark the number of the years. To this virgin deity calves untouched by the yoke were sacrificed, and the spoils of war were often dedicated. Minerva is generally represented as an armed virgin of masculine mould and majestic bearing, with sky-coloured eyes and an earnest countenance, wearing a plumed helmet on her head and an *ægis* round her breast, and holding in her right hand a spear, and in her left the round Argolic shield faced by the petrifying head of Medusa.

MINES AND MINING.

THE object of the present article is to present a view of British mines, the practice of mining in general, based upon the methods pursued in Cornwall and other mining districts of Britain, and to furnish accurate and recent statistics of the produce of our mines as well as their progress. Previous to these particulars, brief notices will be given of some principal facts concerning mineral veins and deposits, British and foreign, the rocks in which they are found, and the circumstances affecting their course and productiveness. Under the heads of the several metals will be grouped these and similar facts, and descriptions of the most important mining countries and districts abroad, with such statistics as can be obtained concerning them.

MINERAL DEPOSITS, VEINS, AND THEIR PHENOMENA.

Mining, strictly speaking, is limited to large and deep excavations of metallic deposits, like those of Cornwall, the Hartz, and other well-known metalliferous districts; but the term is sometimes improperly applied to the washing of alluvial deposits, such as those in which gold is frequently found. In our own country, in some parts of Cornwall, tin has been found included in gravel and similar diluvial matter. Small pebbles of tin, called "tin stones," have occurred under the surface, covered with gravel, clay, sand, or peat, which had to be removed before the rock was reached upon which the tin stones rested. The collecting and separating of these grains and stones is named "streaming for tin," because the covering gravel or other matter is cast upon an inclined plane over which a fall or stream of water is carried, and the whole mass agitated, so that the heavier tin stones remain upon the inclined plane while the lighter stones and earth are washed away. Tin streamworks are now of little importance, and are chiefly conducted by poor persons for small gains.

Some minerals, as iron, are found in beds rather than in veins. The ironstone beds of the coal measures in our country are very extensive and valuable. They supply the greater portion of the iron produced in Great Britain—the remainder being chiefly furnished by the beds and veins of hæmatite in the mountain limestones of Lancashire, Cumberland, Durham, the Forest of Dean, Derbyshire, Somersetshire, and South Wales. The beds at Ulverstone, Whitehaven, and the Forest of Dean are more exten-

sively worked than any of the others, and appear to be inexhaustible. The older works of Devon and Cornwall likewise contain many veins of black hæmatite. The brown hæmatites also of the north of England merit particular attention. They contain from 20 to 40 per cent. of iron, and are found associated in large masses with the lead veins of the lead-mining country; and occasionally they are seen in distinct and regular beds. They exist as "riders" to the vein, but sometimes they compose its entire mass, and then attain a width of 20, 30, and even 50 yards.

Scientific mining is almost entirely confined to the exploration of mineral veins, or "lodes," as they are termed in Cornwall. It is not a work of difficulty or science to lay open and remove minerals deposited either in alluvial deposits or in regular and massive beds, but it requires much skill, patience, experience, and capital, to explore an important lode of copper, or tin, or lead.

Mr W. J. Henwood gives an account of Cornish lodes *Veins*, as follows:—"The lodes may be described as quartzose portions of the rock highly inclined, and of no great thickness, which are more or less mixed with metals and their ores. They have commonly one prevailing direction, subject to slight irregularities and curvatures as well in length as in depth, and traverse granite, slate, and porphyries indiscriminately, and almost always without other interruption than what may take place from their interferences with each other, and with the *cross-courses*, *flucans*, and *slides* (interruptions technically so named in Cornwall). But notwithstanding the workings of adjoining mines have often been extended for a considerable distance on lodes in the same directions, it is not at all certain that the same lode has ever been traced for more than about a mile in length. In fact, they invariably throw off into the containing rock *shoots*, *strings*, and *branches*, in such abundance, that instead of one champion-lode (as the larger lodes are provincially called), the whole forms a complex and irregular net-work of veins. Often, too, the lode first discovered dwindles to a mere line, whilst some of its offshoots swell out, enlarge, and rival, or even surpass, both in size and richness, the vein from which they have been separated. It is, however, rather more frequently the case that the lodes split as they go eastward, than the contrary. It is by no means uncommon for lodes to split directly at the point of their inter-

Mines and
Mining.

section by a *cross-course* or *flucan*, on one side of which the lode appears in two branches, whilst on the opposite but one occurs." (*Transactions of the Royal Geological Society of Cornwall*, vol. v.)

The metallic parts of a lode do not form regular lines of metal running through the whole extent of the lode, but they occur in what the miners call "bunches," or in patches of various sizes and shapes. These very rarely occupy the whole space between the sides (or "walls," or cheeks") of a lode, even when the lode is rich and of tolerable width, but they are commingled with a variety of other substances, the principal of which is quartz. The vein named Gregorius at Freiberg is composed of nine layers, which may be thus represented:—

1	2	3	4	5	6	7	8	9
Quartz.	Galena.	Brown spar.	Silver ore.	Calcareous spar.	Silver ore.	Brown spar.	Galena.	Quartz.
Wall.								Wall.
Gneiss								Gneiss
rock.								rock.

From this it will be seen that the proportion which the metallic parts bear to the other parts of a vein, even in favourable instances, is not so large as might be imagined. One important department of mining, therefore, is to separate, as far as can be effected by mechanical means, the foreign substances from the metallic portions of the lode, as the two must be brought to the surface together. This mechanical separation gives occupation to women and children, in "dressing" the ores on the "dressing-floors" of the mines, and renders necessary a considerable amount of dressing machinery, as "stamps," "crushing mills," "jigging machines," &c., which are briefly noticed under the heads of Copper, Tin, and Lead.

Size of
veins.

The lodes of Cornwall have no determinate size, being sometimes very narrow, and at others exceeding several fathoms in width. Sometimes they extend to a great length and depth, or they terminate after a short course; and they are continually varying in breadth. Certain portions consist of a mere line between the walls or "cheeks" of the lode, while portions have been met with not less than from 30 to 40 feet wide. Such extremes are not common in the same lode. Occasionally, when a vein expands it becomes poor; but instances are known where the thickest part of a lode is also the richest part. There are masses of iron ore in Piedmont 350 yards thick; and the great open mine at Fahlun in Sweden is half a mile long and several hundred yards wide; but these are extraordinary examples. The distance for which lodes range along the surface of a country appears to have some reference to the magnitude of the disturbing forces affecting the district. A certain vein in Chile is 9 feet thick, has been proved for 90 miles, and is accompanied by branches 30 miles in length.

Position.

The lodes commonly occur in a position nearly vertical. Their inclination seldom diverges from the vertical to more than 10° in the north of England lead district; in Cornwall it averages much more (in some cases 70°), yet it does not often exceed 45°; while in many foreign mining countries it is inconsiderable. The inclination of a lode to the horizon is called its *dip*, or *underlie*, or *hade*, in the language of miners, and its intersection with the surface, the *strike*, which determines what is termed its direction.

Systems of
veins.

In every mining district there are what are called systems of mineral veins, each system being characterized by some peculiarities of position or contents; and each appears to be referable to a distinct period of formation.

Mines and
Mining.

Werner observed eight such systems at Freiberg, and the same number has been noticed in Cornwall. The first class appear to have been earliest formed, and constitute a very large majority of the whole number in the district. They are the older tin veins, underlie to the north, and are traversed by those of the second class, which are comparatively few in number and of little importance. These two classes include all the lodes from which tin is extracted. Their breadth varies from a mere string to as much as 36 feet, and most of those which are productive range east and west. The third class are the east and west copper lodes, and these form the greater number of all the copper lodes in Cornwall. They always cut across the tin lodes when the two kinds meet, and they are usually accompanied by small veins of clay. The fourth class comprehend the *contra* (or *counter*) copper lodes, and they are few in number. Their direction is N.W. and S.E., or at right angles to those bearings. The fifth class contain the *cross-courses*, which run due N. and S., or nearly so, and contain no tin or copper, and only a little lead occasionally. They are rather wide, and have been traced on the surface for considerable distances. The remaining three classes are chiefly of importance as adding to the accumulation of facts respecting mineral veins.

It is a long observed fact, that in almost every case in Direction. Cornwall the productive veins run E. and W., and the cross-courses N. and S. The more recently filled fissures and partings are composed almost wholly of clay; so that, as a general rule, veins which contain a great quantity of this clay traverse those which contain a smaller quantity.

In the Freiberg (Saxony) districts, as described by Werner, we find a number of mineral phenomena somewhat analogous to those observed in Cornwall, but the metals are different, as also are the prevailing directions of the lodes; the first and most ancient running chiefly N. and S., and including those veins from which the chief supplies of lead and silver have been obtained. The *contra* lodes are more argentiferous, but much thinner, and their direction is about N.E. and S.W. The veins of the third system are all N. and S., and those of the fourth at right angles to them, corresponding to the Cornish cross-courses. They both contain lead glance. The lead veins of the north of England and Derbyshire are much simpler than those lodes of Cornwall or Saxony. The direction of the lead veins is almost invariably E. and W., and they are traversed by non-productive cross-courses at right angles to them.

A number of perplexities arise out of the various inter-Intersec-
sections of lodes by one another; and it is obvious from tions.
what has been said, that such intersections in a mining county like Cornwall will be frequent and sometimes complicated. A lode intersected *horizontally* is sure to be *heaved*, and the consideration of all the points connected with heaves would comprehend—(1.) the composition of the intersected vein; (2.) the composition of that intersecting it; (3.) the nature of the containing rock; (4.) the widths of the intersected and intersecting veins; (5.) their horizontally-inclined angles; (6.) their inclinations; and (7.) the extent of the heaves at different depths. Again, the determination of these questions would apply equally to—(1.) the intersection of lodes by cross veins; (2.) the intersection of cross veins by lodes; and (3.) the interferences of lodes with each other. Without entering into these points of inquiry, we may notice that some general laws may be deduced from the average of a great number of observations. *Vertical* intersections, or *leaps*, or *throws*, require similar study, as to—(1.) the nature of the intersecting vein; (2.) the vein intersected; and (3.) the influence the angle at their intersection may have in the direction or distance of the leap or throw. In no instance of vertical intersections has the same vein been seen to intersect another more than once, or to interfere with more

Mines and Mining.

than one vein on the line of its dip. It is considered to be a general law, that in intersections of veins the portion thrown out is always on the side of the obtuse angle, and the more obtuse the angle, the more considerable is the out-throw. (See *Trans. of Royal Society of Cornwall*, vol. v., 1843, by W. J. Henwood; also, *Cornwall: its Mines and Miners*, &c., 1855.)

Supposed laws affecting richness.

The practical object of all researches into the course and structure of lodes is to ascertain, if possible, their general laws, so that the miner may follow their course, may retrace them when dislocated and thrown out, and especially determine what circumstances influence their richness in ore. A few circumstances only of the latter kind are generally recognised, while many others which have been received by some miners are subject to numerous exceptions. We may notice one or two of those generally approved. An old proverbial saying is, "ore against ore,"—arising from the fact that whenever a lode is rich, if there be another lode near it having nearly the same direction and in nearly the same country, whatever be the rock, the second lode will probably be found rich in that part which is opposite to the rich part of the first lode. The proverbial phrase "ore against ore" has been acted upon from an early period. Another fact is, that when *elvans* (porphyritic veins) and tin and copper lodes occur together, they are found in connection, as a whole, with good mines. Most of the ore in the principal mines in the Gwennap district of Cornwall have been found in or near large elvan courses. Not a few of the larger and wider bunches of ore, both tin and copper, have occurred in the immediate vicinity of cross-courses and flucans, and frequently also exclusively on one side of their intersections. It has been generally thought that depth below the surface is influential on the quantity and quality of the ore contained in the veins. It is confirmed by several observations, that mineral veins are generally richer near the surface than at great depths. It is a common opinion in Cornwall that copper, on the whole, occupies greater depths than tin. "At about 80 or 100 feet under the surface the first traces of copper or tin are found; rarely nearer to it than 80 feet. If tin be first discovered, even without a trace of copper, it is not unusual that in the course of sinking 80 or 100 feet or more, all trace of it is lost, and copper only is found. But if, instead of tin, copper be first discovered at a depth of 80 or 100 feet, tin is seldom or never found below it in the same vein." Such was the opinion of Phillips the mineralogist; yet tin is sometimes found 100 feet deep without a trace of copper, and there are many instances of tin ore accompanying copper ore to a great depth,—in one case 200 fathoms below the surface, and even under the copper. The meeting of two lodes, either vertically or horizontally, is generally considered a sign of richness, more particularly when the angle at which they meet is small or not very great. It is also a remarkable fact, that in every lode, whether it yields tin, copper, or lead ore, the portions which are the most perpendicular are the most productive.

Breadth.

In Cornwall the mean breadth of tin lodes is about 3·06 feet, of copper lodes about 2·93 feet, of lodes containing both metals about 4·7 feet; and this greater average breadth of lodes, including a mixture of copper and tin, is found in any rock and at any depth. Generally a diminution of the width of a lode is a precursor of poverty. The average breadth of lodes at less than 100 fathoms deep is 3·97 feet; at more than 100 fathoms deep it is but 3·36 feet.

Limits of districts.

The limits of mining districts are often very decided geologically, and are also marked by peculiar physical features. The neighbourhood of Cross Fell, in the north of England, has been worked with the greatest enterprise, but no instance has occurred of a single vein being traced across the great Penine fault to the west. Similar facts have been observed with respect to the Flintshire veins of lead,

occurring in the Carboniferous limestone, and which in no instance enter the Silurian rocks. In this instance, and in many others, the older rocks seem to rise on the line of a great axis of disturbance, and to cut off the whole of the mining ground, as if nature itself marked out the mining districts and set bounds to them.

Mines and Mining.

As a general rule, with some important exceptions, particular metalliferous deposits have affinities for particular rocks or geological formations. Iron at once occurs as an important exception to this rule, for it is found, to speak only of our own country, in the older rocks of Devon and Cornwall. Magnetic oxide and specular iron occur in the granite of Dartmoor. The New Red Sandstone, in its lower measures, yields beds of hæmatitic conglomerate. Important beds of iron are worked in the Lias and Oolites. The greensands of Sussex once furnished a large amount of iron to the ironworks, and recently the greensands of Wiltshire have shown indications of large deposits. But while iron is a marked exception, we shall find the rule hold good in relation to other metals. Thus tin is most plentiful in granite, and the rocks lying immediately above it. Copper is found in various slate formations, and in the *Trias* of geologists; but it is not generally met with in strata more recent than the Old Red Sandstone, although there are in England some exceptions. The celebrated Ecton Mine in Staffordshire, and the Llandudno or Orme's Head Mine in Caernarvonshire, are situated in the Carboniferous limestone. On the Continent copper is mined in a formation still more recent,—viz., the copper-slate of Thuringia, which forms a portion of the New Red Sandstone series. In Cornwall it prevails in the clay slates (*killas*), although one of the most profitable mines in Cornwall (Tresavean) is worked in granite. Lead has a marked affinity with the mountain or transition limestone, as is evident in Derbyshire, Yorkshire, Northumberlandshire, Durham, &c.

Affinities of mineral veins for particular rocks.

There are also other indications of preference more specific even than particular formations. For instance, while copper is found both in granite and slate rocks, the most productive mines are almost invariably situated just upon the junction of these two formations. Experience in Cornwall has shown that no continuous or very abundant supply of this metal is to be expected in any spot far removed from the line of junction. In the serpentine rocks of the Lizard, copper of great purity has been discovered, principally in masses.

The accumulated evidence from all parts of the mineral world proves that the contents of the veins depend on the peculiar character of the rocks they traverse. Although this is an acknowledged truth amongst geologists and miners, yet the ignorance or neglect of it has led to numerous practical mistakes. It has been supposed that because veins were rich in one place, the continuation of the same veins must be a continuation of the same riches. But if the veins intersect unproductive rocks, the riches come to an end. The public are often deceived by a plausible project which is brought forward on the strength of the ground being near a very prosperous mine. Works have been carried on at great expense in unproductive ground without a chance of success, simply because the lode happened to be in the same direction as in a neighbouring rich mine.

The mineralogical modifications, therefore, of the various rocks in metalliferous districts, very commonly bearing the same names, are subjects of careful examination by intelligent miners. When the rocks present certain characters, not perhaps noticed even by geologists, miners find their chances of success increased or diminished. In Cornwall and Devon they prefer a granite or porphyry (*elvan*) which is to some extent decomposed. Other signs are carefully noticed; so that an experienced miner will at once pronounce whether the "country is kindly" or not for copper or tin. Several instances might be adduced to

Mines and Mining. strengthen these views. The principal lode in Fowey Consols Mine affords a good example of ore accompanying a particular set of rocks, and it is found that the "bunches" of ore occur in certain directions. In Godolphin the lodes were rich where the *killas* (argillaceous slate) was of a bluish-white colour, but poor when it was black. In Pol-dice and Huel Fortune the lodes in the *killas* continued productive until they entered a stratum of blue, hard *killas*, which *cut out* the riches. At Penstruthal Copper Mine the lode had been tried unsuccessfully at various times in parts where the granite was hard; but trial being made where that rock was soft, it became one of the most profitable mines in Cornwall. In other countries we find indications of similar phenomena. In Upper Hungary the largest copper lodes are found in fine gray slates; in Saxony the silver ores occur in gneiss; and in the Hartz certain ores are intimately connected with the graywacke. At Andreasberg the veins which pass from argillaceous slate into flinty slate lose their riches in the latter. The Wenzal vein at Furstenberg runs nearly vertically from north to south across many beds of gneiss about 60 feet thick, dipping east, and each of these beds forms a distinct variety of rock. In the first bed the vein formed a nearly imperceptible string of clay; in the second it became 12 or 18 inches thick; in the third the thickness of the vein is preserved; in the fourth the silver ores, which had disappeared in the third, become as abundant as they were in the second, but they gradually disappear in depth. The vein is shifted in depth to the westward by several cross-courses, and between two of these it becomes very rich.

THE PRACTICE OF MINING.

From the manner in which mineral accumulations have been deposited in the earth, it is evident that mining operations must be of two very different kinds. Thus coal, salt, many ores of iron, and some of other metals, appear in regular layers interstratified with and forming part of the series of deposits which make up the earth's crust at particular places; while the usual ores of tin, copper, and lead occur in crevices formed in rocks after they have been deposited, and often since their subsequent metamorphosis.

Discovery. If mineral veins are to be sought for in any unexplored or but partially explored district, the geologist can predict favourably or unfavourably, according to the nature of the strata, but he can only predict. The practical miner can give his opinion whether the "country" (or rocks) be "kindly" or not for metallic veins. One course, however, of a surer nature can be also adopted, that of *shodding*,—an old term by which is signified the search for loose masses of ore of all sizes, either in or under the upper soil, sometimes upon the top, *basset*, or outcropping of the vein, but more frequently a little to the lower side where there is a declivity, and where the vein crosses the slope. This shode ore, varying from the size of a pea to large pieces, is produced by the weathering or decomposing of the sides of a vein, causing the ore to stand higher than the superficies of the rock, which in time slides off where the ground is sloping. Miners who go out shoding will traverse rivulets, gullies, scours, and other similar places where the surface of the ground is broken, or where the strata rise up to the grass roots; and they will even examine newly-ploughed lands and molehills. Shode ore being found upon a slope, or at the foot of it, the finder must look diligently for other signs of a vein, and then circumstances in each case will determine how a trench may be best opened towards the vein. A number of trial pits may be sunk, and other means of a like character may be adopted to prove the presence and character of the supposed vein.

Another similar course is to search for what is called *float-ore*, or that which has been floated down by water act-

ing upon the veins of ore. *Hushing* is the employment of a reservoir of water on a height, so as, by due direction downwards, to wash out pieces of metalliferous stone. If a quantity of water can be thus conducted down a slope, it will clear the superficies of the rock, wash and clean all the veins showing themselves at the surface, and often lead to a valuable discovery. Frequent applications of water will wear a channel to some depth without digging, which may or may not be subsequently employed.

Many lodes, however, afford no shode; for if the upper part of the lode contains no ore, or the detritus is carried too far, or is too minutely subdivided, there is no metallic indication to guide the miner. He may indeed meet with pieces of *gossan* (a hydrated peroxide of iron), which is always considered an indication of metal being near. Where gossan prevails it has been generally found that copper ore is connected with it. But the mode of search adopted where there are no shodes or gossans is that which is provincially named "costeaning," a word which literally means *fallen-tin*. The process consists in sinking small pits through the superficial deposits to the solid rock, and then driving from one pit to another across the direction of the vein, in such manner as to cross all the veins between two pits. The pits are often sunk several feet in the rock before the communications between them are made. It is necessary to the success of costeaning that the miner should have made out the prevalent strike of the principal systems of right-running veins in the district. In cases where the rock is not extremely hard, and is not thickly covered at the surface, open cuttings may be made at a small cost, which will lay the lodes bare for some distance. But the circumstances of the locality must determine or modify the attempts at discovery.

We have named *gossan* as a favourable sign, and it may be added, that in certain districts, and with certain classes of veins, there is so large a quantity of iron present that the decomposition of this metal near the surface makes itself manifest in ferruginous stones; and the tops of many of the lodes, when found near the surface, are frequently cavernous and abound with gossan. So much importance do Cornish miners attach to it, that they consider no large vein to be of much value without this accompaniment. A similar decomposed ore is named by the German miners *eiserne hut* and *eisenhopf*, and by the French *chapeau de fer*. But although these occurrences and names point to a prevailing feature, yet it is quite erroneous to apply this to all mineral veins, for in some valuable districts scarcely any iron exists, and therefore gossans and ferruginous indications are wholly wanting. The opinion may hold good for Cornwall, where gossan abounds and often extends to as much as thirty fathoms below the surface. It is of no value in itself, but attention has of late years been drawn to it on account of small amounts of gold associated with it, generally a few pennyweights to the ton. It was thought that by the use of Berdan's machine, and other apparatus, the gold could be profitably extracted, but after operating on large quantities, this hope has been disappointed. Gossan also contains silver in small quantities, and operations are sometimes successfully carried on for extracting it. Argenterous gossans sell at from forty shillings to forty pounds per ton. They are bruised to small pieces and sent to the smelting works, where they are mixed with certain proportions of lead ore of low average for silver. The two are then melted together and run out into pigs, which undergo further processes.

When the position of a mineral vein is ascertained, and some conjectures have been hazarded, from various signs, concerning its extent, course, thickness, and value, the work of mining properly begins. Shafts must be sunk and *levels* (galleries) must be driven to prepare the way for the extraction of the ore, and at the same time to carry off the

Mines and Mining.

Mines and
Mining.

water which either flows into the mine from springs, or drains into it from the surrounding strata. Two sets of galleries must be driven at right angles to each other, and both horizontal, one being in the direction of the strike of the vein, and the other at right angles to that direction. If we suppose a simple instance in which the mineral veins crop out at the sides of a hill, and follow a direction on the whole uniform, we may illustrate the proceedings by the subjoined figure, in which two lodes of moderate thick-

Fig. 1.

ness (A and B) are seen. A shaft must be sunk to reach the vein at a certain depth, but it will depend on the direction of the dip or underlie of the lode,—whether towards or from the valley or slope of the hillside,—and on many similar circumstances, as to where it will be most desirable to commence the sinking. With reference to the lode A, a cross-cut (1) may be driven at the lowest convenient point above the level of the highest water of the valley, and this gallery, having a gentle slope from the lode towards the hillside, will form the adit-level, and be the channel through which the whole drainage of the works will be carried; while it may also serve to convey the ore that is obtained out of the mine. With reference to the lode B, the driving of an adit-level will offer similar advantages, but there is a difference in the arrangement of the shafts. In both cases it is found advisable to sink shafts upon the upper side of the vein, but in B it is also convenient to have a sinking (3) towards the slope of the valley, and which does not cut the lode itself.

Shafts.

Although a perpendicular shaft has many advantages, and is almost always adopted in coal-mining, where extractions are carried on; yet in metallic mining, such a shaft is not in every case employed. Shafts are occasionally commenced at the outcrop, and, where the inclination is not very considerable, are continued in the substance of the vein itself; but in a slanting shaft the difficulty of raising the ore is much increased, and many practical reasons often render it expedient to sink at some distance from the outcrop, so as to meet the lode at a convenient depth.

The labour of sinking shafts in hard rocks like the Primary is very great, and the cost very considerable. From the records of shaft-sinking in Cornwall we may instance some cases showing the slowness of the descent, arising from the hardness of the rock. At one mine only 20 fathoms, or 120 feet, were sunk from 1828 to 1834, being at the rate of between 3 and 4 fathoms per annum. In Levant Mine, from 1830 to 1837, 90 fathoms were sunk, or at the rate of 13 fathoms per annum. In East Wheal Crofty Mine 77 fathoms were got through in the time between 1833 and 1837, amounting to 14 fathoms per annum. A sinking, therefore, of 1 fathom, or 6 feet per week, has sometimes been all the progress that could be made. To avoid the delays that must necessarily occur in sinking at this rate, a plan has been adopted in Cornwall of excavating several portions of a shaft simultaneously, by operating at different levels at the same time, which of course can only be done in a mine already opened, and requiring

Mines and
Mining.

additional shafts. The great feat is to excavate the several portions so accurately, that when they are finished they may all exactly fit into each other, and form one perfect and perpendicular shaft. One party will work from the surface, another from one of the upper levels, and a third from the lower levels, simultaneously.

Remembering the slow course of excavation in hard rocks, the depth to which some of the Cornish mines have attained is truly wonderful. Rather more than 20 years ago, Wheal Abraham Mine had reached the depth of 242 fathoms, or 1452 feet. Dolcoath Mine had reached 235 fathoms. The Consolidated Mines are 300 fathoms, or 1800 feet deep, and the United Mines 280 fathoms below the adit-level. Tresavean has gradually attained an extraordinary depth; and it was lately reported to the writer by Robert Were Fox, Esq., as being 320 fathoms, or 1920 feet deep below the adit-level, 2112 feet below the surface, and about 1700 below the level of the sea. To realize these depths, the reader may note the height of any lofty public monument or church spire with which he is acquainted, and, standing at its base, multiply in his mind the height of the object in sight by the number of times requisite to reach the depth of one of these mining shafts. Thus, for example, the height of St Paul's in London is said to be 340 feet; now the depth of Tresavean Mine is more than five times, or nearly six times, the height of St Paul's. The shaft of the Monkwearmouth Coal Mine near Sunderland is 1590 feet clear perpendicular depth, which is equivalent to the piling of the Monument of London seven or eight times upon itself. In one mining tour amongst the collieries of the north of England, the writer of this article descended twelve shafts, the aggregate depth of which was no less than *eleven thousand seven hundred and eighty feet*. One of these was the Monkwearmouth shaft first named. The mode of descent was (at that time) by a large iron tub and wire-woven pit-rope. The lapse of time in descent was rather more than four minutes.

Some foreign metallic mines have been carried to great depths. The Eselschacht Mine at Kuttenberg in Bohemia, now inaccessible, was deeper than any other mine, being no less than 3778 feet below the surface. That depth was only 150 feet less than the height of Vesuvius, and it was eight times as great as the height of the pyramid of Cheops or the cathedral of Strasburg. Mines on high ground may be very deep relatively to the surface, but not to the sea-level. The mine of Valenciana, near Guanajuato in Mexico, is 1686 feet deep from the surface, but 5960 feet above the level of the sea. For the same reason the rich mine of Joachimsthal in Bohemia, though 2120 feet deep from the surface, has not yet descended to the sea-level.

It is common to divide the shaft into two by a strong wooden partition running down the middle; and to sink several shafts when the mine is extensive. At the Carn Brea Mine, which extends superficially in length for a mile and a half, and in breadth for about three-quarters of a mile, there are from twenty to thirty shafts; and other mines have even more. Such shafts are often situated along the line of the lode, and they bear different names to distinguish them, as, perhaps, "Taylor's Shaft," "Dixon's Shaft," &c.

It very rarely happens that the lode is perpendicular, but its inclination as it descends is generally to the north. If the underlie is not great, the shaft may to a considerable distance follow the lode; but if it be great, the shaft descends, not in one continuous line, but, as it were, by a succession of steps. It will be sunk perpendicularly by several fathoms at a time, the lode meanwhile diverging from it to the northward; but at certain distances the sinkers pause, and horizontal courses are driven in the direction of the lode until it is again struck. Whenever

Simplest operations.

Levels.

Miner's tools.

the lode is struck the shaft is sunk again, and the lode is again to be reached by a horizontal course as before. Thus, while the shaft is being sunk, the horizontal passages of the mine are being constructed.

The adjoining figure is a vertical cross section of the shaft and lode, designed to show the course of operations in the simplest form. AB is the engine-shaft and CD is the lode. At every 10 fathoms of the sinking of the shaft a cross-cut *c* is driven to meet the lode CD. This process is repeated at every 10 fathoms until the shaft crosses the lode at 80 fathoms, where the direction of the cross-cuts *c* is changed from right to left to meet the lode, while the shaft descends perpendicularly as before. This simplest form of procedure may be varied to answer to the varied conditions and requirements of the lode.

What we mean by the *levels* of a mine will be understood by fig. 3. The levels are parallel courses which diverge on either side from the shaft, and follow horizontally the course of the lode. These courses are usually in Cornwall 10 fathoms, or 60 feet, apart. After the shaft is sunk 10 fathoms, the first level will be run; or, to speak in common language, a horizontal passage will be cut from either side of the shaft, following the direction of the lode. The dimensions of this passage are generally from 5 to 6 feet in height and about 3 feet wide. It is seldom made wider, unless the lode is very rich, and never much narrower, as this width is necessary to the working of the lode. But there is no limit to the length of the level, except the *sett* or bounds of the mine. Where the course of the lode is irregular, as it generally is, the levels will not be directly over and under each other, but may vary considerably according to the course of the lode, which necessarily governs the mining excavations.

The miner's tools consist of his pick and "gad" or wedge, and shovel, together with a series of blasting or shooting tools, such as sledge or mallet, borer, claying-box,

needle or nail, scraper, tamping-bar; added to which are powder-horn, tin cartridges, and safety-fuse. When blasting by gunpowder was introduced, great danger arose from premature explosions. The powder was placed at the bottom of the hole in the stone, when bored to a sufficient depth; the needle was then inserted, and the hole filled up with sand or clay, and rammed in perfectly tight. The needle being then withdrawn, and a rush inserted and ignited, the miner scrambled to a place of safety. But the iron needle, when struck with the mallet, would often give out a spark and explode the whole; a copper needle was therefore substituted for it about 30 years ago, which itself has been generally superseded by the invention of the safety-fuse, consisting of a small hemp cylinder well saturated with tar and filled with powder.

Besides horizontal galleries, what are termed *winzes*, or Winzes short shafts (see fig. 3) extending from one level to another, answer the purpose of making trial of the vein in the intermediate space between two levels, and by dividing the great masses into rectangular portions, these may be examined all round; so that the miner has the means of judging with tolerable certainty of the nature and value of the ores contained in each *pitch*, and can extract the produce in the most expeditious and economical manner, attacking these portions from as many points at once as may be convenient. By this arrangement, no necessity arises for breaking down the unproductive masses which are often found to intervene, even where the vein is richest and the ore most continuous. The vein having been properly laid open, the ore may be worked away round such unproductive masses, and these, when left standing, will form supports to the work on each side of the vein. Thus, for working out the ores, a system of winzes is quite as necessary as a system of levels; and as the levels are driven horizontally at vertical distances of 10 fathoms, so the winzes are sunk vertically at intervals of 20 or 30 fathoms, their position being so regulated as to prove the richest and most promising portions of the veins, and to avoid the harder and more unproductive portions.

Suppose that a continuous body of ore is met with in Pitches one of the upper levels, and that winzes had been regularly carried down to the level below it, then similar operations will be required in the upper, and winzes will be sunk from it to the next lower level in the same manner as before; but they will generally be situated about midway between the former winzes, so that each may expose the ground under the middle of the rectangle formed by the upper winzes and the levels between which they are placed; and

Mines and
Mining.

in this way the vein will be effectually exposed with the smallest number of excavations. A reference to fig. 3 will make this apparent. The tendency of this plan is to divide the vein into solid rectangular compartments of dimensions varying in different systems. When finally subdivided into portions of about 10 fathoms in height and 16 in length, they form convenient pitches for the Cornish miners. These pitches are "set" or let out to the workmen by auction, as afterwards described. In course of time the result of the operation we have described will be a large mine, as illustrated in fig. 3, which represents a vertical section of North Roskear, on the main lode. The references attached to this plate will explain particulars, and briefly illustrate the entire working of the mine. It will be seen that from a main shaft such as E, at vertical descents of 10 fathoms, long and ever extending horizontal galleries (levels) run right and left. These are numbered in the section successively, according to their distances in descent from the adit-level. By this numbering the exact place in the mine of any level can be indicated; and the workmen speak of their place in the 30 or 70 fathom or other level. All the horizontal strong black lines in the plate represent the levels; the long perpendicular lines the shafts, variously named; and the short perpendicular lines the winzes.

Stoping.

To illustrate the mode of working out the rectangular pitches, the irregular procedure according to the character of the vein, and the progress of the excavations, a distinct view of one portion of a Cornish mine is displayed in fig. 4. The different shadings will also show what parts

Fig. 4.

of the lode have been extracted, and what are in process of extraction. The "ground" or metalliferous mass is removed by what is technically called "stopping." To stop is to excavate horizontally, or "to beat away the backs." The word *stope* is evidently a corruption of *step*; and, in fact, the ore was taken away in steps. The French miners use the term *gradins* as synonymous with our word stopes. By the old miners the mass was invariably removed by the process of "under-hand stopping,"—the quickest, but the worst manner of getting the ore. The present method, or that adopted in the best mines, is termed "over-hand stopping." By this it is necessary, after having discovered ore, to sink shafts and drive levels before ore is attempted to be raised. No ore is raised before the ground is "laid open," and levels are excavated under the ore. Then stoping may be commenced over a level; the "deads" or rubbish may be piled up over the level, on a timber frame or "stull" (one only of which is necessary for each level by this plan, instead of several by the old plan); and the whole course of mining may be conducted so as to produce fair and average returns.

Ventila-
tion.

A current of air, commonly sufficient for ventilation, passes through the mine by descending the main shafts, coursing through the levels, and ascending by the winzes. But when

the mine is far extended in the course of many years, the miners do not find adequate fresh air; and the increase of temperature, which is always proportionate to the increase of depth, to the number of workmen present, and to the more confined and remote position of the recesses, is so considerable, that a decidedly injurious result is occasioned to the health of the miners. An analysis of sixteen samples of air taken from four mines in Cornwall, at an average depth of 214 fathoms, and at an average distance of 28 fathoms from any shaft or winze, gave a mean per-centage of 17.067 oxygen, 82.848 nitrogen, and 0.085 carbonic acid gas, instead of the normal proportions of 79 per cent. of nitrogen and 21 per cent. of oxygen. The mean temperature of the Cornish mines is generally higher than that of coal mines; and at a depth of 250 fathoms there is a difference of upwards of 10°. In many of the deeper parts of the Cornish mines the temperature approaches 100°; so that the miners have to plunge into water several times during their relays of painfully laborious work. The miners' health is thus injured; and the timber used to prop up the passages rapidly decays. These evil effects might apparently be avoided by the adoption of the Newcastle system of ventilation in coal mines, for which system the arrangement of Cornish mines offers peculiar facilities. (See a paper by H. Mackworth, Esq., in p. 28 of *Twenty-first Report of the Cornwall Polytechnic Society*, 1853.) The temperature of the deepest level in the Tresavean Mine was recently reported to the writer as 90° and upwards; and some of the water gushing into the deep level of the United Mines has been, says Mr Fox, from 106° to 108°.

Mines and
Mining.

Minerals were originally raised to the surface by the Methods of common windlass, and afterwards by a *horse-whim*. A raising mi-
neral.

water-wheel was next applied; and on the introduction of Newcomen's engine, the water expended was sometimes pumped up again by it. A water-wheel with double buckets succeeded, in order to reverse the motion, and alternately raise and lower the rope. This was improved by Smeaton, who retained the single buckets, but made the rope-roll to throw out of gear and reverse. A step further was to apply Watt's engine directly to the rope-roll by means of a crank. The Cornish bucket that contains the ore and stuff is called a *kibble*. An experienced mining engineer has known as much as L.2 paid for drawing the same quantity of ore to the surface by horses as is now done by steam-power for one shilling. In raising ores the miners generally work upwards from the *back* or upper part of one level towards the bottom of another, and the excavations are so arranged that the ore may readily fall down to the level below them. The modes of bringing the ore, when dislodged, to the surface are various in different districts and countries. The most primitive and most disadvantageous method is, when ore is carried on the backs of the men or lads to the surface. Even women were employed at this degrading labour in Scotch coal mines before the investigations of the Mining Commissioners in 1840. An act of Parliament now excludes females from underground work. Very little ore is now carried on the backs of human beings in Britain.

The conveyance of ores along the level is effected by hurdles or barrows in some places, and by waggons in more advanced districts. The passage is facilitated by laying down wooden or iron rails, and thus forming subterranean railways.

In situations favourable to inclined planes, they are most convenient for the transport of ores to the surface. At the

Wheal Friendship Mine in Devonshire there were two inclined planes, distinguished as the *old* and the *new*, both beginning near the same point on the surface. The old was about 500 yards in length, and the perpendicular depth from the surface at the lower end was 600 feet, the angle formed with the horizon being about 20 degrees; but another plane is now in use, which is 650 yards in length, and attains to a perpendicular depth of about

Mines and Mining.

1025 feet below its mouth, or 1100 below the surface. The inclination which it forms with the horizon varies from 30 to 45 degrees—an angle which exceeds that of the inclination of the steepest mountain in this and probably in any other country; consequently no carriage could be propelled up so steep an ascent without the power of machinery. A single track of edge-rails is carried along the plane from top to bottom; and a wrought-iron waggon, loaded with ore, is propelled by the force of a large overshot water-wheel, 40 feet in diameter and 5½ feet in breast, which is turned by a considerable stream of water, conducted with another stream several miles through a *leat* or artificial channel to work this and other machinery belonging to the mines. The two streams constantly furnish 5000 gallons of water per minute.

A popular illustration of this inclined plane might be drawn from St Paul's in London. The height of St Paul's Cathedral, to the top of the ball and cross, is 340 feet. Supposing, therefore, that two buildings of equal altitude were placed on it, we should have an elevation of 1020 feet, answering nearly to the perpendicular *depth* of the foot of the inclined plane below its mouth, which was before stated as 1025 feet. If from this immense elevation we conceive two ropes or imaginary lines, about 4 feet apart, to be extended through the air, following the line of Ludgate Hill, and reaching the ground at the eastern end of Fleet Street, a distance of above 500 yards, the length and slope of the inclined plane will be nearly correctly realized.

Under-ground economy.

The underground work of a well-managed mine will be of two kinds—(1.) Work for discovery or development; and (2.) Work for extraction of ores. We might distinguish these two kinds of work as *dead* and *live* work; the *dead* being that which proceeds in the dead rock, and the *live* that which is concerned in extracting the ores. The only fair and permanently successful plan of managing the interior work of a mine is to economize the supply of existing ores, so as in some measure to equalize it, and not to take out all the ore which could be immediately obtained. Masses should be left here and there only to be extracted as the general prospects of the mine may require. These should form a sort of reserve fund of ore, to which recourse may be had when less is raised from newly-discovered parts than the average. The ores thus reserved in various parts are expressively termed in Cornwall the *eyes* of the mine. They who take all the ore they can get out of a mine, without making proper reserves, are said to *pick out the eyes of the mine*. By picking out the eyes and sending them to market, a fictitious value has sometimes been imparted to shares,—a process analogous to that of some companies who have paid dividends out of capital. In all accounts of well-directed mines the reserves of ores are alluded to. Heavy expenses in works of discovery can only be profitably sustained by mining establishments of magnitude, which, by sending up a fair general amount of ores, can afford to appropriate a certain portion of the profit for discovery. The Fowey Consols Mine, Cornwall, has long been known as a good example of this management; and expenses have been there incurred for discovery which would have been ruinous if the mine had been divided into three or four separate adventures. The extraction of an extensive mine is very considerable, though by no means so large in mere quantity as that of an extensive northern coal-pit. At the Consolidated Mines, Cornwall, in good times, the daily extraction was about 200 tons, a large proportion of which was raised from a depth of from 200 to 300 fathoms (1200 to 1800 feet).

Mines and Mining.

The extent as to space to which mines are worked depends upon their age, prosperity, and hardness or softness of rock. Success has more to do with the extent than mere age. When the success of discovery has been great, excavation has proceeded rapidly; and conversely. When that very prosperous recent mine, the Devon Great Consols, had been at work only five years, it was found (in 1850) that there were 5853 fathoms, or nearly 7 miles, of excavations, vertical and horizontal.

One of the most formidable obstacles met with in the progress of mining is that of accumulated waters. Water is the arch-enemy of coal-mining in the north of England, and of copper-mining in the south-west. The copious springs tapped in sinking shafts near Newcastle have been the surprise of all who have encountered them. In that district they are termed *feeders*. In the sinkings at the Great Hetton Colliery, Durham, three principal springs or feeders were met with, of which the first issued 2000 gallons of water per minute, the second 1000 gallons, and the third 1600 gallons per minute. In sinking Hebburn Colliery, Newcastle, it was necessary to contend with feeders pouring out 3000 gallons per minute. At Haswell, Durham, an error in endeavouring to sink through a bed of quicksand occasioned an outlay of L.60,000, and yet the attempt was abandoned for another spot not far off, where the quicksand was avoided. The feeders of water in the quicksand supplied the enormous quantity of 26,700 tons of water per diem, probably the greatest amount known, unless we except the Dalton or Dawdon sinking for the South Hetton Company, Durham, where similar feeders were encountered, and where 1300 horse-power in steam-engines was necessary to pump out the water only, sometimes at the rate of 10,000 gallons per minute. In that locality the cylinder of the engines is 84 inches in diameter. They are condensing and double engines, and amongst the largest and most powerful ever erected. In the Cornish mines, although situated in hard rocks, we find vast accumulations of water. They do not issue from feeders in sand, like those just described; nevertheless, the infiltration of the rain and surface water, together with subterranean streams and pools, would soon inundate a mine and put a stop to the work, were not adequate means employed to drain the mine. In some of these mines a great increase of water almost immediately succeeds the commencement of the heavy autumnal rains; in others, on the contrary, this increase, though equally certain, does not take place until after an interval of several months. The necessary inference is, that the increase is owing to the rain and surface waters which, being absorbed, sooner or later find their way into the deeper parts of the mine.

Drainage.

Wherever in mining the workings are driven below the natural means of drainage, or below the level of the plain, recourse must be had to mechanical means to remove the water. The quantity of percolating water is diminished as much as possible by planking, walling, or caulking up with the greatest possible care those pits and excavations which traverse the water-levels; and the lower workings are so arranged that all the waters may unite in wells (*sumps*) situated at the bottom of shafts or inclined galleries, whence they may be pumped up to the surface or to the level of the *adit*¹ or gallery of efflux. In most mines simple sucking pumps are used, as they are less subject to give way, and are more easy of repair. As many of these are placed over each other as there are lengths of 10 yards in the shaft, below the point where the waters have a natural run. These means for draining are set in motion by that mechanical power which happens to be the least expensive in the

¹ The word *adit* is variously used in mining. It sometimes signifies a level taken up at the foot of a hill, and either driven on the lode or to intersect it, for the purpose of draining the mine at that level. It is also occasionally used in bringing out the ores. The *top adit* is that first driven; the *deep adit* is that lowest driven; the *air-adit*, that driven for ventilation. Sometimes the words *level*, *drift*, *adit*, *gallery*, and *sough*, are used synonymously.

Mines and
Mining.

locality. In the greater part of England, and in most of the coal mines of France and Silesia, this motion is communicated by steam-engines. In the principal metallic mines of France, in almost the whole of Germany and Hungary, and in some parts of England and Wales, hydraulic machines perform the work. In other places machines moved by horses, oxen, and even human beings, are used.

If it be merely necessary to lift the waters to the level of the adit or gallery of efflux, advantage may be taken of the waters of the upper parts of the mine, or even of the waters turned in from the surface, to establish water-pressure machines, or overshot water-wheels, for pumping up the lower waters. This plan is successfully adopted in several mines in Hungary, Bohemia, Germany, Brittany, Derbyshire, and Cornwall.

Greatadits.

There are many galleries or adits for drainage of several leagues in length, and sometimes they are so contrived as to discharge the waters of several mines,—as in the environs of Freiberg in Germany. The great drainage-gallery of the mine of Clausthal in the Harz is 11,377 yards, or $6\frac{1}{2}$ miles long, and passes upwards of 300 yards below the church of Clausthal. Its excavation lasted from the year 1777 till 1800, and it cost about L.66,000.

The greatest British work of this kind is what is called the Great Cornish Adit, which extends through the large mining district of Gwennap in Cornwall. It commences in the valley above Carnon, and receives the branch adits of fifty mines in the parish of Gwennap, forming excavations and ramifications which have an aggregate extent of between 30 and 40 miles, and which in some places are 400 feet below the surface of the ground. The longest branch is from Cardrew Mine, and is $5\frac{1}{2}$ miles in length. This great adit drains a tract of about 5550 acres in area, and discharges nearly 1500 cubic feet of water per minute. Rather less than one-third of this stream is collected at the adit-level, whilst the remainder is pumped up from a mean depth of about 190 fathoms. The temperature varies between $60^{\circ}\cdot5$ and 68° , and is on an average more than 12° above the mean of the climate. It opens into the sea at Restronget Creek, and empties its waters into Falmouth Harbour.

Under "*Lead Mines*" we shall notice the Nent Force Level in the north of England, which drains the numerous mines of Alston Moor.

Steam-en-
gines.

The steam-engine, applied to pumping, has been the great helper of deep mining, whether in coal or metallic districts. Without it many first-class collieries could not have been won, and many metallic mines must have been long since abandoned.¹ It is now almost a denizen of all lands; it exerts its mighty energies on the frowning cliffs near the Land's End, fumes in the narrow valleys, and it is planted on the high table-lands of Mexico. The first steam-engine in Cornwall was erected at Huel Vor, a tin mine in Breage, and was at work between 1710 and 1714. This was known as the old atmospheric engine, which continued in use long after Watt took out his patent; but the superiority of Watt's engine became so apparent, that it gradually advanced in fame and use. In 1778 the improved engines of Newcomen were giving place to Watt's engines. Watt required, as his remuneration, one-third of the saving of coal effected by his engines as compared with the old. To ascertain this saving a *counter* was invented,

which, being attached to the main beam, marked the number of its vibrations, and thus the work done and the saving of coals effected were readily calculated. Cornwall being without natural fuel, coal is enhanced in cost by its freight from other parts; hence the Cornish engineers have been ever studious of extracting as much as possible of the heating power from coal. The result of their efforts is, they have extracted more heating power out of a bushel of coals than other engineers.

Mines and
Mining.

The saving of coals by three of Watt's engines at Chace-Engine water mine exceeded L.7200 per annum; and although the patent-right no longer exists, the same mode of calculating the work by counters is still in use, and what is termed the *duty* of an engine is estimated by the number of pounds weight (always expressed in millions) lifted one foot high by the consumption of one bushel of coals. In 1812 Captain Joel Lean suggested the plan of publishing the estimated duty of the Cornish engines, ascertained by a counter placed on every engine. This plan gave a great stimulus to improvement. The counter is furnished with a Bramah lock, the key of which is retained by the reporter, who, by monthly inspection of the engines, and the orders for quantities of coals consumed, ascertains the consumption of fuel and the duty performed. The "duty-papers" are then made public, and include not only pumping-engines but also drawing-engines, and those used for the *stamps* which pulverize the ores. The whole particulars being arranged, the duty of any engine may be found on inspection, and for any reported year. If, for example, we wish to find the duty of the celebrated Taylor's engine (cylinder 85 inches diameter) at the Consolidated Mines, for the half year ending June 1837, we inspect the returns, and see it registered as 63,020,000 lb. lifted one foot high by the consumption of one bushel of coals. The duty of Borlase's engine at Huel Vor Mine (cylinder 80 inches), was, for the same period, 74,073,000 lb. lifted one foot high. Another example for the same time, was the duty of an engine of 70 inches cylinder at North Roskear Mine, namely, 79,535,000 lb.

It appears from a tabular view drawn up in 1838 that, since the establishment of duty-papers, the work performed by the ordinary engines has been more than doubled in twenty-four years, and the duty performed by the best engines during that period has been more than trebled. Taking the two extremes of that table, in 1813 the average duty of the best engine was 26,400,000 lb. lifted, while in 1837 it was 87,212,000 lb. lifted. This is a wonderful advance from the early supposed average duty of less than 17,000,000 lb. lifted. It must, however, be borne in mind that there is a wide difference between the common and the best engines.

The subjoined table presents the average duty of Cornish engines for four years:—

Years.	Number reported.	Average duty.	Average duty of the best engines.
1839	74	48,880,000	82,292,681
1840	58	49,730,000	81,809,036
1841	51	50,920,000	92,231,522
1842	45	51,620,000	99,262,657

The highest duty recorded is that of Taylor's engine, Large engines.

¹ Watt, writing to Boulton in 1783, gives some interesting particulars of Cornish mines at that time. He says—"Poldice has sunk a very great sum, and is not now gaining nor saving. It has cost L.35,000 to fit up a drain, Wheal Virgin, in this working, and it costs above L.10,000 a-year to drain the water, after all that can be done for them. Fool adventurers have sunk near L.14,000, and have no great prospect of recovering any part of it. At Dolcoath, it is said, they use L.500 of timber per month; and a new kibble-rope of above a ton weight is worn out in a fortnight. It takes full fifteen minutes to draw a kibble of ore there, which weighs only about 3 cwt. On the average, about two-thirds of the stuff drawn is barren stones. It cost three years' work, and I believe as many thousand pounds, to sink a new shaft in this mine. Every fathom of an engine-shaft that is sunk under the engine costs from L.50 to L.100. If we had not furnished more effectual means of drawing the water, I believe almost all the deep mines had been abandoned before now." (Letter from Watt, dated May 18, 1783, to Boulton.)

Mines and
Mining.

United Mines—being 110,000,000 lb. lifted. The average duty of the *best* engines has been, during a recent year, as high as 100,000,000 lb. lifted. The total force of steam-engines now at work is estimated as 5510 horse-power. The number of engines at work is reported as 82. The average duty in 1843 was 55,230,000 lb. lifted; in 1853 it was only 48,000,000 lb. lifted; refuse coal being largely used.

The annexed are the largest engines now in use in that district :—

United Mines and Consolidated, Pol-	90-inch and 85-inch cylinders, 90-inch cylinder.
dice	
Huel Prosper and Huel Darlington....	80-inch cylinders.
Godolphin, United Hills, Huel Tor.....	
Fowey Consols, Duffield, and East Huel	
Crofty	

The great 90-inch engine at the Consolidated Mines cost at the foundry L.2000, and the pit-work cost L.2000 more. The expense of putting it up was L.4000: so that no less than L.8000 was expended in its cost and completion with the pit-work. In twenty-four hours it consumed about 180 bushels of coals, delivered at one shilling per bushel. It lifted sixty-four gallons of water per stroke, and can work twelve strokes in a minute.

The great increase of duty above noted arises principally from three causes :—1. A reduction of pit-work resistances, if not balanced by an increase of water delivery. 2. A reduction of engine resistances, conjointly with an increase of power from a given quantity of steam, by using high-pressure steam (of forty or fifty lbs. to the square inch) expansively. 3. An increase of water evaporated in the boiler per bushel of coal consumed, by carefully preventing the radiation of the heat from the boiler, cylinder, &c.

The greatest quantity of water discharged from any of the Cornish mines in 1837 was from the Consolidated and United Mines in the months of February and March, when there were discharged from the Consolidated Mines 1657·18 imperial gallons of water, and from the United Mines 1634·49 imperial gallons, in each case every minute. Such was the estimate of parties connected with the mine, although it has been considered too high. Sir C. Lemon ascertained that the whole quantity of water pumped up by sixty Cornish engines in 1837, reached the enormous amount of nearly thirty-seven millions of tons. A single mine, Huel Abraham, yields the vast quantity of 43,500 hogs-heads of water in twenty-four hours, pumped up from a depth of 1441 feet. In reply to inquiries, we are informed that the average quantity of water raised by Devonian and Cornish engines is about 9000 imperial gallons per minute.

The engines for draining are erected near to the shaft in which the pumps are fixed, which is called the engine-shaft. One end of the beam hangs over the centre of the shaft, and is attached to the pump-rod, which is raised at each stroke of the engine, afterwards sinking with its own weight, which is always counterbalanced by a *balance-bob*; so that the whole power of the engine is exerted in raising the column of water in the pumps. An engraving of the pumps used in metallic and coal-mining is to be found in Plate CLXXVI., illustrating the article COLLIERY, in this work.

A large and substantial building generally houses the engine, having galleries affording convenient access to every part of the machinery. The centre of the beam is supported by the front wall of this house, and a low building attached to it contains the boilers, which in Cornwall, together with the steam-pipe and cylinder, are carefully cased and covered up with some non-conducting substances.

A very large expenditure is necessary for the materials consumed, both in the engineering and mining departments of the Cornish and Devonian mines. Of this the

expenditure for one year (1837) will be a sufficient example :—

		Total values.
Coals.....	56,860 tons at L.0 17 0 per ton,	L.48,331
Timber.....	14,056 loads at 2 12 0 per load,	36,545
Gunpowder ...	300 tons at 44 0 0 per ton,	13,200
Candles.....	1,344,000 lbs.	35,000

The roofs and sides of mining galleries must frequently be supported by timbering. In a gallery it may be sufficient to support the roof by means of joists placed across, and bearing at their two ends upon the rock; or the roof and two walls may be upheld by means of an upper joist resting on two lateral upright posts. From these simplest forms various adaptations, up to the most complex timberings, may be employed. An ingenious system of cross-bars is used in the Hartz for supporting the wall of a lode during excavation.

Considerable timbering is often necessary in shafts. Coal-mine shafts are often lined with timber in the north of England. Woodwork for shafts sometimes consists of rectangular framing, and sometimes of circular. In the Newcastle district coal-pit shafts are frequently *tubbed* to a considerable depth; and, when the feeders of water have been copious, iron tubing is employed. Plank tubing, when well executed, will sustain a pressure of 100 lbs. to the square inch, and endure for many years, when the water is fresh; but if salt, it corrodes the iron nails, spikes, &c. Solid wood tubing, neither requiring planks nor spikes of iron, when solidly and smoothly fitted, is convenient, is very durable, and will often sustain a pressure of twenty atmospheres. But iron tubing is now most frequently used in coal-mine shafts where copious water issues from sands. This, though costly, is very durable, and was applied in a colliery in Durham where all hopes of success seemed unfounded. It will sustain an enormous pressure.

The total quantity of timber in use for mining purposes in Cornwall would require no less than 140 square miles of forest of Norwegian pine, averaging a growth of 120 years. Taking a very speculative year (1836) as our example, the consumption of timber for mines was estimated at 36,200 loads, or 144,800 trees. The cost of timber imported in the same year was L.176,000; the drawback in the duties of which amounted to nearly L.82,000. The cost of timber for the Devon and Cornish mines in that year amounted to L.94,138. In the year 1837 the loads were 14,056, and the cost L.36,545.

The descent and ascent of most metallic mines in Corn- Descent
wall is made by ladders, of about 25 feet long and with and ascent.
steps from 10 to 12 inches apart. Successive ladders are placed slopingly, and at the foot of one ladder is a platform named a *sollar*, with an opening leading to the next ladder beneath, which is generally placed parallel with the one above. The fatigue of descending to great depths by successive ladders, and especially of returning after the day's work, and ascending these ladders, is very great. We may compute that one-third of a miner's whole physical strength is expended in going to, and more in returning from his work. In the year 1833 an accident suggested a new method to one of the Hartz miners, who availed himself of the reciprocating motion given to the pump-rods in the shaft. A portion of 100 fathoms was divided into 22 minor portions, and on each of these an iron step was fixed at intervals of four feet, while hand-holds were placed at convenient distances. A reciprocating motion of 4 feet being given to each rod, the miner stepped from one rod to the parallel one on the other when it arrived at his standing place. As one rod is always ascending while the other is descending, the miner can thereby ascend or descend at pleasure by stepping from one rod to the other. It is evident, for illustration, that if two rods A and B (fig. 5) be alternately descending and ascending by the communication of a reciprocating motion to them, then the steps

Cost of
materials.

Mines and
Mining.

Mines and
Mining.

a, b, c, and d, fixed on A, will, in every motion of, say four feet, be even with the steps *g, h, i, k, &c.*, fixed on B. If A descend and B ascend, then one movement will bring *a* level with *g*, and *b* with *h*, &c., so that a man beginning with *a* can step over to *g* when on the same level, and then he will be borne down, upon the next movement of B downwards, to *b*; from *b* in like manner to *h*; and so on successively until he arrives at the lowest step. In ascending he has only to reverse this action, and he will in due time reach the surface without fatigue. In the Fowey Consols Mine a *man-machine* of this kind extends to a depth of 1680 feet. It is improved by stationary platforms, the rod carrying down 12 feet at a movement. Other improvements may be adopted; and these man-machines are remarkable economists of labour, life, strength, and money. To descend 1700 feet requires only twenty-five minutes.

This machine is one of the most signal alleviations of the miner's toil which has ever been invented or applied. It ought to be generally adopted, as there is no objection on the ground of expense. In Cornwall the loss of time weekly sustained by workmen in descending and ascending ladders is estimated at three shillings, and the loss by man-machines at ninepence. They are now in very general use in the mines of France, Belgium, and Germany; and it has been shown that the saving, even in money, by the use of these machines, is considerable. Thus, in a mine where 250 men descend and ascend a shaft of 150 fathoms, the cost per annum is comparatively as follows:—

Ascent and descent by ladders.....	L.3150	0	0
... .. by man-machines.....	639	0	0

An engineer has shown how 10,000 miners might, by adopting these machines, save no less than L.39,000 per annum in the value of time alone. (For fuller details, see *Cornwall: its Mines and Miners, &c.*, p. 155-161.)

System of
labour.

It remains to explain the peculiar system by which mining labour is conducted in Cornwall. The two great classes of work-people consist of the surface men and the underground men,—the latter being about three to one as compared in number with the former, and being again divided into two strongly-defined classes, called provincially “tutwork men” or “tutmen,” and “tributers.” Tutmen are simply excavators, paid at a fixed rate per fathom. Their undertaking is to bring to the surface so much material, whether ore or mere “stuff,” at the agreed price. Such men are necessarily the first labourers in a mine, as they sink the shafts and drive the levels. They form a party, or *gang*, consisting of several persons, and each party is divided into three gangs, each gang working eight hours at a time, the whole number thus taking their turns in the twenty-four hours. The price at which they are set to work is the only subject of dispute. The work is given out by the officers of the mine at a price per fathom, which the tutmen are to bid for. They bid with a real or supposed knowledge of the nature of the ground, and the party offering to take it at the lowest price secures the work. To fulfil their task they require the use of machinery to raise the excavated matter to the surface, and they are allowed to use the machinery on the ground at a certain rate of charge, to be deducted from their earnings. Other deductions are made for candles, powder, safety-fuze, smiths’ costs, &c. In a case before us six tutmen took a contract for a month, and, after all deductions, each man earned L.2. 16s.

The “tributers” do not work for fixed wages of so much

Mines and
Mining.

per fathom, but become, by a peculiar arrangement, partners of the mine as regards the portions or “pitches” which they respectively undertake. We have already explained that the *pitches* are the rectangular portions into which the part of the mine containing the lode is divided, as shown also in the illustrations. The method of arranging the excavation of these is as follows:—A mine has its regular “setting day,” on which the captain of the underground work meets the tributers at a fixed time and place. A mining auction now takes its course, the captain acting as auctioneer and partly as appraiser. Particular pitches are named and put up by the captain. The tributers who form the bidders have, it is presumed, studied the character and metallic prospects of each pitch, and their knowledge and skill is now brought into exercise and competition. They are now about to agree to get the ores in the pitch in question, to break them, to raise them to the surface, and pay for the whole process of dressing them (if so required) and bringing them into fit condition for the smelter. It is evidently the object of the captain to set each pitch at the *lowest* price, so that his aim is the reverse of that of an ordinary auctioneer; and as the captain represents the proprietors, his interest is to secure the extraction of the ore at the smallest payment. The tributer will bid in proportion to his idea of the richness or the poverty of the pitch put up; if rich in metal, his labour will of course be less than if poor, and his reward greater. Quality and quantity of metal will regulate his offer. For example, he may offer to work the pitch put up, if rich in ore, at five shillings in the pound, that is to say, five shillings deducted from every pound's worth of ore raised to the surface, such being his *tribute*; and hence the name of tributer. If the pitch seem poor in ore, he may not take it under thirteen shillings in the pound; and the prices offered vary from one to thirteen shillings in the pound. The whole setting is generally arranged without much difficulty or difference. The pitches are set in this manner for two months at a time.

When the tributer proceeds to work in the manner previously described, he discovers the value of his bargain. If he finds the pitch much poorer than he expected, two months will terminate his bad bargain, if much richer, two months will terminate the bad bargain of the captain. If the tributer find his pitch to turn out extremely poor, he may throw up his agreement at the end of one month, or previously by paying a fine of twenty shillings. The preference is given to men best known and longest established in the mine. There are great and mutual advantages in this plan of conducting the raising of ores; and although the tributers are often disposed to complain, yet it may be doubted if any other equally beneficial and equitable mode of carrying on the work could be devised.

To show the operation of this system, we shall give an example occurring in actual work. The ore raised by a certain party of tributers sold for L.182, 2s. 2d.; and as the tribute was 7s. 6d. in the pound, the share for the tributers was L.68, 5s. 9d. From this sum the following deductions were made by the “adventurers” or owners of the mine:—For 108 lb. of candles, L.3, 12s.; for 195 lb. of powder, L.6, 10s.; for safety-fuze, L.1, 9s.; for hilts, 1s. 9d.; cams, 2s. 6d.; saws, 6s.; locks, 1s. 6d.; smith's work L.3, 19s. 6d.; drawing, L.3, 0s. 11d.; cost of dressing, L.6, 10s. 8d.; use of grinder, 8s. 10d.; sampling and weighing, 17s. 6s.; “subsist,” or money drawn on account, L.36, 18s.; total, L.63, 18s. 2d. Thus the actual costs amounted to about L.27, or 40 per cent. on the tribute; and the men had drawn so largely beforehand that they had only to receive L.4, 7s. 7d.

The earnings of tributers vary so greatly, from the nature of their work and from the system, that no average can be deduced. It was, however, found in 1837 at the Fowey Consols Copper Mine, that the average monthly wages of

Fig. 5.

Mines and Mining. 340 tributers were L.3, 7s. 1d. each, while the monthly average of 358 tutmen was L.2, 19s. 2d. each.

The remainder of this article will treat of the position, produce, statistics, and mines of the more important and useful metals, under each metal separately. (For additional information respecting gold and silver, not strictly belonging to mines and mining, see the article *PRECIOUS METALS*.)

GOLD.

Gold is less the subject of mining, strictly so called, than almost any other metal, as it is chiefly distributed in auriferous detritus. Some considerable portion is found in combination with iron pyrites and other metals, as silver, tellurium, and mercury. From silver it is obtained by a process termed quartation. Dr Percy has detected minute quantities of gold in almost all lead ores, and is disposed to believe that gold may have been thrown down by deposition from an aqueous medium; while Humboldt suggests that the formation of gold has some closer relations to, or dependence upon, the atmosphere, than lead, copper, or iron.

Great mistakes have been made, and may be repeated, concerning gold in veinstones. For example, about twenty-seven years ago lumps and specimens of gold were brought from North Carolina to London to induce the formation of a gold company. Fortunately a competent mining surveyor was sent out, who found numerous filaments and traces of gold in the pyrites and on the surfaces of the rocks, but he soon satisfied himself that "the veinstones had no body of ore downwards," and thus prevented a ruinous expenditure. Lodes or veins of copper, argentiferous lead, iron, &c., have been found in numerous instances to become more and more productive as they have been followed downwards; while, on the contrary, gold has invariably (hitherto) proved to be much attenuated in its descent, and in most instances to disappear at considerable depths. The auriferous quartz "reefs" in Australia run down sometimes from the surface between sandstone, slate, &c., but always seem to run out at a depth of generally less than 100 feet. This downward attenuation of gold veins in rocks is an opinion held decidedly by Sir R. I. Murchison (see the new edition of his *Silurian System*, the chapter on gold) and some other geologists. Reports from Mr Selwyn, government geologist, New South Wales, and from Mr J. S. Wilson (who has passed three years as a gold miner in the Sierra Nevada of California, and has communicated a memoir to the Geological Society of London), decisively confirm the above-stated opinions and facts concerning the downward impoverishment of quartz veins containing gold, and demonstrate that the richest produce is essentially derived from loose superficial debris piled up on mountain sides or slopes, or in ravines, and at various considerable altitudes above the sea.

It will be found upon examination, that in nearly all the gold countries the chief supply has been derived from the alluvial deposits, and but a small proportion from veins and rocks; and few deep mines have succeeded. Brazil indeed presents some examples of successful subterranean gold mines; and in two establishments at the famous Minas Geraes the veinstones have proved highly remunerative, though the ore is seldom long continuous; but the loose rubbish of Brazil has afforded its chief supplies of the precious metal. Nearly all the gold in Chile is procured from sands, detritus, conglomerates, and loose debris. In Peru and Bolivia the ancient drift or diluvium has afforded most gold; and in Columbia the great mass of gold has for many years been derived from diggings and washings in similar deposits. The celebrated mines of Beresor in the Urals have, however, shafts 105 feet deep, and galleries in which the gold

lies in soft decomposing gneiss, studded with bright veins of quartz and quantities of silvery talc. Brown spots of crumbling iron pyrites are strewn through it; but the large crystals of brown ironstone are only met with where the quartz is deposited in narrow and tortuous streaks and veins. It is from both sides of the hard white lines that the entire iron ore is collected containing the gold, partly dispersed in fine plates, and partly accumulated in lines and filaments like wire. The ore is followed in every direction.

With reference to the precise locality of the most ancient sources, termed Ophir (Supara of Ptolemy), nothing definite is known. The people living near the sources of the Indus obtained, according to Herodotus, a large quantity of gold from the eastern border of the Great Bactriana, and the desert steppes of Cobi. Much was obtained by washing sands, and more by digging. Herodotus again tells us that "in the north there is a prodigious quantity of gold; but how it is produced I am not able to tell you certainly." Pallas, in his *Travels*, describes the remains of these mines. Mines were also visited by Lepechin and Gmelin on the south-eastern borders of the Ural Mountains, which were in all probability the work of a nomadic people like the Scythians. This gold region still continues to yield treasures to industry. The extent of the works shows that the ancient workmen must have been very numerous; whilst an inspection proves that only the first rudiments of the science of mining could have been known. With very imperfect instruments (some of which remain) they must have worked very long and very patiently. They seem to have scraped out the gold with fangs of the boars, and collected it in leather bags or pockets. Some of the pits are 20 fathoms deep, shaped like a bell, and are about 7 feet in diameter. The passages and props are well excavated and arranged, but the former are extremely low. The natural pillars left to support the roofs are still effectual for that purpose in some parts, and in these are still found small portions of copper ore containing particles of gold. Human bones, probably of the workers, are found in the ruins of other pillars. Only the richest ores were worked, and some of them must have been smelted in the mines, for in the rubbish melted copper and smelting implements have been found. The operations of crushing and washing the ores were performed in the rivulets; and the smelting, whether in the mines or at the surface, was performed in small furnaces, of which Gmelin observed nearly a thousand in the eastern parts of Siberia. These were made of red bricks, and in them pieces of melted copper two and three pounds in weight have been found.

From the mines of Nubia and Ethiopia it is evident that much gold was produced. These mines, like those of the Uralian chain, produced a copper yielding gold, which the Africans knew how to separate. Belzoni discovered that a very extensive tract had been worked in the Sahara Mountains. The Pharaohs derived their wealth from these sources at the expense of much human suffering and loss of life. Mr Jacob concludes, from a close examination of the subject, that not less than L.6,000,000 sterling of the precious metals must have been annually produced from these mines, and that a large proportion of this must have been gold. This source of gold may have become very productive.

There were gold mines in Thrace and in the island of Thasus. Thessaly produced ores which were rich in gold, and Epirus rich silver ores, and there were rich silver mines in Attica; and from all these sources the Athenians drew their wealth. (See Boeckh's "Dissertation on the Silver Mines of Laurion," in his *Public Economy of Athens*.) They extended from coast to coast, in a line of about 7 English miles, from Anaphlystus to Thoricus. The ores extracted contained silver and lead, with zinc, and probably copper, but no available gold. These mines were worked by means of shafts and adits, and whole masses were removed, so that the supports alone were left standing. The state was the sole

Thrace and Thessaly.

Mines and Mining.

proprietor of them, but they were never worked at the public expense. They were always granted to private individuals in fee-farm, and these leases were transferred from one person to another by inheritance, sale, and other kinds of legal conveyance. When Themistocles proposed to the Athenians to apply the funds obtained from the mines to the building of ships, instead of dividing them as before amongst the people, the annual receipts appear to have amounted to 30 or 40 talents.

Sources to the Romans.

The Romans, who monopolized as much of the mining produce of the world as they could, found the principal sources in Upper Italy, in the province of Aosta, in the Noric Alps, and in Illyria. From this district gold was abundantly obtained at one period, partly in large grains on the surface, and partly in mines, so pure that an eighth part only was lost in the process of smelting and refining. Its great quantity caused a decrease of one-third in the price through all Italy, and induced the proprietors to employ fewer workmen in order to raise the value. The people named the Tarbelli, at the foot of the Pyrenees, also worked the soil extensively for gold. Amongst the most productive mines in particular belonging to the Roman republic, we may name the rich gold mines near Aquileia, those of Ictimuli near Vercelli, in which 25,000 men were constantly employed (Pliny, *Hist. Nat.*, xxxiii. 4), and the silver mines in Spain, in the neighbourhood of Carthago Nova, which yielded every day 25,000 drachmas to the Roman *Ærarium* (Polyb. xxxiv. 9). We are informed by Pliny that the Emperor Vespasian obtained annually from Galicia, Asturias, and Lusitania, L.60,000 of gold; while the silver was found in such quantities in Spain, that Hannibal extracted from a mine worked by him near Cartagena daily a produce exceeding L.300 of our money. Cato delivered into the treasury 25,000 lb. of silver in bars (L.120,000 in our money), besides 400 lb. of gold, all of which he had accumulated in Spain. Helvetius, who was only governor of Andalusia, delivered 37,000 lb. of silver in coin, and 40,000 lb. of silver in bars. Strabo also informs us that neither gold, silver, copper, nor iron, were found in such quantities and excellence in any part of the known world as in Turdetania (Strabo, *Geograph.*, p. 194). The Hungarian gold mines do not appear to have been worked before the eighth century, and the mines of Sweden and Norway not until a later period. In our own country, to the conquest of which the Romans were incited by the reported wealth of the inhabitants in gold and other metals, we do not find many evidences of ancient mines of the precious metals. Cimboline, prince of the Trinobantes (which included Essex), is stated to have coined gold money instead of rings. It is curious that Henry IV., by his letters-mandamus, commands Walter Fitz-Walter, upon information of a concealed mine in Essex, to apprehend all such persons as he in his judgment thinks fit, that do conceal the said mine, and to bring them before the king and his council, there to receive what shall be thought fit to be ordered.

The Welsh Triads celebrate princes as being possessors of golden cars, and in all probability this induced the Romans to penetrate into the principality. It has been recently found that the Romans worked the Gogofau or Ogafau Mine for gold, which is near Pamsant in Caermarthenshire. A Roman station is indicated by the remains of pottery and ornaments found on the spot; and several gold ornaments, and a very beautifully-wrought gold necklace, probably manufactured in the locality, have been discovered.

Geological and geographical distribution of gold.

It is very remarkable, as has been observed by Sir R. I. Murchison, that the countries which were successively to give laws and civilization to the ancient world—viz., Lower Egypt, Greece proper, Italy, &c.—should all alike have been destitute of procurable gold from their own soils, arising from the geological cause that those countries contain no mineralized old rocks. It were a curious geological problem

to ascertain why the older strata, when mineralized, are pre-eminently auriferous, and the secondary and tertiary strata, when altered and mineralized, are not so. Italy, south of the Po, contains scarcely any stratum older than secondary limestone, and is totally destitute of gold, a part of Calabria being the only exception. In proceeding, however, to Sardinia and Corsica, where silurian and crystalline rocks are found, there we observe that gold mines have been worked in the olden ages.

Adolph Erman, in his *Reise um die Erde*, and *Geographische Verbreitung des Goldes*, Berlin, 1848, gives some valuable information on the geographical distribution of gold, and has appended a gold map of the world to the latter of the above-named works, in which he marks seventy-seven tracts in which gold has been worked, or is known still to exist, and shows, in contradiction to the old-received opinion, how greatly it predominates in the northern hemisphere.

With reference to its geological position, gold is found in the primary group of rocks, including the transition strata of earlier writers, which, as they contain the oldest organic remains, have been technically denominated palæozoic. This series constitutes the dorsal spine of the great mountain chains of both the old and the new world. There are, however, vast regions, amounting perhaps to three-fourths of all known lands, where no such rocks appear. Experience has shown that it is only in the primary group of rocks, as above defined (including certain associated igneous rocks), that gold has been found in quantities sufficient to pay for working. All the veinstones or rock masses from which much gold has been derived, whether by natural catas-trophes or by human endeavour, belong to the primary and transition group (or what are now called the azoic and palæozoic rocks), and especially to those portions which have been modified by the eruption of matter in a state of fusion, or at a very elevated temperature. It is thought that the gold-producing rocks are not confined to particular geographical zones, as formerly supposed, but they are found protruding more or less in meridional bands in all countries where the primary series is visible.

In the Ural district, at Ekaterinburg, and north and south of it, gold was discovered in the beginning of the present century, and being traced to its parent source, small underground mining drifts were sunk on the quartz veins in the schistose and granitic rocks, which gave a scanty revenue. Gold was, however, subsequently discovered in lumps, grains, and scales in the gravel and sand on the sides of the brooks in the same district; and trials soon convinced the miners that it was far more profitable to wash the gravel and shingle, than to follow laboriously the quartzose veins containing threads of gold in the solid rock. The result has been the establishment of diggings and washings at different points between Petropaulosk in the north and tracts south of Minsk, which have afforded for many years yields of gold worth from L.500,000 to L.700,000. All these localities of auriferous gravel, shingle, and sand, are in the vicinity of those spots where Silurian and Devonian sandstones and schists have been penetrated and altered by the eruptive rocks before named. The gold, when traced to its original matrix, is found to occur chiefly in veins of quartz in the form of lumps, threads, and flakes. These veins rise, geologically speaking, from beneath; for they are seen to cut through all the strata or beds of which the hills were originally composed.

In considering the original derivation and formation of auriferous, alluvial, or diluvial deposits, the following theory appears most applicable:—When the primæval breakers, waves, and currents acted on the rocks containing gold, whether it were disseminated through the mass of the rock, or confined to the quartz veins traversing it, fragments of the auriferous rock would be detached equally with other pieces. Such fragments, either slightly water-worn or alto-

Mines and Mining.

Mines and
Mining.

gether broken and ground down, would afterwards be found in the drift clays, sands, and gravels, and would, in all probability, be much richer in gold than the actual gold-bearing rocks themselves. A current of water having sufficient force to bear along sand or pebbles of quartz, or any other rock of perhaps $2\frac{1}{2}$ specific gravity, might not be able to move associated fragments of gold, which metal has a specific gravity of 18 or 19. Moving water, therefore, has formerly effected upon the auriferous rocks that which the miner would now effect, namely, broken them up into fragments, swept away the lighter particles, and left the gold behind.

Rivers are great natural *cradles*, sweeping off all the lighter and finer particles at once, the heavier ones either remaining against any natural impediments, or being left where the current slackened in force or velocity. There are reasons why the auriferous drift may be richer in gold than the mass of the rock from which it is derived; and there are other reasons also why the auriferous drift of a country first deposited after the first formation of the gold, should be richer than any subsequent one.

The Gold
districts of
Australia.

These wonderful and recently-discovered auriferous countries have created the greatest excitement, and given rise to extravagant anticipations, as well as to much personal disappointment in the failure of foolish expectations. In the numerous publications of visitors to these regions, we find but little scientific information, nor are we yet able to form precise ideas as to all the geological conditions of these repositories.

At present the search for gold, at least in Australia, is chiefly confined to the alluvial beds. Of these, we learn from one geological visitor that at the Ballarat diggings, in the gold-fields of Victoria, the alluvial deposits may be thus divided:—

- | | | |
|------------------------|---|---|
| I. Older than Basalt. | { | A. Before the eruption of basalt and the bearing beds (<i>charriages</i>) of basalt boulders. |
| | | B. Contemporaneous with <i>charriage</i> of basalt boulders. |
| II. Newer than Basalt. | { | C. Newer beds covering the basalt boulders, but older than the formation of the existing valleys. |
| | | |

The source of the gold appears to be an indefinite succession of clay-slate, and of argillaceous-arenaceous-micaceous slates, seemingly interstratified, as regards their strike, with quartz veins of all sizes, which form the matrix of the gold. The basalt hems in the gold district on the east and west as an iron framework.

A report of a select committee of the Victorian Legislative Council has just been published, in which a very favourable estimate of the richness of the Victorian gold-field is given. Mr Brache, said to be a reliable authority, estimates the auriferous lands of the colony to be 20,000 square miles, including 20,000 square miles of quartz reefs. He computes that there are about 20,650,000,000 tons of quartz, which would take 100,000 miners about 300 years to work up. The alluvial lands are further estimated at 20,444,000,000 cubic yards, and if worked up by 100,000 miners at the rate of 90,000,000 cubic yards per annum, they would occupy 2240 years. The grand total of the auriferous wealth of that colony is estimated at L.26,783,000,000 sterling. The aggregate receipts for the five years from both districts amounted to L.41,830,696, of which L.7,032,141 came from New South Wales and L.34,830,696 from Victoria. It appears that all of this vast amount, except about two millions, was brought direct to this country. The Australian produce of gold for 1856 has been estimated at 120 tons in weight and L.13,000,000 in value.

Mr Wylds says, that the whole range of the Australian Alps, 200 miles long, is supposed to afford sites for gold-diggings. Sooner or later the working of alluvial gold soils will cease to be highly gainful. The question will then be decided

whether quartz-crushing for gold can be sufficiently remunerative. Many companies for this object have been projected, and nearly all have failed. There are many, however, who still think highly of quartz-crushing. A geological problem also still to be decided is the continuance of the veins or strings of gold beyond a moderate depth.

Mines and
Mining.

Respecting the ultimate production of Californian gold, it has been thought that the metal is too richly sprinkled to promise any very long continuance of an abundant yield; for it is almost a law among miners, that ore too highly condensed in any given locality of lodes or veins is, in the long run, much less profitable than when broadly and widely diffused throughout a mass of rock. Hence other regions whose gold is disseminated through mountain masses may afford a supply for ages to come, long after the rich gravel troughs of California shall have been exhausted. Much, however, may possibly be derived from Upper California. There is a remarkable geographical feature connected with the mineral phenomena of California noticed by Murchison. All the great quantities of gold have been derived from some twelve or fourteen localities in that portion of the western flank of the Sierra Nevada which assumes a north-westerly direction from that parallel to the meridian it had before followed between $37^{\circ} 30'$ and 30° N. Lat. By reference to the map of Fremont, it will be seen that the centre of this westward deflection is directly opposite to where the extremity of an east and west ridge, which traverses the great saliferous basin, impinges on the Sierra Nevada, and is associated with the protuberance which alone has proved to be so eminently auriferous in all the long chain of mountains ranging from the eternal snows of Russian America to Mexico, Peru, and Chile. It is possible that the intersection of ridges may account for a great local development of metal, just as in mining practice at home and abroad it is found that the richest branches are often detected where lodes traverse each other.

From an American state paper just published, we extract the following interesting particulars:—The gold and silver coinage of the United States, from 1793 to 1856, amounted to 549,341,514 dollars. In 1844, before the gold mines of California were discovered, the total of gold and silver in the United States was estimated at 100,000,000 dollars. The imports and receipts of bullion at the mint from American mines, after deducting the exports up to the 30th of September 1856, have added at least 150,000,000 dollars to the amount of gold and silver in the country, without taking into consideration the amount brought in by emigrants and returning travellers, or the amount carried out by travellers and merchants, not entered at custom-house, or the amount used in the manufactures or employed in the arts. In the fiscal year 1856–7 our country received from America imports of gold to the value of 33,000,000 dollars.

The *gold region*, so called, of the United States is a metalliferous belt extending in a south-west direction through the states of Virginia, North and South Carolina, and Georgia. Its length is about 600 miles, and it has a mean breadth, from its southern to its northern edge, of about 80 miles. In every part of this extensive line native gold is met with in alluvial deposits, and in various streams where the contiguous rocky strata abound in quartzose veins more or less auriferous. In Georgia the richest mineral belt is in the talcose slate and granite formations, alternating with hornblende-slate, gneiss, and chlorite-slate. Parallel belts are found also near Augusta, but they cease with the termination of the primitive region. The most productive researches have been made in the branch streams or stream mines, and in the beds of rivers, rivulets, and ravines. A moderate amount of gold has been derived from the metamorphic rocks of the Lower Silurian range in Lower Canada; and very recently intelligence has arrived of larger auriferous deposits in Canada.

Mines and
Mining.

Russia.

Gold in
Britain.

The greatest increase of precious metals, except from Australia and California, has been from the mines of Russia. Sir R. I. Murchison considered the present production of gold from Russia to be nearly equal to L.3,000,000 sterling per annum. The quantity of gold raised in that country during the five years succeeding 1847 was equal to about 296,932 lb. troy.

While our islands contain nearly every geological deposit from the oldest to the latest,—the older occupying all our mountainous tracts of the west,—it is only in some six or seven localities that gold has ever been largely found. British gold was not probably very abundant at any period, although the Druids may have found enough in the superficial gravel of certain limited tracts to serve for the manufacture of their beautiful “torques,” armlets, and other ornaments. There may have been surface accumulations in Britain and Ireland (as in Bohemia, &c.), now totally exhausted. Some little gold, associated with the tin in the old and crystalline rocks of Cornwall and Devon, had long attracted the ancients; and so late as the reign of Edward III. we are told that the mines of North Devon furnished enough specie (possibly silver) to enable that warlike prince to embark in one of his campaigns; and even at this day pieces of gold, some as large as a pigeon’s egg, are occasionally found at Combe Martin. In Cornwall a very small portion of gold is associated with the alluvial tin. In South Wales the Romans opened lofty galleries in the Silurian rocks for the extraction of small quantities of gold mixed with the pyrites. No British locality has afforded so much gold as the lead hills of Dumfriesshire, where, in the reign of James V., 300 miners were very profitably employed, and earned 4d. per diem,—in those days considerable wages. When the gold became scarcer the wages fell to 2d., and the works failed, like those of Bohemia and other exhausted tracts. It is said that some L.20,000 have been expended in this locality to obtain L.5000 worth of gold.¹ In the Wicklow Mountains in Ireland there are rocks which might be expected to be auriferous. Two or three golden streams descend from the granitic mountain Croghan Kinshela, and traverse the quartz veins in slate, and from these all the fragments of the precious metal have been derived, and minute portions are still sometimes found by the peasants. Formerly the government carried on the gold works, but the gains were infinitely exceeded by the expenditure.

In North Wales that part of Merionethshire which contains auriferous rocks lies between Dolgelly and the Moelwyn and Manod range, north of Festiniog. The gold at Cwm Eisen was discovered in 1843, and that mine alone has been worked, although bold assertions were made as to the gold to be obtained in that district. It has never been worked with a steady profit, as far as we can learn. The gold is found in a branching lode containing lead. Its principal branch runs north-easterly, and is mostly composed of exceedingly hard quartz. The neighbouring rocks are much disturbed and altered, and numerous little bosses of greenstone are intruded among its beds. At Dol-y-frwynog gold has been found in unusual quantities, and the lode there is the most promising. It runs W.N.W. and E.S.E., in low ground, and is principally composed of a white saccharoid quartz irregularly traversed by numerous

loose joints. It was first opened for copper, but gold was found in several flakes and grains irregularly disseminated through the quartz,—sometimes visible to the naked eye. Discoveries of gold have been made in the hills north of the Dolgelly and Barmouth Road.

We have instituted some particular inquiries on the present state of the Welsh gold speculations, and learn that the Dol-y-frwynog Mine, 6 miles from Dolgelly, is the principal, or has been such, it having stopped. At this spot the adventurers had erected a steam-engine of, we believe, 70 horse-power, with grinding-pans about 10 feet in diameter, and four balls to rotate in the pans of 3 feet in diameter, together with a number of amalgamators, furnaces, &c. To all these was added an expensive staff. What was the result of mining? At a depth of 9 fathoms they “cut” or met with the quartz lode. At 20 fathoms they found gold-bearing quartz, and this continued to a depth of from 30 to 40 fathoms. Then they drove east and west, and found that the gold greatly diminished and nearly disappeared. Now the mine has stopped, and the adventurers have little hope of further success. In fact, the presumption we have expressed is in this case again confirmed, viz., that gold veins in quartz diminish in richness in proportion to their depth from the surface. The result of the crushing of the quartz in the upper parts is interesting. On the 16th August 1854 they crushed 39 tons of auriferous quartz, and found gold at the rate of 5 ounces 9 pennyweights per ton of quartz. Afterwards they crushed 100 tons, and found gold at the rate of 5 ounces per ton; then successively gold at the rates of 8 ounces 9 pennyweights per ton, and 4 ounces 15 pennyweights per ton. These ratios might have paid well if continued, but the expenses for extracting small amounts per ton are vastly more than the profits. We have examined some of the rich specimens, and found the gold visibly disseminated through the mass of quartz.

The processes by which gold is made ready for the metal-Preparation of gold.
lurgist may be divided into three:—(1.) Washing; (2.) Trituration; (3.) Separation of the useful from the waste.

(1.) The *washing* is necessary to clear off the mud and dirt from the larger fragments, and to set free small particles of the precious mineral which are enveloped in clay. Various machines may be used to facilitate the operations, such as inclined cylindrical sieves, adopted in some of the Russian gold-washings, or annular sieves, or a conical sorting-drum.

(2.) *Trituration* is not so needful in gold as in other metals, for here nature has already been the great triturator. It may be necessary, however, in the case of auriferous quartz, to break down the masses either by hammers (*buchers*) or by crushers or grinders,—machines almost peculiar to this country, and to be seen in simpler forms at the lead mines in Cornwall and Wales, and in their more complicated forms in the northern lead mines. In instances where the portion of gold is very minute, *stamps* must be employed, in the form of a range of massive beams shod with heads of iron, and weighing each from 3 to 8 cwt.

(3.) *Separation* is effected by some of the very numerous contrivances which have been invented to facilitate the fall of the gold to the bottom when the whole mass is suspended in water; or, in another form, to cause the flow

¹ Those who are curious in the history of abortive gold-mining projects will find something to reward them in *The Discoveries and History of the Gold Mines in Scotland*, by Stephen Atkinson: written in the year 1619, and printed for the Bannatyne Club, 1825. From this book one might infer that gold was a staple product of Scotland—that it had been extracted in great abundance—and that from time to time it afforded employment to a considerable mining population. Atkinson speaks of Crawford Moor and Friar Moor in Lanarkshire, and Wanlock Moor in Dumfriesshire, also of a small vein called Glengaber in Peeblesshire, as the chief auriferous districts. To this day, we believe, the shepherds occasionally find grains of gold in the channels of the streams which water these districts. In 1803 Professor Traill found specimens of gold in a vein of quartz near Wanlockhead mines, one of which he deposited in the museum of the Edinburgh University. King James VI. expended about L.3000 sterling (a large sum in his day) in searching for gold on Carnwath Moor, but he never obtained more than about three ounces, worth not quite L.12. At the conclusion of this unprofitable speculation, Atkinson strongly urged the king to renew the national hunt for the precious metal, promising thereby “to make his majesty the richest monarch in Europe; yea, in all the world.”

Mines and
Mining.

of a stream of water down an inclined plane, depositing the heavier particles first, and carrying the lighter away with it to the lower end of the plane. Amongst the former machines are *dolly-tubs* or *keeves*, and amongst the latter are *buddles*, *tables*, *trunking-boxes*, and *cradles*, which last are extensively used in California and Australia. Several processes are finally adopted to cleanse the gold from remaining impurities. (For the physical properties of gold as a metal, see the article GOLD.)

SILVER.

Forms in
which sil-
ver occurs.

Silver occurs in many natural forms and combinations, which are enumerated in the works of mineralogists. Native silver is found crystallized in wedge-form octahedrons, in cubes, &c.; at other times in dendritic shapes, or in arborescences, resulting from minute crystals being implanted upon each other. Fine specimens may be seen in the British Museum. Thirty-four specimens of silver from Sweden were displayed in the Great Exhibition. It most commonly occurs in small grains, without determinable form, or in irregular masses of various sizes. It is soft in its native state, but harder than gold, and its specific gravity is about 10. The ancients were acquainted with silver from the earliest periods; and it is constantly mentioned in Homer, though in a manner indicative of its comparative scarcity. It was much more abundant in Asia than in Greece proper. The Greeks worked the rich mines of their own country and its islands, the chief being in Siphnos, Thessaly, and Attica.

The native metal is found more or less in almost all the true silver mines now worked. Very fine specimens of native silver have come from the mines of Kongsberg in Norway, and some of these, beautifully crystallized, were displayed in our Great Exhibition of 1851. One mass discovered in 1834 at these mines weighed no less than 840 lb., as reported. In the Great Exhibition appeared a mass of native silver from Chile weighing 154 lb. It was found in 1850 at a depth of 200 feet. Its dimensions and weight are not its only interesting characteristics, for it is formed of successive layers folded on each other, like some beds of the coal measures, or like piled cloth when seen in cloth mills or warehouses. A large specimen of gold and silver in one mass lies under a table in the Museum of Practical Geology in London. It weighs 300 lb., and was brought up from the mine of Madre de Dios, from a depth of 45 yards, on the back of a miner. It contains 12 ounces of gold per ton of ore, and 220 ounces of silver per ton of ore. At Kongsberg the native silver occurs in carbonate and fluoate of lime; at Schlangenberg in Siberia in sulphate of barytes; at Allemont in a ferruginous clay.

Cornish sil-
ver.

In our own country some few Cornish mines have produced silver in small quantities of extraordinary richness. There native silver has only been found in clay-slate; and the richest silver mines were Herland and Huel Basset. The former yielded about L.8000 worth of ore, and the latter about L.3000. It has been said that about L.40,000 worth of silver came from a mine at Alva. Some specimens, in very small quantities, from Illogan parish, would yield at the rate of 2000 ounces per ton. The principal portion, however, of our silver is obtained from the "gossans" (ochreous iron ore) and the argentiferous leads.

The proportion of silver in the lead varies in different mines. In Cornwall it is supposed to be 35 ounces of silver to the ton of argentiferous lead. In Devonshire (the highest of all) it is supposed that 40 ounces can be extracted from the ton of lead in favourable instances; in Cardiganshire, &c., the proportion of silver is presumed to be 15 ounces; in the Isle of Man 20 ounces; in Durham, Westmoreland, and Northumberland, 12 ounces. In the year 1851 the total number of ounces of silver obtained from British lead

was 674,458; and its value, at 5s. per ounce, was L.168,614. In 1852 the total quantity of British (including Irish) silver from lead was about 818,325 ounces, valued at L.205,080. In 1853 the estimated total quantity was 700,000 ounces, and the value L.192,500. In 1854 the estimated total yield of silver from British lead was 562,659 ounces. The Beer Alston Mines in Devonshire are the most remarkable for their richness, and two lodes have produced large quantities of argentiferous galena, often containing from 80 to 120 ounces of silver per ton of lead.

Silver is now separated from lead by Pattinson's process, *Desilverizing process*, which is one of the most important of recent metallurgical improvements. From more than 30,000 tons of the lead raised the silver is extracted by Pattinson's process, which would otherwise have been lost to the arts. Thus (at the rate of 5 to 8 ounces to the ton) not less than L.200,000 of silver are obtained annually. The result of this application has therefore been the actual saving of from L.60,000 to L.70,000 per annum to the country.

This desilverizing process is now employed in nearly all the lead-mining districts of Great Britain, and by its adoption the produce of silver has been increased to the amounts we have named, and nearly doubled within the last twenty years. Large quantities of lead, too, are annually brought to England for the purpose of being thus desilverized; and, in fact, it may be everywhere applied to alloys too poor in silver to be treated by cupellation, it being both simple and economical; nor does it occasion more than 2 per cent. of loss of lead. This process has within the last few years been very generally introduced into the provinces of Murcia and Almeria in Spain; and a large quantity of silver, not formerly extracted, is thus obtained from the slightly argentiferous lead ores of the Sierra de Gador and of Cartagena. The cost of refining lead previously to Pattinson's process was from 30s. to 60s. per ton.

The total yield of silver annually from Europe and Asiatic Russia has been rated by Humboldt at 292,000 marcs, by others at 310,000; while at the beginning of the present century that of the Spanish colonies in America was 3,849,160 marcs, or nearly 12 times as much. The sum total is 3,704,160 marcs, which is nearly 1,900,000 lb. avoirdupois, *i.e.*, little less than 9000 tons.

We have already spoken of the richness of Spain in silver, and its yield in ancient times. It is only within the last thirty years that Spain has again become a silver-producing country, several very rich mines of this metal having been discovered since the revival of mining in 1825. The celebrated mines of the Sierra Almagrera, in the province of Almeria, were discovered in 1839, and they have ever since poured a large amount of silver annually into circulation. In 1843 the mines of Hiendelencina, in the province of Guadalajara, were discovered, and these have been very productive. The produce of the Almagrera mines in 1850 was 40,596 marcs of silver, and it has probably since then remained about the same; but this amount is a decline from the earlier productions, the lode having become poorer, and water having hindered full operations. The veins of these mines run nearly north and south, and traverse finely-grained clay-slates and micaceous slates. The great lode of the Jaroso Mine is of extraordinary size, being in some places 6 or 8 yards, and even more, in width. The ores are chiefly argentiferous galena, the chloride of silver occurring but rarely in a separate state. The lodes of Hiendelencina run nearly east and west, and seldom exceed 3 feet in width; and are properly silver lodes, as they produce the ores of silver in chlorides and sulphurets, but unmixed with any ores of lead.

Europeans have undertaken the working of deep, extensive, and abandoned Mexican mines, with a confidence of their own superiority in the art and means of working such mines. The four essential points in mining are capital,

Mines and
Mining.

Produce.

Mexico.

Mines and
Mining.

industry, economy, and skill. These were thought to be at the command of the English; but in practice several drawbacks and obstacles—as distance, suspected frauds, &c.—have overcome the English. The single advantage of the introduction of the steam-engine by the English, burdened by almost insuperable difficulties in conveying it to the spot, and the deficiency of proper fuel when there, is not sufficient to counterbalance the numerous disadvantages under which they labour. Hence the history of English mining adventure in Mexico has been a history of failures and disasters, with occasional partial successes.

The mines of New Spain, the central group of which comprise three mining districts, including an area of about 1700 square leagues, are probably the most abundantly supplied with the precious metals of any in the world. Of the three districts the most southern of the group, that of Guanajuato, is as remarkable for gigantic human labours in the mountains as for its vast natural wealth. A group of porphyritic hills, partly arid and partly covered with the evergreen oak, and the strawberry tree, rises on the ridge of one of the mountains of the Cordilleras, from a part of the great central table-land of Mexico. The absolute heights of the summits of these mountains range from 9000 to 9500 feet above the sea-level; but as the neighbouring plain is nearly 6000 feet above the sea-level, they appear only as insignificant hills to the traveller accustomed to the lofty mountains of the Southern Continent. The celebrated vein of Guanajuato, the *Veta Madre*, crosses the southern slope of this porphyritic range, and the outcrop of the vein runs from S.E. to N.W. The quantity of the precious metals annually obtained from this vein, on the average of a number of years, amounts to *two hundred and eighty-six thousand pounds troy weight of silver*, being nearly double the average of the more celebrated mines of Potosi. The mountain of Potosi, however, has furnished, since its discovery in 1545 to the beginning of the present century, at least as much silver as was worth 235 millions of pounds sterling, although at the present day the quantity extracted is comparatively small, and the proportion of metal only about 1 in 2500.

The vein called the *Veta Madre* of Guanajuato has been worked for a length of upwards of 6 miles, although the silver has been extracted only on a line of about $1\frac{1}{2}$ mile. Its direction is (says Humboldt) N. 52° W., and its inclination from the vertical 45° , or 48° to the S.W. As this great mass of ore seems to have the same direction and dip as the clay-slate, it has been doubted whether it could be properly called a *vein*; but it appears to be a true vein, and divides into branches varying very considerably and capriciously in thickness. There seems to be a certain moderate depth at which the greatest riches occur, and this Humboldt states to be between 6000 and 7000 feet above the sea-level.

At the commencement of the present century the mechanical contrivances employed to work these mines generally were extremely rude. The whole of the ore was conveyed to the surface by human labour, the native Indians carrying a weight of from 240 lb. to 380 lb., exposed to a temperature of from 70° to 80° Fahr., for a space of six hours, and during this time ascending and descending several thousand steps in pits having an inclination of 45° .

The weight of the pure silver afforded by the Mexican mines in 1846 was about 1,047,582 lb. troy, and the value L.3,457,020. The weight of silver yielded in 1850 was 1,631,313 lb. troy, and the value was L.5,383,333. The weight of the produce in 1854 was 1,750,000 lb. troy. By reference to the table of general metallic produce at the end of the present article, it will be seen how far above other silver districts Mexico still rises.

Mines of
the Andes.

The silver mines of the Andes are frequently in ground so high that the profits are diminished by the difficulties

Mines and
Mining.

and cost of carriage, and the expenses of living and labouring in a barren country, destitute of water and sufficient fuel, and exposed to severe cold and snow. At the silver mines of Copiapo in Chile not a drop of water is to be found in a circuit of 9 miles. These mines are said to extend (as to capability) over 150 square leagues. The celebrated mines of Potosi in Bolivia were discovered in 1545, and since their discovery upwards of 1300 millions of dollars have been coined from them. Their total produce in pounds sterling is estimated at the astonishing sum of L.250,000,000. They are situated in an insulated mountain about 18 miles in circumference, which rises to an immense height in the shape of a cone. Spaniards assert that there are 500 mines in Potosi; but these are only lots (*estecqs*) portioned out to individuals, of which in 1826 there were not quite 100 at work. Cerro de Pasco in Peru is famous for its neighbouring rich silver mines. It is situated in $10^{\circ} 48'$ S. Lat., at the height of 13,673 feet above the level of the sea. The mines have yielded, before the revolution, 130,000 lb. troy of silver. They have been suspended in consequence of the revolution. The water, which always occurred at the depth of 400 feet, took full possession of the mines. The house of Abadia, by which they were chiefly carried on, has been ruined. The table of metallic produce given at the end shows the yield of silver for 1854 from Chile, Bolivia, and Peru.

The mode of working many of the Mexican and Peruvian mines is primitive and perilous,—the object being to extract as much ore as possible without consideration of the future. Thus, in the rich Cerro de Pasco many of the mines are worked in a careless and disorderly manner. The dangerous parts in the shafts are never walled up, and the excavations proceed without precautions for security. Hence accidents are of frequent occurrence, and every year many of the Indians lose their lives. In the now ruined mine of Matagente (a word meaning “kill people”) 300 labourers were destroyed by the falling in of a shaft. Rotten blocks of wood and loose stones commonly serve for steps, and where these cannot be placed, the shaft, which generally runs nearly perpendicular, is descended by the help of rusty chains and ropes, whilst loose fragments of rubbish continually fall in from the mouldering walls.

A recent report from Colonel Lloyd, chargé d'affaires in Bolivia, communicated to the Geographical Society of London, shows to what an enormous extent silver may yet be extracted from Copiapo, and from other South American mines; and as veins of silver and argentiferous lead frequently expand largely in their downward course, immense amounts of ore may be extracted. It seems to be the opinion of Humboldt and some eminent men, that the produce of silver will largely increase in the future.

Notwithstanding the very large quantities of the precious metals obtained from the mining districts of South America, the ores are not, *on the average*, richer than those of Freiberg, of Hungary, or of Transylvania. It is not, therefore, as has been generally supposed, from the *intrinsic* value of the minerals, but rather from their great abundance, and the facility of extracting them, that these mines are to be distinguished from those of Europe. The mean wealth even of the richer veins is not greater than four ounces of silver to the cwt. of ore extracted, whilst many districts of Saxony have at fortunate periods yielded ten and even fifteen ounces, and have often averaged not much below three. We find the produce of most of the silver ores of Freiberg in Saxony to ascend from $\frac{2}{3}$ ths and $\frac{1}{2}$ per cent. to various higher per-centages.

The mining district of Freiberg in Saxony abounds in Saxony. veins of silver, or argentiferous lead. They traverse gneiss rocks, and are generally composed of quartz, lime, and fluor spar. The richest of the Saxon mines, that of Himmelfurst, is situated 2 miles S.E. of Freiberg, and the elevation

Mines and
Mining.

of the surface above the level of the sea is 1346 feet; the depth of the mine is 1083 feet. There are five veins, and the principal one is from 1 foot 6 inches to 3 feet in width. The produce of metal is from $\frac{3}{4}$ ths to nearly $\frac{1}{2}$ per cent. The total annual produce of ore was formerly 680 tons, yielding 6160 lb. troy of silver, valued at about L.18,000. In 1750 a mass of silver was dug out from a mine near Freiberg, weighing 168 lb.

Hungary.

Hungary contains some rich and extensive silver mines. Those of Schemnitz and Crennitz have been long celebrated both for their riches and the immense extent of their operations. Some miles to the N.W. of Schemnitz is Koningsberg, another mining town. In the Royal Mine the vein runs between the metallic rock, which forms its *hanging* side, and the granite, which is its *hading* side. Transylvania has ruby-silver mines. The circle of Saaz in Bohemia abounds in various metallic ores, among which the ores of silver occasionally predominate. The veins at Catharinaberg traverse gneiss, and generally run in a north and south direction, and parallel to the mountains in which they are situated.

The Urals,
&c.

In the Ural and Altai Mountains, especially in the district of Kolyvan, silver is as abundant as in any part of the Old Continent. Travellers mention silver mines also in Armenia, Anatolia, Thibet, China, Cochinchina, and Japan. From China a piece of native silver was brought to St Petersburg of such purity that some coin was struck from it without its passing through the crucible. A story is told with reference to the mine of Schneeberg in Saxony, that a rich vein of silver was discovered in 1478, and so rich a block of the native ore or metal was dug out, that Duke Albert of Saxony descended into the mine and used this block as a dining-table; and when it was smelted it produced not less than 44,000 lb. of silver.

Norway.

The silver mines of Kongsberg in Norway are celebrated, and have been already named. They lie about 52 miles from Christiania, the capital of Norway, and are about 1800 or 2000 feet above the level of the sea. They were first discovered by a peasant in 1624, and were immediately taken possession of by the crown. In 1833 the produce amounted to 29,390 lb. troy, being the greatest ever attained by these mines, and this afforded an overplus of L.44,000. During recent years the yield has been somewhat less; but the profits in the four years 1841 to 1844 inclusive were L.46,787.

Copper has been found in addition to the silver, and at different times an inconsiderable quantity of gold. The geological formation is gneiss, and the lode is in felspar. The Fahlaand is a certain range of the strata from 10 to 60 fathoms broad, and when it leaves this, the vein does not bear silver; 100 lb. of this Fahlaand never contain less than $\frac{1}{4}$ th oz. of silver. The veins become metalliferous as they cease to run parallel with the cleavage of the felspar in the gneiss. The dip of the strata to the east is from 50° to 80°. Among the mines at present worked, the principal is called the "Armens-Grube," so named from being originally assigned to the support of the poor. The entrance to the Armens-Grube is by a high and broad level about 2 English miles long, at the termination of which the shaft commences. There are several levels branching off at various distances from the surface. The descent to the bottom of this mine is by forty-two ladders, averaging 5 fathoms each. The richest pieces of silver have been extracted from this mine; and there are now in the Royal Museum at Copenhagen two specimens, one of 6 feet long, 2 feet broad, and 8 inches thick. Although some of the matrix is attached to this specimen, it is supposed to be nearly all silver. The other specimen, though smaller, is perfectly pure, and is about 18 inches high and 12 in length and breadth.

Little blasting takes place in the rock, but a curious burning method of excavation is employed. On Saturday

Mines and
Mining.

at noon, when the workmen leave the mine, large quantities of wood are placed against the portion of the rock to be extracted. This being ignited, softens the rock, and on the following Monday the workman commences his labours. In very stubborn rocks gunpowder is used. The excavations are large, and the ventilation is good. Small bundles of wood are ignited instead of candles. Lodging-houses for the miners are near the mines, and they remain there the whole week absent from their families. They are searched previous to their return home. Their pay is equal to about 10d. per day; and they are supplied with provisions at a cheap rate. On the road to the mines we pass the roasting-house, washing-house, and stamps for pounding the ores, all of which are guarded by armed men. About 700 labourers are employed in the mines and at the stamps. The smelting-works are situated in the town, and the smelting takes place twice a year, occupying two months at each period. The fuel consumed is 500 cases of charcoal and 800 fathoms of wood.

The number of silver mines in Sweden has diminished like Sweden some of the other mines of that country. In 1767 only three were reckoned under exploration. The Sahla or Sahlberg Mine is now the only one of importance. It is situated in Westmannia, about 23 leagues N.W. of Stockholm, and is very ancient. At present it yields only from 4000 to 5000 marcs of silver per annum. Highly argentiferous lead is its principal product. It is explored to a depth of more than 200 yards. The soundness of the rock has allowed of large excavations and galleries, and in the interior there are winding-machines and carriages drawn by horses for the transport of the ores.

PLATINA.

Platina is a most useful but scarce mineral in large quantities. Its refractory and unalterable nature, even when exposed to intense heat, and its resistance to action by salts and acids, fit it in a very peculiar manner for chemical purposes, and accordingly crucibles and caldrons, sometimes of very large size, are made of it. Its polish and freedom from rust and tarnish, its slight dilatibility, and the regularity of its expansion for equal increments of heat, render it valuable for pendulums, &c. Medals were struck of it; and in Russia it was introduced as a current coin, but it having been found in greater quantities in Siberia, its value for coinage was lowered. From 1831 to 1833 the Russian mines produced 14,000 lb. weight of platinum. The Russian mines are all in the Ural Mountains, ^{in the} and the ore is disseminated in an argillaceous sand of a greenish-gray colour, resulting from the disintegration of the surrounding rocks, and constitutes from 1 to 3 parts in 4000 of the sand. Occasionally it has been found in lumps which contain 70 per cent. of platina and 3 to 5 of iridium. One locality contains small flattened grains with 88 per cent. of this valuable metal. It has only been known in Europe since 1748, and was at first brought into the market under the name of *white gold*. The whole produce of the Urals is sent to St Petersburg.

In the New Continent it is found chiefly in three districts, ^{At Choco,} and principally at Choco, in the neighbourhood of Barbacoas, and generally on the coasts of the South Sea, or on the western slopes of the Cordilleras of the Andes, between 2° and 6° of N. latitude. The gold washings furnish platina, the former being separated by hand-picking and also by amalgamation. Platina grains are found in Brazil, but always in the alluvial lands that contain gold, particularly in those of Mato-Grosso. Grains are also found in Hayti or St Domingo, and the sand containing them is quartzose and ferruginous.

A remarkable specimen was found in the Ural in 1827, not far from the Demidoff Mines, which weighed 9 $\frac{1}{2}$ lb.

Mines and
Mining.

avoirdupois; and at about the same time another was met with weighing 27 lb. These exceed any mass found in South America. Von Demidoff has also sent several other large masses to St Petersburg, weighing from 10 to 20 lb. From the discovery in 1835 to 1840, about 53,336 lb. were obtained from the Demidoff deposits. (Dickson in *Featherstonhaugh's Journal*, No. 3, Sept. 1831.) In 1847 the production had fallen to about 18 lb., representing, at the old price, a value of L.352.

The rarity of this valuable metal will render the following notices of its occurrence interesting. In 1847 platina was discovered in the Chapeau Mountain, and in the valley of the Drac, Upper Alps. It was found in a gray copper ore in the transition limestone. This metal has also been found in the alluvium of Columbia and Brazil, in the diorite rock of the high mountains of Columbia, and the serpentine rocks of the Ural. It has also been discovered in Saxony, on the right bank of the River Beus, in the territory of Presles, in a gray carbonate of copper. The quantities were too inconsiderable to justify exportation. In March 1848 it was found at Cavalles in the Mountain of Rousse, in gneiss and talcose schist, and also connected with a green carbonate of copper. The existence of platina in the silver of commerce has been recently certified by a money assayer at Munich, who has likewise obtained more than 500 grains of platina from the slag of the Bavarian coin.

MERCURY OR QUICKSILVER.

This metal is distinguished by its fluidity at common temperatures, its density (= 13.6), its silver-blue lustre, and extreme mobility. Native quicksilver occurs in most of the mines of the other mercurial ores, in the form of small drops attached to the rocks, or lodged in the crevices of other ores. Argentiferous mercury, or native silver amalgam, has been found in Hungary, in a canton of Tyrol, in Sweden, Siberia, &c., but only in moderate quantities. Cinnabar, or sulphuret of mercury, is the most abundant and important of the ores, and by sublimation yields the metallic mercury. Vermilion is pure cinnabar, being a compound of mercury and sulphur in nearly the same proportions. The finest crystals come from China and Almaden in Spain, and produce (Klaproth says) 85 per cent. of mercury.

Pliny has recorded two interesting facts—(1.) That the Greeks imported red cinnabar from Almaden 700 years B.C.; and, (2.) That Rome in his time received annually 700,000 lb. from the same mines. They have been worked from time immemorial, and even Theophrastus (300 B.C.) speaks of the cinnabar of Spain.

These mines are the most celebrated for this mineral in the world. The veins extend all the way from the town of Chillan to Almanedijos. Since 1827 they have produced 22,000 cwt. of mercury every year, with a corps of 700 miners and 200 smelters. The veins are so wonderfully rich, that though they have been worked pretty constantly during so many centuries, the mines have hardly exceeded the depth of 330 yards, or something less than a 1000 feet. The lode actually under exploration is from 14 to 16 yards thick, and at the crossing of the veins it becomes thicker still. The whole ore is extracted. It yields in their smelting-works only 10 per cent. upon an average; but there can be no doubt, from the analysis of the ores that nearly one-half of the quicksilver is lost and dispersed in the air, to the great injury of the workmen's health. A certain barbarous apparatus employed in its sublimation, has remained without any material change for the better since the days of the Moorish dominion in Spain. The ores are treated in thirteen double furnaces.

The hill in which the mines are situated is chiefly composed of sandstone, and on its summit rises a crest of naked

rocks streaked with cinnabar; indications which unquestionably led to the discovery of the mineral wealth concealed beneath. The whole of the country abounds with ferruginous ores, and in the mines themselves portions of mineral are sometimes found in which iron, quicksilver, and sulphur are blended together. The direction of the hill is from N.E. to S.W., and its height is about 125 feet. Two veins, from 2 to 14 feet wide, varying in richness, cross it in a vertical manner. These veins meet near the most convex part of the hill, when they expand into a bed nearly 100 feet wide, constituting the prodigious mass of ore known as "the Rosary" (*El Rosario*), the discovery of which was deemed miraculous. A belt of hard stone, from 3 to 4 feet wide, extends across the hill from N. to S., intersecting the veins. Beyond this the line of quicksilver does not pass.

These two veins are the only ones worked at Almaden, and they have already been excavated to such a depth that the drainage has become the heaviest item of expense. Should steam be applied, this charge would be considerably reduced. Thrice during the political contests was Almaden taken by the Carlists, and the last time they partly destroyed the machinery.

The labouring department has been carried on by convicts, each of whom costs the government 2s. a day; whereas peasants would perform double the work at less cost. The quantity of ground bored for shafts, and formed into caverns or resting-places, has not been precisely ascertained, but it is known to be immense. Scenes of the most terrific kind have sometimes occurred within these gloomy recesses. Soon after the junction of the two veins, owing to the confined state of the air, the gaseous exhalations have caught fire, when numbers of the miners have perished. Of this calamity the natives speak in most painful terms. Additional shafts diminish the risk of its recurrence. Remarkable cases of heart-rending misery and oppression have likewise occurred in these abodes of wretchedness. The surrounding scenery is exquisitely picturesque, and sometimes even majestic. The mineral wealth of this interesting hill was not scientifically explored till towards the middle of last century. In 1752 Mr William Bowles, an Englishman and naturalist, was commissioned to make excursions into the interior to survey mines, &c. His first trip was to Almaden, of which he gave some account in a work printed at Madrid in 1775. From the period of his visit the works were conducted on a better principle, but owing to old defects, the mines were inundated a few years afterwards.

About 2 leagues from Almaden another quicksilver mine was discovered in 1755, and commenced working in 1780. In the province of Valencia two quicksilver mines were discovered towards the middle of last century. The "Little Almaden," as it may be called, has produced in some years 1,217,160 lb. avoirdupois, but its average is 304,290 lb.

The quicksilver mines of Idria (a town of Illyria, near the mines of Idria), situated in the Austrian dominions, in the Alpine valley, are the next largest to those of Almaden. They employ upwards of 600 persons, and produce annually from 3200 to 3500 cwt. of quicksilver, according to one account; but it said that the Austrian government, in order to uphold the price of the metal, has restricted the produce to 150 tons. The workings have been carried to the depth of 280 yards. The memorable fire of 1803 was most disastrous to these mines, and it was only extinguished by drowning all the underground workings. The mercury sublimed in this catastrophe occasioned diseases and nervous tremblings to more than 900 persons in the vicinity. The bituminous sulphuret of mercury appears to be the base of these great explorations. It is of a dark, liver-red hue, of a slaty texture, with straight or twisted plates, and exists in large quantities in the bituminous schists. The produce of these mines has been very large, and it is said that in 56 months, from 1809 to 1813, they yielded 1,419,425

of Idria.

Mines and
Mining.

lb. of mercury, 270,029 lb. of vermilion, and 76,225 lb. of lump cinnabar; besides 6400 lb. of calomel, 2867 lb. of red precipitate, and 2450 lb. of corrosive sublimate.

These mines were discovered in the year 1497. The mountain in which they were first excavated has been exhausted, and the operations are now carried on in an opposite mountain, whence it is said a supply of mercury to almost any extent might be obtained, but the produce is mostly retained for the amalgamation of the Austrian gold and silver ores. A traveller who visited the place states that, having descended by 727 steps, reaching to a depth of 120 fathoms, he arrived at the region where the cinnabar is principally procured. The mining operations are carried on chiefly by galleries, the friable nature of the rock seldom admitting of large chambers. The cinnabar lies in beds from 2 to 6 inches in thickness, and is of a variety of colours from dark to light-red; the native quicksilver being sometimes mixed with it, and sometimes occurring in the intervening strata of earth or stone. The strata yielding the quicksilver do not appear to have any precise direction, and occupy about one-third or one-half of the entire mass of the rock. Proceeding a short distance, the visitor arrived at the galleries where the cinnabar is less common, and where quicksilver is the chief object of search. Here it occurs sometimes imbedded in a friable rock, sometimes in a kind of earth resembling talcose slate, but principally in the former—generally in particles too minute to be discerned by the naked eye. Often when the rock is broken, small globules present themselves, varying up to the size of a common pin's head. They are not distributed at random through the mass, but the matrix in which they occur forms strata usually about one or two inches in thickness.

Descending still lower into the richest part of the mine, the matrix consists almost entirely of talcose earth, and the globules of quicksilver are so large, that when it is broken they roll out and fall to the bottom of the gallery. The labourers, being unable from the state of the atmosphere to work longer, are relieved every four hours in this part, but in other parts they work eight hours. The total number employed was 360, divided into three companies, and their pay was only the usual pay of day-labourers in Germany, viz., from 15 to 17 kreutzers per diem (6d. to 7d.) Several appeared to be suffering from the effects of the mercury.

The masses containing the metal are carried to the washing-rooms, which are situated a few hundred yards from the mines. If the ore is of the earthy kind, it is broken up and laid upon large sieves, by means of which the loose or native quicksilver is separated from the earth. It is then put into little shallow boxes open at both ends, and a little inclined. A gentle stream of water being made to pass over it, and a rake being used, the earthy matter is carried off. Several of these boxes are employed in succession, and by the time the residuum reaches the last of them, it resembles a heavy gray powder, and is sufficiently pure to be carried to the vapour furnace. The stony fragments require only a slight washing to cleanse them from the outward earthy impurities. The furnace is half a mile lower down the valley, and consists of a circular walled building about 40 feet diameter and 60 feet high. The ores being there roasted, the vapour resulting from this operation passes into condensers, where the little drops of mercury collect, and are conducted into a porphyry vessel placed to receive them.

California.

Cinnabar has recently been discovered and mined in California, where it occurs in a quartzose vein in clay-slate. The veins are vertical, but the slates themselves lean considerably eastward. Great importance is attached to this discovery by the Californian miners.

Reduction
of ores.

The ordinary method of reducing the ores of quicksilver is by distillation. In some places the richer ores are burnt separately; but it is more common, and thought more eco-

nomical, to mix the richer with the poorer ores, and expose the whole mass together to the action of heat in closed retorts, which also contain a certain proportion of limestone. The retorts filled with the mixture of ore and limestone are ranged, to the number of twenty or upwards, in recesses of a furnace, and heat being applied, each retort is made to communicate with a vessel of water, in which the vapours of the mercury are condensed.

Mines and
Mining.

The imports of mercury into this county, chiefly from Imports. Almaden, are about 2,200,000 lb. annually, of which little more than an eighth is retained for home consumption. The remainder is exported principally to South America and Mexico, the United States, and the East Indies; while smaller shipments are made to Russia, Belgium, and other countries.

COPPER.

(On copper as a metal, see the article COPPER.) Some of the principal localities for copper may be noticed before we treat of the mines of this metal in our own country.

The copper ores from Australia are strictly analogous to those from the Ural. They occur in nodules disseminated in a slightly coherent sandstone, or ochrey clay, and the surface of the nodules is studded over with crystals, the interstices between which are filled with clay or sand. Some of the nodules are of large size; one of them from Burra-Burra measuring $2\frac{1}{2}$ feet by 2 feet superficial, with a thickness of 6 inches. The principal mass in this specimen consists of oxide of copper, with the green and blue carbonates of the same metal forming an external coating; but the three minerals are not superimposed in zones, the red oxide, although principally in the centre, sending out shoots in every direction. A little native copper occurs with the oxide. The Burra-Burra mines have yielded 56,428 tons of ore, averaging 40 per cent. of copper, between the time of their first opening in 1845 to the end of 1850, at which date more than 1000 workmen were employed. For some time these mines have been reported to be unworked, owing to inundations or desertion of miners to the gold diggings; but they are now said to be at work again, and highly productive. Many of the shares are held by British capitalists. The mine was commenced 5th September 1845, and the following are its returns of ore for the first five years:—

	Tons.	Cwt.	
September 30, 1846.....	6,359	10	Total produce in five
" 1847.....	10,794	17	years, 56,428 tons
" 1848.....	12,791	11	3 cwt. of copper
" 1849.....	7,789	16	ore; value of same
" 1850.....	18,692	9	L.738,108.

The ores yielded from 30 to 70 per cent. of copper.

No copper mines have ever yielded such rates of profit as the Burra-Burra. At a meeting held in April 1850, it was stated that the amount of paid-up capital was only L.12,320, on which dividends had been paid, from June 1847 to March 1850, amounting to L.172,480, equalling a total profit of 1400 per cent. upon the capital. In several of the dividends, in particular, the profit was at the rate of 200 per cent. upon the capital, and in none less than 50 per cent. The balance-sheet showed an undivided profit of L.99,779, thus making the total profits since the commencement L.272,259. In five years the shareholders had received net dividends amounting to nineteen times the money they advanced.

The most productive deposits of copper in the United States are those lying upon the shores of Lake Superior. The discovery of these was made many years ago, but the first scientific researches commenced only in 1842 by a geological surveyor attached to the government of the state of Michigan, and have been continued by Mr Jackson, who has made a detailed study of the district.

Mines and
Mining.

There the native copper exists in two distinct deposits, one towards the northern extremity of the state of Michigan, at Keweenaw Point, which forms a projecting headland towards the middle of the shore of Lake Superior; and the other in Isle Royale, situated in the lake, about 50 miles N. of Keweenaw Point. This island, which ranges S.E. and N.W., lies exactly parallel to Cape Keweenaw, and to the strike of the beds of which it is composed. It presents also a geological construction identical with that of the shores of the lake. The two deposits occur in the same formation, and under circumstances precisely similar. Mr Jackson's geological map shows that the Michigan shore of the lake consists of granite, trappean rock, and red sandstone belonging to the Lower Silurian series. The sandstone and trap form parallel bands running due N.E. and S.W.

Native copper and silver are found at Cape Keweenaw and Isle Royale only in the trap formation; all the important veins forming together a narrow zone in the amygdaloid. When a vein of copper penetrates the trap, it at once thins out, and only affords a scanty film not worth working. The sandstone and conglomerate form also another limit of the metalliferous band, and when the veins do not terminate at the contact of the sandstone, the part extending into this rock is filled with calc-spar instead of copper; hence it results that the thickness of the amygdaloid band intervening between the trap itself and the sandstone becomes the limit of the cupriferous veins, which are of the most solid metallic form. The depth of the veins is unknown. It is uncertain if they extend below the sandstone. At Keweenaw Point the cupriferous zone may be about 120 miles in length; and in Isle Royale it ranges through the whole extent of the island, which is about 45 miles long. The richer portions are unequally distributed. Mr Jackson (*Geological and Mineralogical Reports*, by Charles Jackson, November 1849) has made numerous researches for several years, and states the direction of the veins, of which he has explored more than a hundred. In Copper Fall Mine they take a direction from N. 25° W. to N. 30° W., and S. 25° to 30° E.; almost at right angles to the line of separation of the trap and sandstone; and the dip is here 70° W. These veins are 18 inches wide, of which metallic copper occupies a fourth part. Mr Jackson had seen a mass 20 feet long, 9 feet wide, and from 4 to 6 inches thick, taken from these mines; the mass weighed about 10 tons.

The Cliffe Mine, the deepest and most extensive, commenced in 1848. It has repaid its original capital four times over. The lode is regular and continuous, and improves to 500 feet in depth. The produce of other mines for one year had been nearly 43 tons (95,994 lb.) of ore, containing 70 per cent. of metal, or about 30 tons of copper in all. The annual produce of Lake Superior mines has been 3000 tons. Among the masses of copper are mentioned four, the respective weights of which were 7018 lb., 7484 lb., 7678 lb., and 14,000 lb. One very extraordinary lump of copper was found on these shores which was estimated to weigh about 80 tons, and measured 50 feet in length, 6 in depth, and averaged 6 inches in thickness.

Siberia.

In Siberia there are two principal copper mines, situated in the Ural Mountains. From one of these, in the central part of the chain, have come those magnificent specimens of malachite which have often excited wonder. Two large polished doors of Russian malachite, and several minor masses, were displayed in the Great Exhibition of London in 1851, and a splendid malachite vase presented to the Queen is kept in Windsor Castle.

Sweden.

One of the most celebrated and productive copper mines is that of Falun in Sweden. It is said to have been explored before the Christian era. In its greatest prosperity it yielded about 5000 tons of copper per annum; it now

Mines and
Mining.

furnishes about one-seventh of that quantity, and about 70,000 lb. of lead, 50 oz. of silver, and 3 or 4 oz. of gold. The mining district occupies a space of 9 leagues in length by 2½ in breadth, and is surrounded by a reddish granite, succeeded by a micaceous rock. The principal mass, which is of enormous dimensions, consists of iron and copper pyrites, lying in a vertical position from N.W. to S.E. along the valley in which it is deposited. Here there is an immense opening or gulph of 840 feet in length, 720 in breadth, and 240 feet in depth, which was produced in the year 1687 by the falling in of a mass, in consequence of the unskilful manner of mining. The mass of ore lies in the form of an inverted cone, and the excavation has been carried to a depth of more than 200 fathoms. Latterly the operations have been carried on upon a more limited scale. In this mine Gustavus Vasa, when driven from his throne, worked for the means of subsistence. In the mine of Garpenberg, 18 leagues from Falun, there are fourteen veins in a vertical position, and all parallel to one another.

Cornwall—where before 1712 the yellow copper ore was thrown aside—now furnishes nine-tenths of the copper of our own country. Altogether it is found in larger or smaller quantities in nine counties of England. The number of copper mines in England is about 220; in Wales, 12; in Ireland, 15; in all 247. In this number are included several mines producing small quantities, and about 50 are excluded which do not produce any ore. The following tables will show the advance of Cornish copper mining:—

Produce of Cornish Copper Mines from the Year 1745 to 1800, in Decennial Periods.

Years.	Tons of ore.	Average price per ton.	Amount realized.
		L. s. d.	L.
From 1745 to 1755...	98,790	7 8 0	731,457
" 1755 to 1765...	169,699	7 6 6	1,243,045
" 1765 to 1775...	264,273	6 14 6	1,778,337
" 1775 to 1785...	304,133	6 3 0	1,827,106
" 1785 to 1795...	Not known.	—	—
" 1795 to 1800...	249,834	8 9 6	2,177,724

The next table exhibits the annual produce and sales of copper ores for eight recent years, with the quantity of copper yielded by the ores:—

Years.	Ores.	Copper yielded.	Value.
	Tons.	Tons. cwt. qrs. lb.	L. s. d.
1848	147,701	12,241 19 2 5	720,080 17 0
1849	146,326	11,683 13 0 22	763,614 19 0
1850	155,025	12,253 10 2 21	840,410 16 0
1851	150,380	11,807 8 2 18	782,947 8 6
1852	165,593	11,776 17 2 24	975,975 14 0
1853	181,944	11,913 12 0 12	1,155,167 3 6
1854	184,858	11,979 4 2 21	1,192,696 12 6
1855	195,193	11,578 11 0 23	1,263,739 6 0

The quantities of copper ore bought by private contract by the great copper-smelting firms could not be included in the above table. The amount of sales at Swansea, in this form, in the year 1853, were 24,633 tons ore, which yielded 5875 tons 2 qrs. 11 lb. of copper. This quantity was bought by about ten firms or companies. The subjoined table displays the total quantities of copper smelted in this county for the last three years, the quantities bought in Cornwall, at Swansea, and by private contract, being distinguished:—

Year.	Cornwall.	Swansea.	Private Contract.	Total.
	Tons. cwt.	Tons. cwt.	Tons. cwt. qrs.	Tons. cwt.
1853	11,913 12	4,559 9	5,875 0 2	22,348 8
1854	11,964 12	4,726 19	5,426 3 0	22,117 14
1855	12,578 11	5,926 1	7,440 12 0	25,945 4

Mines and Mining. It will thus be seen that the production of copper during 1855 in this country shows a large increase.

The mode of mining for copper ores has already been treated of above under "*Practice of Mining*." We have only therefore to add in this place, that the greatest enterprise has been shown in Cornwall, both in copper and tin mining. Some of the Cornish copper mines are remarkable, and chiefly that named Botallack, established at the western extremity of the great copper and tin lodes, conjoined with lead, which run eastward through Cornwall. This mine was formerly worked only for tin, and was nearly abandoned in 1841, when, however, copper was found. In 1853 it yielded 1001 tons of copper ore, or 93 tons 8 cwt. of copper, and 147 tons 9 cwt. of black tin. The value of the copper was L.9248, and that of the tin L.8656.

At this and two other small mines in the vicinity, the hardihood of the miners has tempted them to follow the ore upwards, so close to the sea, that small openings were thought to have been made, and a covering of wood and cement was applied. A detailed account of the processes for dressing copper and tin ores will be found in *Cornwall; its Mines and Miners*, pp. 203, &c. In a table in p. 232 of that book, we observe that the average produce of the Cornish copper ores for eight years was from $7\frac{1}{2}$ to $8\frac{3}{8}$ per cent. of metal to the ores.¹

The first process in dressing copper ores, so as to fit them for the smelter, is to throw aside the *deads* or rubbish, and this is cleverly performed by girls of seven or eight years of age, for 3d. or 4d. a-day. The largest fragments of ore are then *cobbed*, or broken into smaller pieces, by women. After being again picked, they are given to the "maidens" (as girls of sixteen or seventeen are named), who *buck* the ore with a *bucking-iron* or flat hammer, by which they bruise the pieces to a size not exceeding the top of the finger. The ores are now given to boys, who *jig* them, or shake them in a sieve under water, by which means the ore or heavy part keeps at the bottom, whilst the *spar* or refuse is scraped from the top. That portion which passes through the sieve is also stirred about in water, the lighter parts being thrown on the surface; and the ores thus dressed being put into large heaps of about 100 tons each, are then made ready for the market. The copper ores of Cornwall are all shipped for Wales, and mostly for Swansea, to be smelted there, it being cheaper and better to carry the ores to the coals than the coals to the ores. (For the methods of smelting, see COPPER SMELTING.)

Details of a mining establishment. The most productive copper mines now in Cornwall are the Devon Great Consols, Carn Brea, Consolidated, United Fowey Consols, Par Consols. Some particulars of a more general nature respecting one of these, viz., the Consolidated Mines, will illustrate the extensive business of so great a concern:—

Consolidated Mines in 1836.

Quantities of ore raised	Values.	
	Copper, 18,498½ tons..	L.143,039 12 5
	Tin.....	2,533 0 10
	Arsenic.....	144 7 10
		L.145,717 1 11

Value of ore, deducting dues.....		L.139,645 10 7
Total expenses for the year.....		102,007 12 1
Total profit on the mines.....		L.37,637 18 6

Details of Expenses (some of the principal items).

Agents' salaries.....	L.3,343 19 0
Tutwork bargains.....	26,177 3 8
Materials.....	15,008 6 4
Engine or water cost (with rent of water, L.405, 13s.)	15,415 7 4
Expenses on ores.....	7,803 8 7
Tribute, subsist, and balances.....	25,030 17 0

Number of Persons Employed.

Agents.....	28
Tutwork men (working by task for a fixed price).....	441
Tributers (working for an agreed proportion of the ore raised)	392
Surface men.....	335
Boys underground.....	109
Boys at surface.....	327
Females.....	755

Total.....2387

Rate of Wages to Work-people.

Per Month.		Per Month.	
Tutwork men.....	L.3 11 6	Girls from 14 to 17....	L.0 15 0
Tributers.....	4 5 0	Girls from 12 to 14....	0 12 0
Surface labourers.....	2 6 0	Girls from 9 to 12....	0 8 0
Women and girls above 17.....	0 18 0	Boys above 12.....	0 13 0
		Boys under 12.....	0 9 0

The usual rate of wages should be estimated lower, as there was a great demand for miners in 1836.

TIN.

Cornwall and Devon afford all the tin yielded in the United Kingdom. Its foreign repositories are Bohemia and Saxony in Europe, and Malacca and Banca in Asia. One of the richest known deposits of tin is in the province of Tenasserim, on the east side of the Gulf of Martaban, in the Malayan Peninsula. There the richest layer of tin lies in a stratum of sand and gravel 8 or 10 feet thick, in which masses of oxide of tin are often found of the size of a pigeon's egg. The ores are also found in large caves near the surface; and although actively mined for many centuries, there is still easy access to unexhausted portions. The mines in the island of Junkseylon sometimes yield 800 tons per annum. The mines in the island of Banca, to the east of Sumatra, discovered in 1710, are said to have furnished in some years nearly 3500 tons of tin. It is found in the alluvial tracts through every part of the island, but rarely more than 25 feet below the surface. Great deposits of tin occur in the Siberian mining district of Nertschinsk, near the desert of the Great Gobi, and near Oruro in Bolivia. The Peruvian and other foreign tin contains large admixtures of tungstates of iron and lime, which depreciate its value; but an eminent metallurgist has discovered and patented a process by which the separation of these can be easily effected.

The tin mine of Altenberg in Saxony is remarkable for Saxony. an interlaced mass of ramifying veins, termed a *stockwerke*, in a primitive porphyry (superposed upon gneiss), through which the ore is disseminated in minute particles. This mine has been wrought since the year 1458. In the year 1620 it was worked by twenty-one independent companies in a most irregular manner, so that it was damaged by a dreadful fall of the roofs to a depth of 170 fathoms. This mine yielded, some years ago, annually 400,000 quintals of tin ore, affording 1600 Leipsic quintals of tin, this amount being four-fifths of the whole furnished by the district of Altenberg.

A somewhat similar deposit of tin occurs in the soft Cornwall.

¹ The following are the sales of copper ores in Cornwall for the three quarters of 1856:—

Quarters ending	Tons.	Pro-duce.	Amount.	Average Price per Ton.	Product in Fine Copper.
Mar. 31, 1856	53,934	6.202	L. 317,337 17 6	L. 5 17 8	Tons cwt. 3358 9
June 30, "	54,273	6.311	308,633 18 0	5 13 8	3427 13
Sept. 30, "	49,636	6.976	299,273 16 0	6 0 7	3455 18

Mines and
Mining.

decomposed granite of Carclaze Tin Mine, near St Austell, Cornwall. This singular mine has been wrought for nearly 400 years, and is the only one entirely open to the day. It consists of a large excavation of a mile in circuit. Its exact dimensions are 250 fathoms in length, 100 fathoms in breadth, and 22 in depth. The excavation occupies 5 statute acres, the solid contents are 63,000 cubic fathoms, and more than a million tons have been removed. There are no shafts or other usual appurtenances of a deep mine. The ground is almost wholly composed of decomposed granite, through which runs a numerous assemblage of schorl and quartz lodes in the usual direction. These contain the tin minutely disseminated. The ore is separated from the stone by repeated washings in little streams, conducted to and moving various water-wheels arranged in the bottom, and along the sides of the excavation.

In Cornwall the number of tin mines is about 130, and some are included in this number which produce copper as well as tin. Tin was probably obtained in this county at an earlier period than any other metal. Mr Carne has given a table of the Cornish produce of tin from 1750 to 1837; and Mr Hunt has formed a table of the produce of British tin from 1800 to 1855; thus affording records of tin mines of a more authentic kind than we possess of other metals. We are thus enabled to trace the course of the produce of this metal, of which a few specimens may be quoted:—

Produce of British Tin Mines from 1800 to 1855.

Year.	Tons.	Year.	Tons.	Year.	Tons.
1800	2522	1820	2990	1848	6613
1805	2785	1825	4358	1849	6952
1810	2036	1830	4444	1850	6729
1815	2941	1835	4228	1855	6000

It will be observed that the produce of tin has been steadily progressing, notwithstanding the precarious nature of the search for it, and the various fluctuations of mining.

The following are some of the principal Cornish mines, with their produce in 1855:—

Name of Mine.		Quantities of Black Tin.			Value.		
		Tons	cwt.	qrs. lb.	L.	s.	d.
Penzance District.	Balleswidden.....	252	8	3 27	18,086	18	7

Liskeard.	Drake Walls.....	264	17	0 8	17,748	19	3

Mr Carne informs us, that the prices paid to the tinner in Cornwall between the years 1746 and 1788 varied from 60s. to 72s. the cwt. We find that from 1783, when the price was L.4, 1s. 7d. per cwt., it varied considerably, reaching in 1810, L.7, 9s. 8d. per cwt., and falling in 1825 to L.4, 16s. 6d. per cwt. The annexed table gives the annual value of the tin ore raised in England within the last three years, and of the tin:—

Years.	Tin Ore raised.		Average value of Ore.	Total value of Ore.	Estimated value of Tin per Ton.		Estimated value of Tin.
	Tons	cwt. qr.	L.	L.	L.	L.	L.
1853	8866	0 0	68	593,088	112 to 118	700,000	700,000
1854	8747	0 0	64	559,808	112 to 118	690,000	690,000
1855	8947	0 0	68	608,396

In 1855 the average prices of tin were—

English blocks.....	L.125	0	0
... bars.....	126	0	0
... refined.....	129	0	0

Mines and
Mining.

The existence of tin in Australia and Van Diemen's Land is known; and in the tin forwarded to this country from Victoria a considerable quantity of gold has been found. It mostly lies in grains in sand, and is analogous to our stream-tin.

In this country there has not been for a considerable period a discovery of any new locality of tin. The stream-works are by no means so productive as formerly, and the mines are being worked at a constantly increasing cost; yet the demand for tin in our white-metal manufactories is constantly increasing. The principal importations of tin to our country are from Singapore, Java, and the East Indies, and Holland. The total imports to us from Singapore during eleven recent years (from 1844 to 1854 inclusive) have amounted to 8303 tons of tin; from the East India Company's territories, during the same period, 2738 tons; and from Holland, for the same years, 4567 tons. In 1855 we imported 1612 tons of tin; and exported 1337 tons of British tin, also 280 tons of foreign tin.

It remains to speak of the processes for dressing tin ores. These commence with cleaning and sorting, and then proceed to washing and stamping, and finally to calcination in the "burning-house," and to smelting. The same great principle rules these processes that rules in dressing copper or lead ores, viz., the agitation of the mass reduced to fragments, so that the metal, by its much greater specific gravity, shall separate and sink down from the lighter earthy matter. The stamping is in the best mines performed by stamps or pestles of wood, carrying lifting-bars, and terminating in a lump of cast-iron called the head, and weighing 2½ or 3 cwt. A turning-shaft communicates motion to the stamps by cams, which are so arranged as to secure the falling of the second stamp while the first and third are uplifted. Each stamp gives 28 strokes per minute. With six batteries of six pestles each, at Poldice Mine 120 bags of ore are stamped in 12 hours, each bag containing 18 gallons of 282 cubic inches, measuring altogether 352 cubic feet and 864 cubic inches. At Boscean Tin Mine there is a 24-inch stamping-engine, to which are attached 48 heads of stamps, and there are 20 heads of stamps worked by water-power. At Botallack the tin stuff is returned by water-stamps of 24 heads. At Levant Tin Mine there is a 34-inch stamping-engine, working 64 heads of stamps. At Polberro Consols one large engine drives 120 heads at a time. By repeated pulverization, washing, and agitation, the ores may be obtained in a very fine state. As tin is often combined with wolfram, tungstate of iron, and other materials, which cannot, owing to their greater specific gravity, be so easily separated from the ores of tin as earthy matter, a new process has been invented by Mr Oxland, by which wolfram, &c., may be separated, and eventually the wolfram is saleable separately.

The ores of tin raised in Cornwall and Devon are always smelted within those counties, their transportation being prohibited. The market price of tin has lately risen considerably, and it still remains at a high figure; the mines of this metal are therefore more flourishing than usual. Tin ore is worth from L.56 to L.68 per ton. In its natural state, when dressed, the ore is called "black tin," to distinguish it from "white tin," which term is applied to tin in its smelted and refined state.

LEAD.

Before speaking more particularly of the lead deposits of our own country, we may briefly allude to those of other countries. One of the most remarkable lead deposits in the world is found in the western section of the United

Mines and Mining.

States, particularly in Washington, Jefferson, and Madison counties, Missouri; and at Galena in the N.W. part of Illinois; in Iowa and the territory of Wisconsin. In this latter district the length of the lead deposit is 87 miles and its width 54, covering 80 townships, or 2880 square miles. In 1839 thirty million pounds of lead were smelted from this deposit; and during the eight subsequent years the smelted quantity varied from 72 millions to 54 millions of pounds. It is thought that it would readily yield annually 150 millions of pounds.

France.

France possesses considerable deposits of lead, and some very old mines, although the development of these is not commensurate with their value. The most important are those of Poullaouen and Huelgöet in the department of Finisterre. These have been worked in two parallel veins, and have been known for upwards of three centuries. In 1816 they furnished 500 tons of lead. The mine of Pont-gibaud is well known to English adventurers, and contains nine lodes or veins. It was worked as early as Poullaouen, although the last workings commenced in 1825. The ore is an argentiferous galena, of which 7800 tons have been extracted annually, which extraction yields 1077 tons in dressed ore, and 980 tons in "schlick." Vialas yields 81 tons of lead, 20 tons of litharge, and 12 cwt. of fine silver. The Pont Pean Mine is working upon a vein which is known for a run of $1\frac{3}{4}$ mile, and the works have reached a depth of 78 fathoms. Here they obtain about 244 tons of dressed ore, which is sold for about L.1400. The produce of the other lead mines is insignificant.

Germany, &c.

Germany has also some valuable mines of lead, particularly in Saxony and in the Hartz. These are so rich in silver as to cause the lead to be almost overlooked. Hungary and Bohemia yield a good argentiferous lead. The mines of Bleiberg and Villach in Carinthia, where galena or sulphuret of lead is the prevailing ore, furnish the finest specimens of the molybdate of lead. At Tarnowitz in Silesia there is a remarkable deposition of lead ore, the beds in which it is distributed reposing in horizontal strata of compact limestone, which contains petrified shells. The lead ore is there deposited in veins, in rounded masses, and in small grains. The Ural Mountains in the Russian empire, so rich in other mineral productions, do not seem to contain lead; a chromate of lead is found in the gold mine of Beresov, where it is seen in a small vein of ferruginous quartz traversing a gneiss rock of a reddish colour.

Spain.

Spain possesses numerous and valuable lead mines. The most important are those of Linares, which are situated to the east of Bailen, near the Sierra Morena. They have been long celebrated, and probably no known mineral field is naturally so rich in lead as this. The lead deposits, associated with much silver, and occasionally copper ores, occur in each of the local limestone districts. The expense and difficulty of conveying stores to the mines, and the ore to the market, are almost the only impediments to the prosperity of these mines, but they are sufficient to check it, excepting when lead bears a high price in the market. The lead ores of Spain are highly argentiferous, and of late years a considerable quantity of this ore has been imported by us from Spain. In the year 1851 we received 14,402 tons of lead. In 1854 the imports from Spain were 11,337 tons of lead.

Sweden.

The lead of Sweden is highly argentiferous, and is worked chiefly with a view to the silver. In Daouria are numerous mines lying in a rich transition limestone which rests on primitive rocks, the lead being neglected in consideration of the silver. It is thought that the galena of the primitive formations contains more silver than that of the calcareous or carboniferous limestones.

Produce of British lead mines.

It has often been supposed that England, so rich in regard to iron, copper, and tin, is comparatively poor in lead, or that her lead mines are of secondary importance; but this

is so far from being correct, that it will be found that our own country supplies more lead than any other in the world. We do not speak of the amount contained, but of that raised. The following table will show the amount of lead ore raised, and lead smelted, in the United Kingdom during nine recent years; and the table subsequent to it being included, we shall have the quantities for the last ten years:—

Years.	Lead Ore.		Lead.	
	Tons.	cwt.	Tons.	cwt.
1845	78,267	0	52,695	0
1846	74,564	0	50,161	0
1847	83,747	0	55,703	0
1848	77,864	0	54,853	0
1849	86,773	0	58,703	0
1850	93,043	8	64,572	14
1851	101,964	12	65,110	11
1852	91,236	...	64,987	...
1853	85,121	8	61,021	2

The annexed table will still further exhibit the lead districts of the United Kingdom, with the produce of each in ore and metal, from returns for one year, viz., 1854, being the latest as yet made:—

Summary of Lead and Silver Produce of Great Britain and Ireland.

County.	Lead Ores.		Lead.		Silver.
	Tons.		Tons.		Ounces.
Cornwall.....	7,460		5,005		179,675

	90,548		63,999		562,659

The number of mines is 322. They give employment to 14,499 male persons in England, to 5982 in Wales, and to 897 in Scotland; as well as to 371 females employed in works at the surface. The total is 21,749 persons. The price of pig lead in the London market in 1853 was L.23, 10s. per ton; in 1854 it was the same, and in 1855 it was L.24 per ton. It has been rising from 1844, when it was L.17, 5s. per ton.

When we examine the returns of the principal lead mines in each of the above districts, we find considerable differences in the yield of the several mines in different years. Thus, in 1850 the richest lead mine in Cornwall was East Huel Rose, then yielding 4206 tons of ore, equalling 2524 tons of lead; but in the returns of 1854 we observe the same mine yields only 1215 tons of ore, equalling 828 tons 5 cwt. of lead. On the other hand, we find South Tamar Consols Mine in Devonshire yielding in 1850 only 477 tons of ore, but in 1854 as much as 1469 tons 19 cwt. Another instance of this difference for the same two years is noticeable in the Brownley Hill Mine in Cumberland, which in 1850 produced 263 tons 4 cwt. of ore, while in 1854 it yielded no less than 1722 tons of ore. To take a

Mines and
Mining.

mine in the north of England, Derwent produced in 1850 the amount of 1770 tons 1 cwt.; in 1854 only 1000 tons. The above-named mines are about the most productive in their respective districts for one or other of the two years named. The galena of the Beer-Alston mines in Devon has sometimes contained from 80 to 140 ounces of silver per ton of lead.

The lead ores¹ most interesting in the arts are:—1. Sulphuret (or bisulphuret) of lead (specific gravity from 7·4 to 7·6), or, as it is commonly called, *galena*, almost the only lead ore which occurs in sufficiently large masses to become the object of mining and metallurgy. It is found amongst the older rocks, as talc-schists and clay-slates, but is much more abundant among the transition rocks where it exists in interrupted beds, masses, and veins. The blackish transition limestone is that rock which of all others contains most galena in Normandy, the Hartz, and in Sweden. 2. Seleniuret of lead. 3. Native minium, or red lead. 4. Carbonate of lead, or white lead. 6. Vitreous lead, or sulphate of lead. 7. Green lead, or phosphate of lead. 8. Chromate of lead.

In our own country the lead of Cornwall and Devon is found in veins in *killas* or clay-slate. The galena of the Leadhills of Scotland occurs in a transition slate of a similar character. But in North Wales, as well as in Cumberland and the whole northern lead district, and in Derbyshire, the galena occurs in the carboniferous limestone which underlies the coal measures. Technically speaking, galena occurs in plutonic, metamorphic, and fossiliferous sedimentary deposits. A specimen of a lead vein from the Laxey Mines (Isle of Man) represents the total thickness of the lode, which amounts to nearly 23½ inches. The specimen is about 5 feet long by 30 inches wide. It consists of five solid layers or veins of galena separated by thin bands of sulphate of barytes. It was in the Great Exhibition, and was presented to the Museum of Practical Geology in London.

A magnificent lump of galena from the mines of Snailbatch or Snailbeach near Shrewsbury, is still more curious. It is composed of an assemblage of large cubes of galena measuring 3·15 inches a side, and of rhombohedral crystals of violet-coloured calc-spar 9½ inches long, the edges replaced by large facets. This specimen measured above 55 inches by 43½ inches, its thickness being 14 inches. (For the metallurgy, &c., of lead, see the article LEAD.)

The great lead-mining country of the north of England lies around the junctions of the counties of Northumberland, Cumberland, Westmoreland, Durham, and Yorkshire. It comprises Alston Moor, the mountain ridge of Cross Fell, the dales of Derwent, East and West Allendale, Wear-dale, and Teesdale. The three rivers—the Tyne, the Wear, and the Tees—take their rise from the bold and lofty hills in that locality.

Geological
characters.

The coal beds so extensively worked at Newcastle-on-Tyne and in the Durham coal district gradually rise to the west, and one by one crop out, or basset, according to the undulations of the country. At length at about 20 miles W. of the German Ocean, the lowest of the beds crops out, and from beneath it gradually appear the limestone strata, which continue to rise nearly coincidently with the general rise of the country, until they reach the summit of Cross Fell (2901 feet). This general and very gradual inclination of the strata is a feature of the greatest importance in the practice of mining. In a thickness of about 2000 feet of the alternating beds of sandstone, clay, and limestone, which form the mining districts of Allendale, Alston, and Wear-dale, there is one single bed of limestone, named the "Great Limestone," the metallic veins in which have produced

nearly, if not quite as much, lead ore as all the other strata put together. This stratum lies at a depth of about 850 feet below the summit of Kilhope Law. A little more than 2 miles eastward of this, at Allenheads, the top of the Great Limestone is 230 feet from the top of a shaft called Gin-Hill Shaft. Its thickness, which is tolerably uniform over several hundred square miles of country, is about 60 feet.

Kilhope Law is a hill rising 2200 feet above the level of the sea, on the boundary line of the counties of Northumberland and Durham, and is the highest point in Durham. About a quarter of a mile to the W. of Kilhope Law, the great limestone and all other associated beds are thrown down a depth of about 150 feet for a space of nearly 700 feet; and again, at the distance of nearly a mile from Allenheads, a vast dislocation takes place by which the Great Limestone is brought nearly to the surface, the amount of displacement being about 400 feet. By far the most extensive portions of the workings of the Allenheads Mines are situated in the Great Limestone. These mines being for the most part at depths from the surface varying from 200 to 600 feet, they are drained by ordinary water-wheels, and partly by the new hydraulic engines of Armstrong, four of which are now in use for draining and other mining purposes at the Allenheads mines. The most extensive mineral property in England, in the hands of a single individual, is in the mines of East and West Allendale and Wear-dale, belonging to Mr Wentworth Blackett Beaumont, M.P. The produce from these mines in 1854 was 12,220 tons of lead ore, or 9200 tons of lead, and 49,000 ounces of silver. The pigs of lead manufactured from the produce of these mines bear the well-known mark "W. B.," and weigh each 1½ cwt. The number of pigs commonly made in one year, if laid in a continuous line, would extend upwards of 70 miles. The produce of the Beaumont mines is about one-sixth of the total amount of lead raised in Britain, and about one-tenth of that of all Europe.

This part of the country happens to be at once about the Mining centre of our island, and by far the most elevated part; districts. and is thickly peopled. Scattered over hills and dales, which present to the eye a succession of verdant fields and heathy moors, are to be found some thousands of inhabitants, nearly the whole of them being employed either in lead mines or in smelting mills, or indirectly deriving a livelihood from the lead-mining business. Allenheads forms a central position in the midst of these mines. The agent's house is 1400 feet above the level of the sea, and is said to be the highest house of its magnitude in Great Britain; not many even of the shepherds' cottages and other moorland habitations in England having a greater elevation.

The mining district of Alston Moor (situated at the south-eastern extremity of the county of Cumberland) comprises the whole of the parish of Alston; but by far the most extensive and productive mines are situated in the vale of the small river Trent, a tributary of the Lyne. In the vale of the Lyne, from Alston to Lynehead, are also numerous mines; and trials for mines and workings, which occasionally yield lead, are seen all over the parish. This mining district belongs principally to the commissioners of Greenwich Hospital, who let the mining ground on leases to various companies of adventurers, by whom the mines are wrought. The principal of these is the London Lead Company, producing about one-half of the ore raised in the manor.

One of the most celebrated of the Alston Moor mines, Hudgill Burn, was commenced by the Flow Edge Mining Company: a level driven 250 fathoms in the bed under the Great Limestone, and found only two weak veins. They sunk shafts and pursued other operations, discovering only

¹ Plumbago, graphite, or black lead, is one of the numerous forms in which carbon occurs, and is familiar to us in lead pencils. The celebrated Borrowdale mines, in Cumberland, supplied pieces which could be sliced and used in the natural state. It is not a lead ore.

Mines and
Mining.

Mines and
Mining.

another small vein, which they explored for 20 fathoms, and produced but a few trifling specimens of ore not worth washing and cleansing. Having lost L.2000, this company abandoned the undertaking, which then lay neglected for eight years. In 1812 some miners obtained leave to continue the search, and their success was so great that their discovery has proved a source of wealth to themselves, and has afforded employment to vast numbers of the labouring classes.

A work of great interest in this district is the Nent Force Level, which drains the numerous mines of Alston Moor. This is a stupendous aqueduct 9 feet broad, and in some places from 16 to 20 feet high. For more than 3 miles it passes under the course of the River Nent to Nentsbury engine shaft, and is navigated underground by long narrow boats. At the distance of a mile in the interior, daylight is seen at the mouth like a star, which continually enlarges as the passenger proceeds outwards, until he finds himself in open daylight.

Lead veins.

The veins of lead are similar in their nature to the lodes of copper, tin, &c., in Cornwall, though the accompanying strata are different. A lead vein may be popularly described as a crack descending in a nearly vertical direction through the various beds, which have usually been separated not only a few inches or feet (forming the thickness of the vein, and subsequently filled with *vein-stone*, *riders*, and *galena*), but also by a vertical shift or dislocation, so that a vein may be between limestone on one side and sandstone on the other, or sandstone and clay may be opposite. One vein throws the strata down 25 fathoms (150 feet). The lead miner obtains all his treasures in those very dislocations which interrupt coal workings, and are by coal miners called *faults* and *troubles*.

Old miners have distinguished the lead veins by the names of *rake*, *pipe*, and *flat* veins. Rake veins are the most common in Cumberland, &c. They are generally narrower in the sandstone that covers the limestone than in the calcareous and siliceous beds. In the rich vein of Hudgill Burn the thickness is 17 feet in the Great Limestone, while it does not exceed 3 feet in the overlying sandstone. The influence exercised on metallic veins by the enclosing rock has been mentioned before, and is confirmed by wide observation in other countries, particularly in the veins of Kongsberg in Norway. Perhaps, however, the phenomena are nowhere more satisfactorily displayed than in the north of England. The mining districts consist of shales, grits, and limestones, traversed by east and west, and north and south veins, which variously dislocate the strata. In the course of these unequal dislocations, coupled with unequal thicknesses of strata, various oppositions of the argillaceous, arenaceous, and calcareous rocks take place. It is chiefly in the limestone that the veins are productive, although the fissures traverse a vast thickness of overlying strata, as shales, grits, and coal. In a series of limestones, gritstones, and shales, adjoining or forming the margin of a vein, it happens that when inclosed between *cheeks* or walls which are both argillaceous, the vein will be unproductive and generally *nipped* or reduced in width. With argillaceous beds on one side, and gritstone or limestone on the other, the same effects appear, but in an inferior degree. Gritstone opposing gritstone yields irregular results, according to the mass or quality of the gritstone; so that in several districts (as Allenheads, Grassington, &c.) much lead ore has been found in such situations. But when limestone is opposite to limestone the vein is almost always most productive. Of the stratum called the Great Limestone, and its metallic productiveness, we have already written. The *rake* vein is by some divided into two kinds, one of which, the *slip* vein, prevails most commonly in Alston Moor. *Pipe* veins are seldom of great length, but often have considerable width. They appear to be the result of a segregation of the metallic

contents of a vein into portions inclined at various angles in different veins, but nearly parallel in the same vein. The *pipes* or *shoots* are usually very productive for a long course in a long vein. *Flat* veins seem to be expansions of the matter of the vein between the planes of the strata, and contain the same ore as the veins in their vicinity. When metalliferous, they are worked along with the adjacent rake vein, and are productive only to a certain distance from that vein, unless they become enriched by crossing a rake vein. The rake veins are the most productive of all in the north; and observations made in Derbyshire point to the conclusion that nearly the same conditions govern the lead veins in that county. An opinion prevails in the north that the greater number of lead veins are at right angles to the plane of stratification, and this opinion is not without foundation.

The numbers of males employed in lead mining in the northern counties of England are as follows:—In Durham, 2628; in Northumberland, 1070; in Cumberland, 1840; in Westmoreland, 317; in all, 5855.

Considerable numbers of young persons are employed at the surface works in dressing the ores. This process consists in—1. The sorting and cleansing of the ores; 2. The grinding; 3. The washing, properly so called. These operations are much alike in the English lead districts, but they are most perfect in the north.

The lead and argentiferous lead districts of South Wales lie chiefly along the shores of Cardigan Bay. The district containing the known argentiferous and lead ores stretches from about the centre of Carmarthenshire on the south, through Cardiganshire, and some distance into Montgomeryshire, on the north, and from about 5 to 20 miles from the sea towards the interior, or from W. to E. The most productive portion of the country as regards silver lies about 7 miles to the eastward of Aberystwith, perhaps the most beautiful of the Welsh watering-places. This contains the great mines Cwm Symlog, Goginan, Daren, Cwm Sebon, Bwlch Consols, &c. The district in which these mines are situated abounds in majestic scenery; the great mountainous region, commencing at Snowdon on the northward, passes southward through its centre, Plynlimmon being in the midst of the metalliferous deposits, and rising at 17 miles from the sea to the height of 3300 feet above its waters. The views on the rivers are amongst the most beautiful in the British Isles, and the well-known Devil's Bridge overspreads a cataract on one of the streams, and falls over a ledge of rocks from a height of 480 feet into the bed of the Rheidol.

The present annual produce of these mines must not be taken as showing the produce in past years, for some of the mines formerly yielded immense profits. The lode in Esgair-y-Mwyn Mine is said to have been filled with lead for 30 feet wide, nearly solid; and although a royalty of L.3 per ton was paid to Earl Powis, it is not improbable that the mine has returned L.600,000 worth of ore. Of the other more profitable mines, it is estimated that Cwm Ystwith has yielded L.500,000, Grogwinion L.250,000, and Logylas L.200,000 worth of ore. In the main silver-lead districts of Cardiganshire, amongst the mines of which are Goginan, Bwlch Consols, Daren, &c., the total produce has been estimated to have been L.1,500,000 for lead, and L.1,000,000 sterling for silver. Yet the whole of these mines have been worked to but a comparatively shallow depth.

The group of mines adjacent to Talybont, 7 miles north of Aberystwith, includes Esgair-fraith, formerly called the "Welsh Potosi," and famous for having yielded immense masses of ore. The history connected with these mines is very remarkable, but we can only briefly notice it. The estimate of Mr. Waller sounds extravagant to us at this day; but it is believed that he proposed to realize a profit of

Mines and
Mining.

Welsh lead
mines.

Mines and
Mining.

L.75,000 a-year from these mines alone. It is reported that Sir Carberry Pryse (ancestor of the Gogerddan house) refused L.75,000 for a moiety of them. It may be presumed that the whole of the mines in this part have actually yielded not less than ores worth one million sterling. It is very curious, when we are made acquainted with such facts, to read this passage in Cicero's Letters (Epist. ad At.) written almost immediately after the disembarkation of Cæsar's troops on our island:—"One thing we are already certain of, that there is not a grain-weight of silver in that island, nor the least prospect of plunder, but from the slaves that may be brought away."

The metalliferous district of Cardiganshire and Montgomeryshire is formed exclusively of clay-slates and grit-stones underlying the lowest beds in the Silurian system of Murchison. Large portions of this principal district are as yet not known to contain mineral veins; and the intermediate parts which are the most noted for their productiveness, are defined by certain limits intimately related to the lithological character of the rocks. The prevailing strike of the beds is from N. by E. and S. by W., to N.N.E. and S.S.W.; and in the same direction bands of various width may be traced in which a number of the most successful mines have been worked. There are several anomalous features in this district, if compared with other mining districts. The presence of ore cannot be directly ascribed to the proximity of granites or porphyries, since this is the only large portion of the slaty rocks of Wales in which not a vestige of any rock of igneous origin is met with. The various directions of the lodes gives no clue to the determination of their relative age.

The band known about two centuries ago as the "Welsh Potosi," from the enormous returns it yielded to Middleton (afterwards Sir Hugh Middleton), is at the present day distinguished by the mines of Goginan, Cwm Sebon, Cwm Symlog, Daren, &c. The slaty rock there assumes a paler tint, inclining to a bluish or greenish gray, and exhibiting on the whole a more massive bedding, in consequence of which it would appear that the mineral veins increase in width, expanding in some cases to upwards of 20 feet. This ore is generally argentiferous, sometimes to the amount of 38 oz. in the ton. Several facts have been observed with reference to the ore-bearing portions of the lodes, which are in perfect accordance with the experience of other districts. When the lodes approach each other under a small angle, the junction is nearly always marked by a larger deposit of ore. The lead veins of this part of Wales differ from those of Cornwall in one point, upon which all the miners are agreed,—viz., that when they pass from a harder to a softer rock, their mineral contents *decrease*. In Cornwall, however, we observe, that at the exceedingly productive mine of East Huel Rose, not only is the *killas* or clay-slate very soft, but the lode itself, including its saccharoid quartz, is in so disintegrated a condition that a blow with the pick will often cause it to run down like a quantity of sand or mud.

There are about 120 named lead lodes in Cardiganshire,—some worked, and others not. The most productive of those at present in work are, first, those named Pen-y-Gist South Lode, Logaulas, &c., forming the Lisburne Mines. From these the lead ore returns in 1845 were 2492 tons; in 1846, 1724 tons; in 1853, 2752 tons; in 1854, 2595 tons. 500 persons were employed there. Secondly, the next most productive mines are Goginan North and South Lodes,—the lead ore returns being 1768 tons in 1845, and 1627 tons in 1846. The number of persons then employed was 400. The above mines were very far more productive than the remainder in the county. In Montgomeryshire we find 38 named lodes, of which the principal are,—that named Llechwedd-ddu, a rich and regularly-worked vein; and Esgair-galed, which averages 15 feet wide, and has been produc-

Mines and
Mining.

tive in former times. Both these united yielded in 1845 586 tons of lead ore, and in 1846, 557 tons of lead ore; the number of persons employed being 200. In 1854 we find the most productive mine in this county to be Machynlleth, which, including Delife, yielded 637 tons of ore, affording 470 tons of lead.

Many considerations tend to encourage the development of the mineral resources of this district: the great number of lodes lying idle, or only in some cases tried to a small depth; the probability of the existence of many more, in consideration of the difficulty of discovering them from the surface; the facility of drainage; and the fact of the resumption of the two most profitable mines from very fortuitous circumstances,—the very profitable mines of Logaulas and Goginan. Logaulas had been erroneously worked, and the true lode was missed, until the present holders, after making an accurate survey, altered the drivings, and shortly discovered, not only the lode, but a rich *bunch* of ore, parallel to which their predecessors had been toiling for many a fathom through barren rock at the distance of only a few feet. The mine has ever since continued to yield several thousand pounds of profit yearly. Still more hopeless did the condition of Goginan appear to be when commenced; yet the mine has since produced upwards of 1500 tons of silver-lead ore yearly. The mode of working these veins is very similar to that adopted in our southern counties, and most of the mining captains are Cornishmen.

In Derbyshire the metalliferous limestone occupies a Derbyshire length of about 25 miles from north-west to south-east, with a very variable breadth, which, however, towards the south, amounts to 25 miles. Castleton to the north, Buxton to the north-west, and Matlock to the south-east, lie nearly upon its limits. This limestone district is surrounded nearly on all sides by the millstone grit which covers it, and which is in its turn covered by the coal strata. The nature of the rocks beneath the limestone is not well known. In Cumberland the metalliferous limestone includes a bed of igneous rock, called *trap* (from the Swedish word for stair) by mineralogists, but locally *whinsile*. Igneous rock is much more abundant in Derbyshire, where it is termed *toadstone* (probably from the German *todstein*, dead rock), and it is there thrice interposed between the beds of limestone. These two rocks of themselves constitute the whole mineral mass through a thickness of about 550 yards, measuring from the millstone grit; only in the upper portion—that is, near the millstone grit—there is a considerable thickness of argillaceous schists. The toadstone is of various thicknesses and colours, and is sometimes very porous, and presents the appearance of scoria or volcanic lava. It is the miner's dread, as it is thought to cut off the vein of ore. On Tideswell Moor, however, where toadstone intersected the vein that was worked in the incumbent limestone, it at once cut off the vein; but when the miners cut through the toadstone, they met with the limestone underneath, and the continuation of the lost vein. At Black Hillock Mine, where the vein was cut off by toadstone, they sank for 600 feet in its mass, and yet could not get through it; while at a distance on either side miners got through the toadstone in a few fathoms. It appears that though the vein may be retraced on the other side of the toadstone in the limestone again, yet it is generally very thin, and sometimes extremely poor.

The veins in this district are of three descriptions:—1st. The *pipe-vein*, which lies between two rocks of limestone extending regularly above and below. It consists of several lines or branches running nearly parallel to each other; and although they sometimes deviate from that course, they generally return after a short distance. The branches communicate with each other by means of slender threads or *leadings*. Sometimes the surrounding rock is penetrated by these transverse threads, and by pursuing the thin veins

Mines and
Mining.

a new repository of metal may be discovered. 2d. *Rake veins* traversing the strata; and, 3d. *Flat veins*, forming beds along with the horizontal strata, and generally lying near the surface. A variety of the ore, termed by the miners *slickensides*, abounds in some parts, and forms the sides of cavities. Some fabulous tales of its explosive violence are narrated in the district. It presents a smooth surface with a bright metallic lustre. The blocks of lead bearing Latin inscriptions, which have been found here, have led some to think that the mines of this county were wrought in the time of the Romans.

General
returns.

In the table of lead-ore returns for 1854 it will be seen that those of Flintshire are nearly equal to those of Cardiganshire. The most productive mines in Flintshire are those called Talargoch, which in 1854 yielded of lead ore 1910 tons; and these afforded 1490 tons of lead, from which was extracted 10,430 ounces of silver. The next richest mine is Maes-y-safn, yielding 1423 tons of ore, equalling 1117 tons of lead and 3071 ounces of silver.

The most important items of returns from other lead-mining districts for 1854 are as follows:—Derbyshire yielded 7554 tons of lead ore, affording 4508 tons 15 cwt. of lead. The largest mines in Yorkshire are Swaledale and Arken-dale, yielding 4817 tons of ore, or 3276 tons of lead; Grassington is the second in yield. In Scotland the Wanlock-head Mines yielded 795 tons of ore, or 596 tons of lead. In Ireland the Newtownards Mine afforded 1379 tons of ore, and 1084 tons of lead; the Luganure Mines in Wicklow yielding 1095 tons of ore, and 710 tons of lead and 4970 ounces of silver. In the Isle of Man the principal mines, the Foxdale, yielded 1900 tons of ore, or 1449 tons of lead, the proportion of silver being 19,926 ounces.

IRON.

For information respecting iron, its localities, &c., see the article IRON.

MINES OF ZINC, ARSENIC, ANTIMONY, &c.

Zinc.

Our islands produce considerable quantities of zinc. There were obtained from the mines of Cornwall, Wales, Cumberland, and the Isle of Man, during the year 1855, not less than 5000 tons of zinc ore, in the form of sulphuret of zinc or *black-jack*, and calamine, a carbonate of zinc. The estimated value of this product was at least L.17,000. As the price for zinc is advancing, and as it is now selling at prices varying from L.2, 10s. to L.3 per ton, we may expect a new business for our zinc mines. The great supply of zinc for this country has hitherto been derived from the works of the Vieille Montagne Company. Our imports in the last five recent years have been as annexed:—

Years.	Zinc.	Oxide of Zinc.	
	Tons.	Tons.	Cwt.
1850	18,626	170	16
1851	22,936	495	9
1852	18,505	787	9
1853	23,418	342	0
1854	19,583	336	0

Calamine is very abundant in England, as in the Mendip Hills and parts of Somersetshire; at Holywell, Flintshire; at Castleton, Derbyshire, and in Cumberland. In 1854 the English zinc mines produced 4531 tons 3 cwt. of sulphuret of zinc, and 280 tons 11 cwt. of calamine. The value of the zinc smelted in England in 1854 was about L.16,500.

Arsenic.

Cornwall and Devonshire yield annually not less than 1500 tons of arsenic, a considerable proportion of which is employed to give the required whiteness to copper in our white-metal manufactures, and hardness to steel; and a large

quantity is exported to Russia and other places, where it is used in dressing furs and skins.

Mines and
Mining.

We have also in our country antimony, nickel, cobalt, manganese, and some other metals, which are of use in the arts. Cornwall formerly supplied antimony to the type-founder, but now we import nearly all the antimony we use. Antimony is found at Rosenau in Hungary; in Saxony and the Harz; in Spain, Tuscany, France, Siberia, Mexico, and the Indian Archipelago. The St Austell Consols Mine sold two years ago about 150 tons of nickel and cobalt; and the mines of the Duke of Argyle in Scotland produced about 300 tons, averaging about 6 per cent. for nickel. All the nickel which our white-metal manufacture requires is supplied from Norway and Germany. Cobalt is of interest to us as being the basis of the blue colour in our earthenware, &c., and nickel as an essential ingredient in various metallic alloys, such as albatra and German silver. The two metals are often associated in the same mass. A specimen of ore found near Keswick, Cumberland, contained from 2 to 3 per cent. of cobalt, but no nickel. The ores found in Cornwall include both nickel and cobalt; but as they seldom contain more than from 2 to 7 per cent. of available metallic matter, while the ores on the Continent frequently contain from 12 to 15 per cent., the process which may answer in the reduction of the richer ores may prove too costly in the poorer ones. The Swedish method has been tried with the Cornish ores, and failed.

This metal, used as a glaze or pigment by potters, &c., occurs native in the Hartz Mountains, in Piedmont, in the Mendip Hills, Somerset, and in the counties of Devon and Aberdeen. It has been recently found that a certain proportion of this metal, added to steel manufactured from British iron, produces a cast-steel nearly equal to that obtained from Swedish iron. Great quantities of the peroxide have been found near Tavistock in Devonshire and Launceston in Cornwall.

When sulphur was high-priced, considerable quantities were manufactured from our iron pyrites; but its present comparative cheapness has greatly reduced the demand for our own sulphur. Some, however, being still employed in our chemical works, it is produced from a few mines, chiefly from the Irish. Since 1839 the mines of Wicklow have sold, in fifteen years, 338,368 tons; the mines of Arklow, 606,972 tons; collectively, 945,340 tons. In the last year of the fifteen, viz., 1854, the quantities were,—Wicklow, 34,000 tons; Arklow, 90,000 tons; collectively, 124,000 tons. Cumberland and Westmoreland sold in that year 2400 tons. The Wicklow and Arklow mines, which produce the iron pyrites, all contain the same "sulphur course," which traverses them in a north-eastern and south-western direction. The iron pyrites consists, in 100 parts, of iron 46.67, sulphur 53.33.

Rock-salt is mined in some countries, and especially at Wielizka, near Cracow, in Poland (in the Cretaceous formation), where the excavations are of vast extent, and have been continued, it is said, from the year 1251, extending more than a league from east to west. The salt is of an iron-gray colour, in which are found rocks of a pure white. The annual product is reported to be about 2,000,000 cwt.

The great beds of rock-salt in the New Red Sandstone of Salt. Cheshire, in our own country, are known to extend one mile and a half north-east and south-west, and to be upwards of three quarters of a mile wide. There are two beds lying one over another, and at Northwich at least 60 feet in thickness. The top of the lower bed is about 220 feet from the surface; and no bottom has been found. The salt is mostly of a reddish hue, and is so hard that blasting by gunpowder is often necessary for its extraction.

The brine springs do not fall within the description of mines. A remarkable deposit of rock-salt has recently been discovered on the Marquis of Downshire's property at Car-

Mines and Mining. rickfergus, about 8 miles from Belfast, Ireland. The discovery was made in searching for coal, and at a depth of about 550 feet from the surface. It is comprised in a series of strata lying contiguous to each other, and the aggregate thickness is about 100 feet. The quality is said to be superior to the Cheshire rock-salt. Hitherto no springs have been discovered. The low price of coals in Cheshire will always be in favour of the manufactures there. From all these sources the British and Irish production of salt in 1854 has been nearly as follows:—

From Cheshire about.....	Tons. 850,000
„ Worcestershire about.....	100,000
	950,000
From vicinity of Belfast.....	15,000
Total.....	965,000

MANAGEMENT AND FINANCE OF MINES.

Many of the foreign mines are under the control and management of the respective governments. This is not the case with British mines, some of which belong to private individuals (as the lead mines of Mr Beaumont), some to institutions (as the Greenwich Hospital Lead Mines), and many to public and private companies.

When a company undertakes to work a mine, the lord of the land must be arranged with, and he grants a lease (*sett* is the mining term) upon certain terms, and demands a rent (royalty) either in ores or money. A ratio of one-fifteenth may represent the lord's average dues. Mines are worked by a greater or less number of adventurers or shareholders, either on what is termed the "cost-book system," or under joint-stock laws.

The cost-book system is very peculiar, and differs mainly from that of joint-stock companies in the control directly exercised by the whole body of the shareholders over the management of the concern. They appoint a *purser*, who acts as the financial servant of all, and renders an account to the shareholders at their frequent meetings. There are many advantages in this system; but legal questions and complications may arise which are difficult to decide. Many of its customs or usages are still *sub judice*. Coal mines alone are under government inspection, and that exclusively with reference to accidents, their causes, and preventives. The numbers of shareholders of which the associations for working mines consist are very various; but they are more than in ordinary trading partnerships, on account of the risks and expenses of mining. In the old adventures in Cornwall the number of shares in each mine was commonly either 64 or 128. It is now desired by many to increase the number of adventurers in these concerns. If the mine be a scrip concern, there are directors, &c. In Cornwall the mining agents are termed *captains*; and these are divided into "grass-captains" (at the surface), and "underground captains." The purser is the chief financial and managing officer. (*Cornwall; its Mines and Miners*, pp. 136, &c.)

The amount invested in British mining in 1852 was about five and a quarter millions, and these investments yielded dividends of L.1,409,060. Of these, mines representing L.2,345,624 produced something more or less; and mines representing L.1,476,666 produced nothing. Of the former class, mines representing L.498,196 produced dividends of L.253,057, or on the average 50 per cent. The amount of dividends paid on mining in the first nine months of 1856 may be thus classified:—

English mines.....	L.288,869
Irish „.....	17,970
Welsh „.....	15,485
Isle of Man.....	11,240
	L.333,564

From this statement an idea may be formed of the magnitude of business in British mining companies. There is a Mining Exchange in London.

Mining schools have long been established upon the continent of Europe. The most celebrated in Germany are those of Freiberg in Saxony, and Clausthal in the Hartz. Schemnitz in Hungary has a good mining academy, founded about 1760; France has its Mining School; and generally the foreign mining districts are well provided with scientific instruction. In England there has been a lamentable deficiency of mining schools. However, the Government School of Mines was opened in London on 6th November 1851, in connection with the Museum of Practical Geology. It is a well-provided institution, having able professors, a fine museum, many models, and a good library. A mining school has been established, after many difficulties, in Truro, Cornwall, and one smaller in Bristol.

GENERAL VIEW OF THE MINERAL WEALTH AND PRODUCE OF THE PRINCIPAL COUNTRIES OF EUROPE.

Great Britain is the most favoured country in the world for the development of mineral industry, as well as for its mineral possessions. Fuel, the indispensable agent in the treatment of metalliferous ores, and the most powerful element in the production of motive force, is distributed, though unequally, throughout the three countries of England, Scotland, and Ireland. The coal formation in these three divisions of the British Empire occupies rich and widely-spread basins, several of which (especially those of Newcastle-on-Tyne, Scotland, and Wales), being situated near to the sea, which surrounds the whole country, are enabled to export the coal to those places in which the metalliferous ores exist in abundance; but in some districts (as in Cornwall), the absence of fuel renders the work costly and difficult. The ores of iron, abundantly distributed in several of the coal basins, add greatly to their value. Each coal basin so situated has become the centre of a metal-working district, where numerous works produce iron at a price so comparatively moderate, that no nation has as yet been able to compete with us with any great success. The insular position of Great Britain allows the coal to be conveyed at a minimum cost wherever it is wanted, and is equally important in permitting iron or other metals to be shipped to any part of the world. Hence the importance of these particulars of situation, &c., is strongly shown when we state, that while England is thus enabled to supply her iron at a price which ejects all rivals from the market,—and while she exports annually upwards of 800,000 tons (her mean annual importation during the five years ending 1852 being 32,197 tons), and could supply the whole European continent,—yet the quality of her iron is considered by foreigners to be but middling, and it is not applicable to the purposes for which she imports the finer iron; while for the manufacture of steel she imports from Sweden and Russia. The manufacture of steel is very backward in Russia. Asia and European Turkey take more than two-fifths of the Russian exported iron, England and the United States nearly two-fifths, and other countries somewhat less than a fifth.

From time to time a few conjectural estimates have been formed of the value of the produce of the British mines. Dr Buckland, in his address to the Geological Society in 1840, remarked,—“The average value of the annual produce of the mines of the British Islands amounts to the enormous sum of L.20,000,000, of which about L.8,000,000 arise from iron, and L.9,000,000 from coal.” Sir Henry de la Beche in 1851 stated, that “the raw mineral produce of Great Britain and Ireland is valued at L.24,000,000 per annum, or about four-ninths of that of all Europe, including these islands; the coal being estimated at the pit's mouth, the iron in the pig, and so on.”

Mines and Mining. The following is Mr Hunt's estimate of the annual value of our produce of metals and minerals for two recent years, taken from the Government Geological Survey:—

	Value of British Produce for	
	1853.	1854.
Iron (pig).....	L.10,000,000	L.9,500,000
Copper.....	1,500,000	1,229,807
Lead.....	1,000,000	1,472,115
Tin.....	400,000	690,000
Silver.....	210,000	192,500
Zinc.....	10,000	16,500
Coal at pit's mouth...	11,000,000	14,975,000
Other minerals, as Nickel, Arsenic, Sulphur.....}	400,000	500,000
Total,	L.24,520,000	L.28,575,922

The number of persons employed in British mining is as follows:—

	Men and Women of all ages.
Coal.....	219,995
Iron.....	26,106
Copper.....	21,169
Tin.....	14,764
Lead.....	21,769
Zinc, &c.....	174
Total.....	303,977

An analysis of this number affords the following particulars:—

Males under 20 years of age.....	86,647
Do. 20 years old and upwards.....	208,520
Total Males.....	295,167
Females under 20 years of age.....	4,994
Do. 20 years old and upwards.....	3,816
Total Females.....	8,810

Total Males and Females ... 303,977

Russia.

According to the estimates of Tegoborski (*Commentaries on the Productive Forces of Russia*, by M. L. de Tegoborski, Privy Councillor, &c. of the Russian Empire, 8vo, London 1855, vol. i., p. 213), the latest and most reliable Russian authority, the principal products of the Russian

mines of gold, silver, platina, iron, copper, lead, zinc, coal, and salt, together represent a value of L.5,460,000 sterling, of which more than 55 per cent. is gold alone. This estimate excludes the accessory products of the mines,—granite, malachite, gems and precious stones, &c., found in mountains of Siberia. With the addition of these secondary articles of the mines and quarries, the author carries the gross value of the whole productions of the Russian mineral kingdom to L.6,333,333 sterling.

In Austria, the whole products of mines, salt excepted, Austria. on an average of the years 1841–1844 inclusive, represented a value of 22,102,000 florins. Adding the gross value of salt, at 1 florin per quintal, the gross total product of the mines will be 27,602,000 florins, equal to L.2,750,000 sterling. Taking into account the progress of production during preceding years, the present total Austrian production is estimated at about L.3,166,666.

In Prussia, according to statistical information published Prussia. in the Berlin newspapers, the total produce of the mines amounted in 1848 to nearly L.5,000,000 sterling.

In France, according to M. Schnitzler's statistics, founded France. on official returns, the total produce of the mines represented in 1843 a value of L.16,640,000, and according to the progress of production assigned by this author, it may now be carried to about L.16,800,000 sterling; but in the French estimates the produce of quarries and peat bogs, to the amount of L.1,600,000, is included. It would appear, too, that M. Schnitzler's rates of valuation are much higher than those of Tegoborski.

Thus an approximative comparison may be instituted, from which it would follow that the produce of mines in Russia exceeds that of the mines of Austria in the proportion of 2 to 1; exceeds Prussia by more than a third; but attains only two-fifths of the mining produce of France, and is therefore, of course, greatly inferior to that of Great Britain.

An approximative attempt at exhibiting a complete view of the metallic produce of the world for 1854 has been made in the subjoined table by Mr Whitney, an American:—

Table of Metallic Produce for 1854.

Countries.	Gold.	Silver.	Mercury.	Tin.	Copper.	Zinc.	Lead.	Iron.
	Lb. Troy.	Lb. Troy.	Lb. Avoird.	Tons.	Tons.	Tons.	Tons.	Tons.

With reference to Great Britain, mining operations are carried on to a greater or less extent in 21 English counties and the Isle of Man, in 12 Welsh counties, and in 17 counties in Scotland. Coal and iron, of some varieties, are found in greater or less proportions in nearly all the coun-

ties of England. In examining the counties in Wales and Scotland, we find a similar wide diffusion of coal and iron, and in Wales of lead. In Ireland we observe a wide diffusion of coal and lead, and argentiferous lead. Other minerals are far more rare. (J. R. L.)

MINES, MILITARY. See SAPPING AND MINING.
MINGRELIA. See CAUCASUS.

MINHO (the ancient *Minius*), a river of Spain, rising in the N.E. part of the province of Galicia, about 30 miles N.E. of Santiago, and flowing southward till it reaches the borders of Portugal. It then takes a westerly direction, and forms the boundary between Galicia and Portugal to the sea, which it enters at Caminha, after a course of about 130 miles.

MINHO, or *Entre Douro e Minho*, a province of Portugal. (See *ENTRE DOURO E MINHO*.)

MINIATURE PAINTING, a delicate kind of painting, consisting of little points or dots, usually done on ivory, vellum, or drawing-paper, with very thin, simple water-colours. Miniature painting is generally limited to portraits, which are for the most part executed on ivory, owing to the superior durability of that material and the peculiar brilliancy with which it bears out the colours. In composition, drawing, and finishing, the execution of miniatures is subject to the same laws as painting, although the process of miniature painting in water-colours is not at all similar to that employed in water-colour drawings generally. The outline, which must be extremely delicate, is traced upon the ivory with a silver-pointed pencil, and is afterwards drawn in with thin carmine. The colours, instead of being washed on or applied by successive tints laid over each other, are entirely dotted on the surface after what is called the dead colouring has been applied. In the dead colouring, which consists in laying on the colours in the smoothest manner, as painters do in oil, the shades are left less dark and the lights stronger than they ought to be; the finishing being performed by the process of dotting already referred to. The speediest method of dotting is the patching process, which consists of drawing delicate lines intersecting each other in all directions till the surface presents a regularly dotted appearance. The artist generally commences his shading with vermilion and carmine, using indigo afterwards for the bluish shade, and ochre and vermilion for the yellowish tints employed on those parts of the face which rise towards the light. The backgrounds, which, when very dark, are composed of bistre, umber, or Cologne earth, are formed by two coats, the first being of a light thin nature, and the last of a darker tint of the same colour. The most usual and appropriate dark grounds are of a greenish colour, consisting of a mixture of black, Dutch pink, and white. This ground is mostly preferred, owing to the rich appearance which it communicates to the carnation or naked parts of a picture. Landscapes and

flowers are also occasionally done in miniature; but as the process requires great nicety and patience, it is scarcely fitted for any subject beyond the face and bust of a figure. It is accordingly very seldom used except for likenesses, which, besides being portable, are much admired for the rich softness and delicacy of the colouring.

MINNESOTA, a territory of the United States of North America, bounded on the N. by British America, E. by Lake Superior and the state of Wisconsin, from the latter of which it is separated chiefly by the St Croix River and the Mississippi, S. by the state of Iowa, and W. by Nebraska, from which it is separated by the Missouri and White Earth Rivers. It lies between Lat. 42. 30. and 49. N., and Long. 89. 30. and 103. 30. W., and is 630 miles in length from E. to W., by about 380 in breadth from N. to S.; area 141,839 square miles. Minnesota occupies the most elevated tract of country between the Gulf of Mexico and the Arctic Sea, and forms the watershed of three of the greatest basins of North America—the Missouri, Mississippi, the St Lawrence, and the Hudson's Bay. The sources of the Red River of the North, and of the Mississippi, are nearly in the centre of the territory, at an elevation of about 2000 feet above the Gulf of Mexico. The *Hauteurs de Terre*, or Highlands, are a range of heights which extend W. by S. about 300 miles, and form the dividing ridge between the Mississippi and Lake Superior. The region W. of the Mississippi has several plateaus or tablelands, which mark the limits of various river basins. The most remarkable of these are the *Coteau des Prairies*, or Prairie Heights, about 200 miles in length by from 15 to 40 in breadth, running through the middle of the southern part of Minnesota; and the *Coteau du Grand Bois*, or Wooded Heights, extending for more than 100 miles nearly parallel with the *Coteau des Prairies*, and mostly covered with an extensive forest of hard wood. A range of less altitude than the Coteau des Prairies, but continuing in the same direction, forms the watershed of the streams flowing into the Missouri on the W., and those flowing into the Red River on the E. The rest of the country generally alternates between sandhills and swamps, river bottoms and prairies.

One of the most distinguishing features of the territory is the great number of its lakes of every size, from 40 miles to less than 1 mile in extent. The largest of these lakes are the Lake of the Woods, Rainy Lake, Red, Minni-Wakan, Leech, and Spirit Lakes. These have generally clear pebbly bottoms, and are well stocked with fish. The rivers and streams of Minnesota are also very numerous. The

Minnesota. Mississippi takes its rise in Lake Itasca, which it leaves by a small rivulet only a few feet in width, and subsequently flows through a number of small lakes. Its length in this territory is about 800 miles, for 500 of which (200 below and 300 above St Anthony's Falls) it is navigable. The Red River, passing north, and ultimately falling into Hudson's Bay, is the outlet of numerous small lakes. It has a winding course of about 500 miles in Minnesota. The Rum and St Croix tributaries of the Mississippi drain the S.E. portion of the territory, the latter of the two forming the boundary between Minnesota and Wisconsin. The slope toward Lake Superior is drained by the St Louis River, and by a chain of small lakes forming the N.E. boundary. The great valley formed by the slopes of the Coteau des Prairies and the Coteau du Bois is drained by the St Peter's, which flows first S.E. and afterwards N.E., till it falls into the Mississippi, after a course of about 460 miles. It is navigable for steamers for about 60 miles, and for flat-bottomed boats for about 120. Its principal affluent is the Blue Earth or Mankato River. The Rivière à Jacques and the Sioux are the principal affluents of the Missouri from this territory. They have both an almost directly S. course, the former being about 600 and the latter about 350 miles long. The Missouri, which forms the western boundary of the territory, is navigable by steamboats throughout Minnesota.

The larger part of Minnesota, including the central and N.E. portions, appears to belong to the igneous and metamorphic formations. In the N. and S.E. districts there are extensive formations of Lower Silurian rocks; and in the valleys of the St Peter's and Mississippi magnesian limestone forms the basis of many of the bluffs. Extending from the centre eastward to Lake Superior is a narrow band of new red sandstone, and on the shores of the lake are alternations of metamorphic schists, slates, and sandstones, with volcanic grits and other bedded traps and porphyries, intersected by basaltic and greenstone dykes, with occasional deposits of red clay, marls, and drift. The Missouri through its whole course in Minnesota appears to flow through cretaceous rocks, which are bordered on the E. by tertiary formations. The mineral resources of the country are as yet little known. Iron and coal exist in the southern parts, but it is not supposed that either are very widely diffused. Copper and lead have also been found, the latter on the Waraju River, and the former in masses having the appearance of having been carried by the action of water. Salt is abundant in the N.W. The most remarkable mineral, however, is the red clay, from which the Indians manufactured pipes, and which is believed to be peculiar to the region of the Coteau des Prairies.

The winters of Minnesota, especially in its northern and western sections, are extremely severe; but owing to the great stillness of the air, the coldest weather in winter is endurable. At Pembina settlement, under the 49th parallel of latitude, the cold is frequently so intense as to freeze mercury. The mean temperature of the month of January 1847 was $12\frac{1}{2}^{\circ}$ below zero, and the greatest cold 48° below zero. The hottest day in the month of July was 96° , showing a range of 144° between the greatest heat and the greatest cold. From the 17th of June to the 17th of July 1848 the mean temperature was 69° . The weather nearer the lake is milder, and of course the climate in the south yields to the influence of the latitude. The rivers are frozen over early in November, and generally remain close to the middle of April. On the whole the climate is dry; and while the early winters prove unfavourable to the ripening of Indian corn, the steady cold, and the dryness of the atmosphere, are favourable to wheat and other winter grains.

The soil varies greatly in different parts. In the valleys of the rivers it is mostly excellent, especially those of the

St Peter's, and of the Mississippi and its tributaries in the S.E. of the territory. Above the Falls of St Anthony, with the exception of the river alluvions and some prairie land, the country is generally covered with drift, interspersed with marshes too wet for cultivation; but much of the elevated portion is often of tolerable fertility, though inferior to the calcareous land of the river bottoms, and not unfrequently covered with dwarf timber. The country on the Red River, however, is excellent, and equal in soil to the best bottom lands of Illinois, producing fine crops of grain, fruit, &c. Wild rice, berries of various kinds, plums, wild grapes, and the crab-apple, are indigenous. According to the census of 1850, there were only 5035 acres of land under cultivation, producing 1401 bushels of wheat, 125 of rye, 16,725 of Indian corn, 30,582 of oats, 10,002 of peas and beans, 21,145 of potatoes, 200 of sweet potatoes, 1216 of barley, 515 of buckwheat, 2019 tons of hay, 85 lb. of wool, 2950 lb. of maple sugar, 80 lb. of bees' wax and honey. Value of live stock, L.18,575; of market produce, L.31; and of slaughtered animals, L.570. Parts of Minnesota are densely covered with pine forests, though it cannot be said to be a well wooded country. According to Professor Owen, a belt of forest crosses the territory in Lat. 44. 30. On the Rum, St Croix, and Pine Rivers, there are extensive forests of pine. The ridges of the drift districts are usually covered with small pine, birch, maple, ash, elm, fir, and poplar. In the swamps between the ridges the tamarisk and cypress are found; while the river bottoms furnish a good growth of oak, ash, linden, elm, walnut, maple, &c. Wild animals abound. Vast herds of buffalo, elk, deer, antelope, and other game, roam over the western plains, and occasionally the grizzly bear is met with. The black bear, wolverine, otter, mink, musk-rat, wolf, and raccoon abound; and over the prairies grouse, pheasants, and partridges are plentiful. The golden and bald-headed eagle are occasionally met with, and many kinds of water-fowl are common.

Previous to the organization of the state of Wisconsin, all that part of Minnesota lying on the E. side of the Mississippi River had been included in the territory of Wisconsin; and all the portion W. of that river had been included in the territory of Iowa. By the act of Congress 3d March 1849, Minnesota was erected into a territory.

The government comprises a governor appointed by the president of the United States for four years, a Council of 9 members elected in districts for two years, and a House of Assembly of 18 members elected for one year. Members of either body must be resident in their districts, and every district is represented according to its population. The suffrage is vested in every white male inhabitant twenty-one years of age, and who has taken an oath to support the constitution. In 1850 Minnesota was divided into nine counties, and had a total population of 6077; of whom 3695 were white males, and 2343 white females; 21 free coloured males; and 18 free coloured females. In 1855 the population of the territory was estimated at 45,000 to 50,000, and the counties had increased to 29. St Paul, the capital, is situated on the left bank of the Mississippi, at the head of the steamboat navigation, 15 miles below the Falls of St Anthony. Pop. (1850), 1338; (1855), estimated at 5000 to 6000.

MINOR, in *Music*. See *MUSIC*, §§ *Intervals*, *Scales*.

MINORCA, or **MENORCA**, the second in size of the Balearic Islands, is situated between 39. 47. and 40. 4. 55. N. Lat., and 3. 48. and 4. 20. E. Long.; 27 miles E.N.E. of Majorca, 140 miles S.E. of Catalonia, the nearest European coast, and 180 miles N. of Bujia in Africa. Its surface is uneven,—flat in the S., and rising irregularly towards the centre, where the mountain named El Toro has an altitude of 5250 feet. Owing thus to want of shelter from mountains, the climate is not so equable as that of Majorca, and it is

Minor
||
Minorca.

Minorca. exposed in autumn and winter to the violence of the N. winds. This want of shelter also, and the sterility of the soil, are the causes of the scarcity of trees and of the frequent failure of the crops. The surface is rocky, and the soil of very unequal quality; that of the mountains being light, fine, and fertile, and producing regular harvests without much labour or cultivation; while that of the plains is chalky, scanty, and alike unfit for pasture and the plough. Some of the valleys have a good alluvial soil; and where the hills have been terraced, they are cultivated to the summit. The wheat and barley raised in the island are sometimes sufficient for home consumption: rarely is there a surplus. Wine, oil, potatoes, legumes, hemp, and flax are produced in moderate quantities; fruit of all kinds, including melons, pomegranates, figs, and almonds, is abundant. Horned cattle, sheep, goats, &c., are reared, and the island abounds with small game. Stone of various kinds is plentiful; a soft stone, easily quarried, and acquiring hardness by exposure is used for building. In the district of Mercadal and in Mount Santa Agueda are found marbles and porphyry superior to those of Italy. Lead, copper, and iron are said to be abundant, but owing to the scarcity of wood, would not repay the expense of working. There are manufactures of the wool, hemp, and flax of the island; and formerly there was a good deal of boat-building, but, with the exception of agriculture, all branches of industry are in decay.

The coast is deeply indented, especially on the N., with numerous creeks and bays, that of Port Mahon, the capital, being the most considerable; after it come those of Addaya, Fornells, Ciudadela, and Nitja.

Port Mahon is situated on the E. coast, in 39. 52. N. Lat., 4. 20. E. Long., and occupies an eminence on the S. side, and 2 miles from the mouth, of a bay a league in extent. Its lofty position gives it a picturesque appearance, and contributes to its extreme salubrity. The city is of modern construction, and contains some fine public buildings, four churches, two ex-convents, two hospitals, a normal school, and one for higher instruction, with other private schools. The bay forms the finest and most capacious harbour in the Mediterranean, and one of the largest in the world, as a saying of Andrea Doria testifies,—

“Junio, Julio, Agosto y puerto Mahon,
Los mejores puertos del Mediterraneo son.”

“June, July, August, and Port Mahon are the best harbours of the Mediterranean.” On one side stand the fine large lazaretto and the marine arsenal; and on the largest island in the bay is the naval hospital, begun by the English in 1722 and finished in 1795. Of the fort of San Felipe, famous in the history of the island, and once deemed impregnable, no vestige remains since 1805. A road of 29 miles in length, S.E. to N.W., connects Port Mahon, by Alayor, Mercadal, and Ferrerías, with Ciudadela, the second city in the island; this road was constructed in 1713 by Brigadier Kane, to whose memory a marble monument was erected at the first milestone. The surrounding country produces abundant crops of wheat, some barley, excellent cheese, and honey; horned cattle are reared in considerable quantity, and there are fisheries. There are manufactures of tackle, soap, earthenware, &c.; these, together with the commerce, now confined to the coasting trade, are in a state of progressive decay. Pop. (1846) 13,280.

Minorca was taken possession of in 1287 by Alfonso, grandson of Jayme, the conqueror of the Balearic Isles, and continued under Spanish rule till 1708, when Port Mahon was taken by the English under General Stanhope, and the island secured to them by the peace of Utrecht. In 1756 it was invaded by a force of 12,000 French, who, after defeating Admiral Byng, captured Port Mahon. Re-

stored to England in 1769 by the peace of Versailles, the island remained in our possession till 1782, when it was retaken by the Spaniards. Again taken by the English in 1798, it was finally ceded to Spain by the peace of Amiens in 1803.

The Menorquins, especially those of the district of Mahon, who have been under English influence, are an enterprising and industrious, grave, and religious people. The general decay of manufactures and commerce has caused of late years a large emigration, chiefly to the French colony of Algeria, where they prosper. In 1846 the population amounted to 31,443.

MINOS, a king and lawgiver of Crete, was the son of Lycastus, and is sometimes confounded with another Cretan monarch of the same name, who was the son of Jupiter and Europa, and one of the judges in the infernal regions. He married Pasiphaë, the daughter of Sol, and became by her the father of Catreus, Deucalion, Glaucus, Androgeus, Acalles, Xenodice, Ariadne, and Phædra. According to the prevailing legend, he aspired to the vacant throne of Crete on the death of King Asterius. To prove to the people that his claims were favoured by the gods, he asserted that he could obtain from Neptune whatever he might choose to ask. He prayed that the god might send forth a bull from the sea. His prayer was granted, and the crown in consequence was immediately yielded up to him. But since the bull was not sacrificed to Neptune, as Minos had vowed, the god in revenge infected Pasiphaë with a passion for the brute. The queen concealed herself in a wooden cow constructed for the purpose by Dædalus, and thus became the mother of the *Minotaur*. This monster, who had, according to some, the head of a man on the body of a bull, and according to others, the head of a bull on the body of a man, was imprisoned by the king in the famous labyrinth. Minos is said to have been the master of a powerful fleet. With this he wasted the Greek islands of the Ægean, and cleared the neighbouring seas of pirates. He also sailed to Athens, and in revenge for the supposed murder of his son Androgeus, forced the Athenians to send him annually seven youths and seven maidens as food for the Minotaur. His next expedition was made to Sicily in pursuit of Dædalus. There he is reported to have been deceitfully put to death by Cocalus the Sicilian king. The legislative code of Minos is said to have been framed with the advice of Jupiter, and to have been the model of the Spartan lawgiver Lycurgus.

MINSK, a government of Western Russia, between 51. 12. and 55. 50. N. Lat., and 25. 10. and 30. 45. E. Long. It is bounded N. by Witepsk, E. by Mohilev and Tchernigov, S. by Kiev and Volhynia, and W. by Grodno and Wilna. Area 34,467 square miles. The surface is for the most part very flat, except towards the N., where a low chain of hills separates the rivers which flow into the Black Sea from those which flow into the Baltic. The principal rivers of the government are the Düna and the Dnieper; the former constituting the frontier between it and Wilna, and the latter flowing between this government and that of Tchernigov. The principal rivers that join the Düna are the Desna and the Ulla; and the Dnieper receives in this government the Pripetz and the Beresina. Besides these, Minsk is also watered by the Niemen and its tributary the Vilia, both of which take their rise in the government. The northern parts of Minsk are covered with extensive forests, and the soil is there dry, and in many places sandy; but the southern regions are marshy, and the country is generally inundated in the spring time, so as to present the appearance of a large lake. Although the soil is generally poor and sterile, there are nevertheless some fertile tracts. Agriculture forms the chief employment of the inhabitants, and the produce is more than sufficient for the consumption of the inhabitants. Rye is

Minsk
||
Minstrel.

the sort of corn grown in the greatest quantity, but barley, oats, and wheat are also produced. Flax and hemp are grown in great abundance. The inhabitants are also employed in cutting timber in the forests, and conveying it down the rivers. Cattle and sheep are reared in large numbers, but they are generally of inferior breed, and the wool of the sheep is very coarse. The country abounds in deer, wolves, bears, wild boars, foxes, and other sorts of game; and the rivers are well stocked with fish, but the quantity got is not equal to the demand, so that large supplies are imported from other parts. The principal manufactures are weaving and distilling, but these are not carried on to any great extent. The trade also is far from extensive, and is chiefly in the hands of foreigners; the chief articles of exportation being timber, flax, hemp, corn, honey, cattle, &c. The inhabitants belong for the most part to the Greek Church, but there are also many Roman Catholics and some Protestants; and the towns and villages are principally occupied by Jews. Pop. (1850) 1,067,000.

MINSK, the capital of the above government, is situated on the Swistocz, a tributary of the Beresina, 154 miles E.N.E. of Grodno; Lat. 53. 40. N., Long. 27. 40. E. The town is irregularly built, with narrow and dirty streets; but it contains some good public buildings, among which are a cathedral, an abbey, and a theatre, besides several handsome palaces belonging to the nobility. It is the seat of the government of the province, and of a Greek archbishop and Roman Catholic bishop; and has manufactures of cloth, hats, and leather, as well as a considerable trade. Pop. (1851) 25,352.

MINSTREL, an ancient term applied equally to a singer and an instrumental performer, derived from the French *menestral*, and not used in this country before the Norman Conquest. Our old monkish historians, in speaking of this class, characterize them by the epithet *minus, hystrio, jocolator*, or some other word which implies gesticulation. Hence it would seem that the minstrels, occasionally at least, set off their singing by mimicry or action, uniting the powers of melody, poetry, and dancing. According to Percy, "the minstrels were an order of men in the middle ages who subsisted by the arts of poetry and music, and sang to the harp verses composed by themselves or others." The Teutonic races generally, and especially the Danes, had been accustomed to hold men of this profession in the highest reverence. Their skill was considered as something divine, their persons were deemed sacred, their attendance was solicited by kings, and they were everywhere loaded with honours and rewards. In short, poets and their art were held in that rude admiration which is ever shown by an ignorant people towards such as greatly excel them in intellectual accomplishments. When the Saxons were converted to Christianity, in proportion as letters prevailed amongst them, this rude admiration began to subside, and poets were no longer a peculiar class or profession. The poet and the minstrel became two persons. Poetry was cultivated by men of letters indiscriminately, and many of the most popular rhymes were composed amidst the leisure and retirement of monasteries. But the minstrels continued to be a distinct order of men, and obtained their livelihood by singing verses to the harp at the houses of the great. There they were hospitably and respectfully received, and retained many of the honours conferred upon their predecessors, the bards and the scalds. Although some of them only recited the compositions of others, many of them still composed songs themselves, and all of them could probably invent a few stanzas upon occasion. There is no doubt that most of the old heroic ballads were produced by this order of men. Although some of the longer metrical romances might come from the pen of the monks or others, yet the shorter narratives were probably com-

posed by the minstrels who sung them. From the striking variations which occur in different copies of these old pieces, it is evident that they made no scruple to alter one another's productions, and the reciter added or omitted whole stanzas, according to his own fancy or convenience.

That in the early ages this profession was held in great reverence amongst the northern tribes is curiously illustrated by incidents recorded of several Saxon and Danish princes (of whom the most noted are Alfred the Great among the Saxons, and Anlaff among the Danes), who assumed the disguise of gleemen, and chaunted to the harp, while they successfully explored the camp of the enemy.

From the Conquest downwards, through long ages in England, the profession of the minstrel was a popular and privileged one. There was no period, however, immediately subsequent to the Conquest, in which this entertaining class met with so much royal patronage as during the reign of Richard I. This brilliant Crusader, himself an adept in the minstrel's art, invited to his court, according to Hoveden, many minstrels and troubadours ("*cantores et jocolatores*") from France, whom he loaded with honours and rewards, such as arms, clothes, horses, and money. And the well-known story of Richard's favourite minstrel, Blondell de Nesle, discovering his master by singing a French chanson under the walls of the German castle in which royalty lay imprisoned, if more popular than well authenticated, possesses at least the merit of recording symbolically the traditional devotion of the royal minstrel to his art. It appears from a passage in a letter of Hugh, Bishop of Coventry, that the superior officers of Richard's court had also learnt to patronize these "Jestours that tellen tales;" for William, Bishop of Coventry, chancellor to the king, brought over French minstrels, and loaded them with handsome presents, to sing the praise of *Cœur de Lion* in the public streets.

We occasionally find the *minstrels* and *jestours*, or reciters of *jestes* (gestes) or tales, named separately, as in a prologue of Nassyngton; but they for the most part belonged to the same class. The minstrels were also sometimes distinguished from the *harpers*. "In the year 1374," says Warton (*Hist. of Eng. Poet.*, vol. ii., p. 369), "six minstrels, accompanied with four harpers, on the anniversary of Alwyne the bishop, performed their *minstrelsies* at dinner in the hall of the convent of St Swithun at Winchester, and during supper sung the same *gest*, or tale, in the great arched chamber of the prior."

The instances of regard shown to minstrels during subsequent reigns are very abundant. Edward II. rewarded his minstrel William de Morle, known as "Roi de North," with certain houses in the vill of Pontefract, which had previously belonged to the degraded minstrel John de Boteler, called "Roi Brunard." We find from Rymer, in his *Fœdera*, that in 1415, when Henry V. was on his voyage to France, he was accompanied by eighteen minstrels, who were to receive twelve pence a day each. Indeed, the minstrels were often in those days more amply paid than the clergy. "In this age, as in more enlightened times," says Warton (vol. ii. 309), "the people loved better to be pleased than instructed. During many of the years of the reign of Henry VI., particularly in the year 1430, at the annual feast of the fraternity of the Holie Crosse at Abingdon, a town in Berkshire, twelve priests each received four pence for singing a dirge; and the same number of minstrels were rewarded each with two shillings and four pence, beside diet and horse meat. Some of these minstrels came only from Maydenhithe or Maidenhead, a town at no great distance in the same county. In the year 1441 eight priests were hired from Coventry to assist in celebrating a yearly obit in the church of the neighbouring priory of Maxtoke; as were six minstrels, called *mimi*, belonging to the family of Lord Clinton, who lived in the

Minstrel.

Mint
||
Minuet.

adjoining castle of Maxtoke, to sing, harp, and play in the hall of the monastery, during the extraordinary refecton allowed to the monks on that anniversary. Two shillings were given to the priests and four to the minstrels; and the latter are said to have supped in *camera picta*, or the painted chamber of the convent, with the sub-prior, on which occasion the chamberlain furnished eight massy tapers of wax."

So late as the reign of Henry VIII. these reciters of verses found free access into all companies; into the mansion of the noble as well as into the plebeian tavern. Yet they were gradually sinking into contempt and neglect, and were seldom called upon to furnish a specimen of their venerable art, except when some royal or other great personage condescended on some public occasion to smile benignantly upon the rude pastimes of their ancestors. It should not be forgotten, however, that the genuine minstrel was now seldom to be found in England; that, indeed, the name had become so far degraded as popularly to denote a mere musician. So singular a phenomenon had a veritable minstrel become in the reign of Queen Elizabeth, that when that august personage was entertained at Kenilworth Castle in 1575 by the performance of one of those ancient singers, his appearance and dress excited so much wonder among the spectators, that old Laneham felt called upon to transfer to his book the *Princely Pleasures of Kenilworth*, a provokingly minute description of the person, dress, and adornments of this extraordinary man of the harp. After describing this "squire minstrel of Middlesex," from his "fair kembed," "finely smoothed" head, to his feet, which were encased in "a pair of pumps; not new, indeed, yet cleanly blackt with soot, and shining like a shoeing horn," the author says,—“After three lowlie coursiez, he cleered his voice with a hem and a reach, and spat out withal, wiped his lips with the hollo of his hand, for fyling his napkin, temper'd a string or two with hiz wreast, and, after warbling on his harp for a prelude, came forth with a sollem song, warranted for stoory out of King Arthurz acts.”

Towards the end of the sixteenth century this class of men had lost all credit, and were sunk so low in the public opinion, that in the thirty-ninth year of Elizabeth a statute was passed, by which "minstrels," wandering abroad, were included amongst "rogues, vagabonds, and sturdy beggars," and were adjudged to be punished as such.

(For valuable information respecting the minstrel's character and poetry, see Wright's *Biographia Literaria Britannica*, Anglo-Saxon Period, pp. 3-7; with illustrations from the early Anglo-Saxon poem of *Beowulf*.)

MINT. See COINAGE.

MINUCIUS, FELIX. See FELIX.

MINUET, a very graceful kind of dance, consisting of a coupee, a high step, and a balance. It begins with a beat, and its motion is triple.

The invention of the minuet seems to be generally ascribed to the French, and particularly to the inhabitants of the province of Poitou. The word is said by Ménage and Furetière to be derived from the French *menue* or *menu*, small or little, and in strictness to signify a small space. The melody of this dance consists of two strains, which, from being repeated, are called *reprises*, each having eight or more bars, but never an odd number. The measure consists of three crotchets in a bar, and is thus marked $\frac{3}{4}$, though it is commonly performed in the time $\frac{3}{8}$. Walther speaks of a minuet in Lully's opera of *Roland*, each strain of which contains ten bars, the sectional number being 5; a circumstance which renders it very difficult to be danced. Modern instrumental composers have introduced into their symphonies and quartets, &c., minuets of a rapid movement and fanciful character, and which are followed by trios in a different style.

Miösen
||
Mirabeau.

MIOSEN, a lake of Norway, in the province of Christiania, and 36 miles N.E. of that town, has a length of 55 miles, and a breadth at the widest part of 12 miles. It is fed by the large river Lougen, which has a length of 130 miles, and falls into the lake at the village of Lillehammer. The surrounding scenery is very fine, the banks, which rise gradually from the surface of the water, being covered with forests and pastures. A steamer plies upon the lake; and a railway is projected from Christiania to its southern extremity. In 1755, at the time of the great earthquake at Lisbon, the waters of Lake Miösen were much agitated, rose suddenly to the height of 20 feet, and then as suddenly subsided.

MIRABAUD, JEAN-BAPTISTE DE, a French writer, was born at Paris in 1675. His intercourse with La Fontaine was the means of inducing him to abandon the military profession which he had adopted, and to devote himself to literature. To obtain greater facility for study, he entered the Congregation of the Oratory. His French translation of Tasso's *Gerusalemme Liberata*, in 2 vols. 12mo, Paris, 1724, first introduced him to notice. The French Academy recognised his merit by admitting him soon afterwards among their number, and by electing him in 1742 their perpetual secretary. He died in 1760. The other works of Mirabaud are a translation of Ariosto's *Orlando Furioso*, in 4 vols. 12mo, Paris, 1758; *Alphabet de la Fée Gracieuse* 12mo, Paris, 1734; *Opinions des Anciens sur les Juifs*, 12mo, 1769; *Le Monde, son Origine et son Antiquité*, 8vo, Amsterdam, 1751; and *Sentiments des Philosophes sur la Nature de l'Ame*, inserted in the collection entitled *Nouvelles Libertés de Penser*, 12mo, Amsterdam, 1743. The atheistical work of Baron d'Holbach, entitled *Système de la Nature*, was published under Mirabaud's name.

MIRABEAU, GABRIEL HONORÉ DE RIQUETTI, *Comte de*, was born at his father's chateau of Bignon, between Sens and Nemours, March 9, 1749. He seemed destined from his entrance into the world to excite perplexity and wonder. "Don't be afraid!" said the nurse, as she presented to his father a huge-headed infant already armed with a pair of grinders, one foot twisted, and tongue-tied. His calamities began early: at the age of three his remarkable face was seamed and disfigured by confluent small-pox, mismanaged through the impatient anxiety of his mother. "Your nephew," wrote the Marquis to his brother the Bailli, "is as ugly as the nephew of Satan." Still uglier in the eyes of the pedantic Friend of Men was the exuberant activity of the boy. At four years old he was incessantly burrowing among books and papers; all Paris talked of his precocity,—the "marmot" had all at once become waggish, very inquisitive, and very troublesome. The Marquis's bulletins regarding him varied with his humour. At one time he "promises to be a very fine subject," though "turbulent, yet mild and easily controlled;" he shows a "high heart under the jacket of a babe, a strange instinct of pride—noble nevertheless—the embryo of a dishevelled bully, that would swallow all creation before he is twelve years old;" possesses "an intelligence, a memory, and a capacity that strike, amaze, and terrify." At another time he is "a type quite unparalleled of baseness, absolute senselessness, and the quality of the dirty rough caterpillar, that will never uncrust itself;" he is "a nothing set off with trifles, who will throw dust in the eyes of gossips, but will never be but the fourth part of a man, if, perchance, he be anything;" "an almost ungovernable maniac, possessing all the vile qualities of the maternal stock;" and so on. The Marquis's feelings towards his too promising child would, in fact, notwithstanding his eccentricity, be quite inexplicable, did we not know what evil influence reigned at the family hearth. The Marchioness had retired, on the death of her father in 1757, to his estates in Limousin; during her absence a certain

Mirabeau.

Swiss lady, by name De Pailly, came to reside at Bignon, and the Marchioness returned no more. This bird of ill omen carried discord and misery into the peaceful house of Mirabeau, thenceforth divided against itself. Keeping in view, then, the influences amid which Mirabeau was trained, and the tyrannous pertinacity with which they were directed to his ruin, the wonder is, to find this excitable and headstrong being pass through it all so little injured; to see him still reverentially kissing the rod that had smitten so unjustly and so sorely; still nourishing in his wild and lacerated heart that "unutterable tenderness," that generosity, that love of virtue, which even "so much scoria" could not obscure.

At length it was evident that Gabriel had become too strong for his mild tutor M. Poisson, and he was put under the care of M. Sigras, a retired officer, and friend of the family; but, to the annoyance of the Marquis, the new governor became quite "fascinated" by his pupil, and gave far too flattering an account of him. A severer discipline was ordained; and in June 1764 young Mirabeau, now fifteen years old, was placed with the Abbé Choquard, who kept a military school at Paris. The Abbé was instructed not to spare the rod; and a more grievous than bodily punishment was administered in his being entered under the fictitious name of Pierre Buffière. Choquard soon reported very favourably; his pupil studied passionately, and with prodigious success, classics, modern languages, mathematics (under Lagrange), drawing, music, &c. An unfortunate discovery checked this hopeful progress. The Marchioness had been "secretly sending money to that reprobate;" Gabriel was absolutely forbidden to correspond with any member of his family; and at the suggestion of the enemy, it was resolved to remove him. On the 19th July 1767 he was entered as a volunteer into the Berri regiment of cavalry, commanded by the Marquis of Lambert, a man notorious for severity. He was accompanied by a man named Grévin, an auxiliary of Madame de Pailly, duly authorized by the Marquis to "watch and denounce" M. Buffière. Despite this vile espionage and the extreme harshness of discipline, the fiery youth behaved so well as to extort some expressions of satisfaction even from his father. The sunshine was brief, however; nature took her way in spite of the *furca*. The Marquis, whose errors of judgment and heart were as remarkable as his genuine sagacity and kindness, seemed to think that pocket-money was a sinful luxury even for the heir of all the Mirabeaus. That the young soldier, then, contracted "a few debts" will not be surprising; that being inexperienced in gaming, to which he never was inclined, he lost 40 louis at play, will admit of palliation; that he, still farther, took leave to fall in love with a pretty maiden of Saintes, and even to win her heart, will not shock the most lofty moralist. Unhappily, however, the close conjunction of these discoveries was coupled with other aggravating facts:—the ugly young subaltern had outrivalled his colonel; stung by insults and oppression, he had fled to Paris to complain to his friend the Duke of Nivernois; when brought back to his regiment and confronted with his superiors and accusers, he had energetically defended himself;—all which, to the stern eye of the Friend of Men, afforded conclusive proof that his son was a "sink of vice," fit only to be securely hedged within four stone walls,—nay, perhaps to be more effectually got rid of under the burning heat and pestilential vapours of Surinam. On second thoughts, the anxious parent (who at this very time was intensely occupied in the establishment of public ovens for economical baking) decided on the less barbarous alternative, and the young Count was duly lodged in the fortress of the Isle of Rhé, there to soothe his chafed spirit with the wintry roar of the Bay of Biscay.

The bailli of Aulan, governor of the castle, had strict injunctions to allow his prisoner no manner of liberty; and

the spy Grévin, whom the unsuspecting youth had begged as a favour to have with him, fulfilled his base office admirably. But in vain: not many days had passed before the "terrible gift of familiarity," the frank and fascinating warmth of the prisoner, had made a captive of his gaoler, who presently became his intercessor, and recommended his release. The French expedition to Corsica against the native patriots offered an eligible opening for a troublesome "monster;" Mirabeau received a second lieutenant's commission in the Legion of Lorraine under the brave Baron de Vioménil; and on the 16th April 1769 embarked for Corsica. During a year of active and harassing service he distinguished himself by his courage, ability, and industry, winning the esteem and confidence of his superiors and even some qualified approbation from the Friend of Men. On his return he was permitted to go and kiss his uncle's hand at Mirabeau: the honour of beholding the paternal countenance was as yet too much to grant. The Bailli was delighted with his nephew, and sounded his praises day after day. "I think I never encountered so much wit; it quite absorbed my poor brains—quite astounded me; he would cast the very devil into the shade. "Still better, this brilliant youth showed "a feeling heart," and the grave Abbé de Castagny was ready to cry when he exclaimed to him in a transport—"Alas, that my father would deign to know me; I know he thinks I have a bad heart, but let him only try me!" To these affecting relations the iron Marquis responds very cautiously; he is glad to hear them, but will take his own way; there is no necessity for throwing off restraint too soon with a fellow whose "head is a wind and fire mill;" he never approved of "fathers and sons being hail-fellow-well-met." From a distance he condescends to direct and mould the mind of the too aimless and romantic youth: there must be no more reveries, literary or military—no more voyagings in the planets; he must set himself steadily to the study of the paternal science; otherwise he will be a laughing-stock, and disgrace his father.

These repeated advices were unfortunately quite thrown away on *M. le Comte Ouragan*, who, so far from aspiring to the apostleship of political economy, could see nothing in the whole system but radical falsehood and barren pedantry. This blasphemous opinion was never hazarded in his father's presence, but easily found its way to his ears, with such result as may be imagined. The young Count had strong leanings towards a military life. "It is in battle only," he said, "that I am cool, calm, and lively without impetuosity. I then feel myself grow taller." The Friend of Men, however, was determined to throw cold water on his son's "smoke and military fire;" "does he think I have money to get him up battles like Harlequin and Scaramouch?" He must "become rural;" must be well crammed in the *Economics* and *Ephémérides*. Rural, accordingly, the young man did for a time become, active employment being for him a necessity of nature; and in surveys of the Mirabeau estate, and plans for all kinds of improvements, he found abundant occupation, working "like a galley slave." The Bailli was charmed by his nephew's energy and industry, and gently pressed his brother to relax a little. "You will find," he said, "as I do, that the furnace is hot,—very hot; but, my dear brother, let us bear in mind his age, and the brimstone peculiar to our blood. It is well that he should be within reach of being known; for, being perfectly open to reason, he listens to nothing else, and finds it a frightful task to submit to any other human restraints." At length the Friend of Men gave in; and received his son with what he called "tenderness." A course of lecturing followed, with the best effect; and shortly after the young Count was permitted to assume his proper title. A severe famine, attended by much misery and disorder, soon gave occasion for a display of his wonder-

Mirabeau.

Mirabeau. ful power of dealing with men. He exerted himself from morning to night, found work and food for the people, and cheered them by his vivacious example, working with them and presiding at the head of the common table. His father had planned a court of rural arbitration for the settlement of the disputes which abounded in the district, but despaired of getting it established. Not so his son. By dint of energy and tact, frankness and persuasion, he "reconciled everybody," and set the new institution agoing with success. "In one word," said the Marquis, "*he is the demon of the impossible.*" As the reward of his good conduct, the Marquis allowed him, in the spring of 1771, to visit Paris. There, as elsewhere, the young Count took everybody by storm, astonishing even the old stagers of Versailles. In the summer he was sent back to Limousin, the "black lady" becoming jealous of the good understanding between father and son. Happily his mission prospered, and a still more difficult and even dangerous errand to the Mirabeau estate was crowned with like success.

His prospects, at their brightest, now began to be clouded. The Marquis, separated from his son, and restored to De Pailly influence, soon relapsed into his old mood, listening to all ill reports, and doing well, as he thought, to be eternally angry. The perpetuation of the name and honours of the Riquetti lineage was with him at all times a fixed idea, amounting to a kind of mania, and to get his fatiguing "wolf-cub" off his hands there seemed no better device than marriage. After some looking about in the market, it was decided that an alliance with the rich Marquis of Marignane was highly eligible. His only daughter, Marie Emilie de Covet, was eighteen years of age, small, plain-featured, and dark-complexioned; but she had fine eyes and hair, a gay and amiable though weak disposition, and "great expectations." Her the young Count consented to woo; but richer rivals were in the field. His overtures were rejected, and he at once drew off. Spurred on, however, by the taunts of his father, he again entered the lists, determined to carry all before him, and he succeeded. His matchless powers of persuasion conquered not only the young lady, but "all the female relations, both old and young;" and on the 22nd June 1772 she became his wife. The income assigned to the young pair was far short of the original bargain, and utterly inadequate to maintain their position in society. Mirabeau was already in debt, and the bridal arrangements had been made regardless of expense. No wonder, then, if the exchequer soon ran empty. Help from the Friend of Men being out of the question, Mirabeau appealed to his father-in-law, who offered to lend him 60,000 livres if his father approved. A peremptory refusal, backed by threats, was the reply; and Mirabeau, now driven into a corner, retired from Aix to his patrimonial castle. Here, however, his thoughtless magnificence of taste, and his passion for improvements, brought matters to a crisis. The Marquis, ever ready to believe the worst, adopted his infallible resource, a *lettre de cachet*, and Mirabeau was forced to retire, an interdicted exile, to the small neighbouring town of Manosque. In this banishment he lived more than a year, during the course of which his wife bore him a son. Here also, warm from the study of Tacitus and Rousseau, he gave the first vent, in an *Essay on Despotism*, to that fiery hatred of oppression which was the ruling impulse of his life. Though full of haste and imperfections, its merits are as conspicuous as its faults.

And now came the chivalrous offence which led to new and deeper woes. That reckless ride of 20 leagues, to save a foolish young chevalier from matrimonial shipwreck—that fatal meeting on the highway with the aristocratic bully who had insulted his sister and refused satisfaction—that incontinent hiding of the noble recreant on the spot—who has not sympathized with? The whipped Baron

instituted criminal proceedings; sentence was delayed for two years; but a less tardy vengeance had been decreed by the inexorable Marquis; and on the 23d of August 1774 Mirabeau was caged in the gloomy fortress of If, perched on a barren rock near the entrance of the port of Marseilles. A friend had provided the means of escape, and urged him to fly, but he submitted obediently to the paternal mandate. The governor was instructed to use the utmost severity, and bar all communication with the world; and to add to the prisoner's sorrows, his wife, who had retired to her father's residence, declined to join him. They never met again. But no restrictions could prevail against that winning frankness and buoyancy which vanquished every heart of man or woman that ever came under their influence; and as usual the governor became his friend and intercessor. As usual, also, the prisoner was busy with his pen, and composed during this confinement the interesting sketch of the family history prefixed to his Memoirs.

In vain did his wife and family pray for his release, and the commandant Dallègre bear testimony to his irreproachable patience and resignation. The Friend of Men had his own plans; and on the 25th May 1775 the prisoner was removed (passive as before, though armed, and with but a single keeper) to a still drearier lodging, the castle of Joux, far up among the snow and clouds of the Jura Mountains. In this "owl's nest, enlivened by a few invalids," Mirabeau at first abandoned himself to solitary gloom. His keeper, the Count of St Mauris, was not a person to sweeten his solitude; but he permitted the prisoner occasionally to visit the neighbouring town of Pontarlier. Here Mirabeau was introduced to the only noble family in the place, that of the Marquis de Monnier. This wealthy and aged seigneur had, four years before, in revenge for the marriage of his daughter against his consent, taken to wife (or, properly speaking, bought) the daughter of M. de Ruffey, a Burgundian law dignitary. His years were seventy-one—hers eighteen; his character and habits were reserved and ungenial,—she was beautiful, ardent, and high-spirited. But home was dreary, and the choice lay between the old man and a convent. So early sacrificed to parental avarice and senile revenge, her gloomy life at length suddenly irradiated by the light of genius and kindred sensibility, the result was inevitable. For some time Mirabeau endeavoured to resist the fatal attraction that now drew him to Pontarlier. He avoided the society of Madame de Monnier, and wrote to his wife, passionately urging her to come and share his confinement and strengthen his resolve. In reply he received "a few cold lines," in which his gay little wife, otherwise occupied, gently insinuated that he had lost his senses. What wonder that the Riquetti flesh and blood took their way,—that the desolate prisoner continued to prefer the society of Pontarlier to that of his harsh-grained Cerberus at Joux? Meantime the jealous governor, himself a baffled suitor of Madame de Monnier, found a ready pretext for venting his spite on the prisoner, and Mirabeau learned that aggravated horrors were in store for him. His father, now in the thick of a law-suit with his wife, was "interested in continuing the confinement of the rascal, lest he should come and support his mother." Roused to desperation he escaped, January 16th 1776, into Switzerland, returning, however, in two days to Pontarlier, where he lived concealed. Madame de Monnier, subjected to the most humiliating bondage, at last broke loose and fled to her family at Dijon, Mirabeau following close behind. On the 24th March, she was sent back to Pontarlier, and immediately thereafter Mirabeau surrendered himself to the authorities. He lost no time in appealing to the benevolent Malesherbes. A commission was appointed to examine his case, and reported favourably; but meantime his father pressed for his removal

Mirabeau.

Mirabeau. to another fortress, and the minister, now on the eve of retirement, could only advise him to go abroad and enter foreign service. Nothing remained but flight; and having got back his parole, he set out for Verrières, thence to Geneva, and back to Lyons. Here he met his sister, Madame de Cabris, accompanied by her "friend" Brianson, a low and worthless adventurer. This foolish sister, for whose sake he had suffered so much, had no better advice to give than that he should escape with Sophie to a foreign country, she and Brianson lending their aid. Distracted, but not yet wholly lost to reason, he chose rather to hide himself for a season in Provence. Forced to fly, he went to Nice, and thence to Turin. Sophie meanwhile, goaded by daily persecution, overwhelmed him with passionate letters. The climax came at length: she tells him that her situation is too terrible to be borne; it must have an end—"Gabriel or death!" Such appeals were hard to resist. But the paternal vengeance was now on his trail; and for nearly two months he was hunted over hill and dale, over ford and ferry, through Nice and Turin, over the Great St Bernard, and down into the Valais. His route had been betrayed by his base companion Brianson, and on the 23d August, as he descended on Verrières, the enemy were only two days' march behind. But they were too late; that night Sophie, dressed in man's attire, crossed the garden wall by a ladder, and flew to Verrières.

On the 7th October they reached Amsterdam. Mirabeau, who had assumed the name of St Mathieu, was now left entirely to his own resources, and at once applied for employment to the booksellers. After waiting for three months, he was at last successful, so far at least as quantity was concerned; he was "overwhelmed with work." Among the books which he partially translated were Mrs Macauley's *History of England*, Watson's *Philip II.*, and some of Gesner's works. Of his original compositions the most important was his *Advice to the Hessians*, an eloquent pamphlet against the Hessian subsidy to Britain for putting down the American revolution. Rest in this quiet haven was not long permitted to the fugitives; their retreat became known in France, and the Marquis de Monnier offered to take back his wife. Mirabeau would listen to no such proposal, and the Marquis instituted a criminal action. On the 10th May 1777 the bailiwick of Pontarlier convicted Mirabeau of "forcible abduction and seduction" (*rapt et vol*), sentencing him to be beheaded (in effigy), with 40,000 livres of damages; while Sophie was condemned to life imprisonment in the Besançon house of correction, with forfeiture of marriage rights and dowry. The parents on both sides were not satisfied with a mere sentence; the police were again unleashed, and on the 14th May their old pursuer, Inspector Brugnières, descended on his prey. Sophie was carried off to a private penitentiary in Paris; Mirabeau to the donjon of Vincennes.

Now at length the unmanageable heir of the Riquettis was tightly fixed under the *furca*, no more to spring up and shoot his arms at his own wild will; straitly trained to a stone wall, he might bring forth the fruits of repentance at his leisure. The Marquis was now satisfied: his son was ruined; but he had brought an heir to the house of Mirabeau, and that was his "chief end" as man. That end having been attained, the future destiny of the criminal was fixed with icy determination. After the usual communion with his "conscience," he resolved on perpetual imprisonment. As to the opinion of the stupid world, what mattered it? He would, so long as health and spirits lasted, "please God, play the part of Rhadamanthus." Thus, then, the door of hope seemed absolutely shut. But hope and effort were never, save for one brief season of utter despair, abandoned by the prisoner. Shut up in a chamber ten feet square, environed in winter by

"smoke and ice;" miserably clothed; tormented by failing eyesight, stone, gravel, and blood-spitting; visited only by a turnkey charged to silence; one hour a day for exercise; few books, and these bad; denied the solace of music or any other recreation,—this ruined man battled indomitably with fate, and laboured as industriously as any journeyman in Paris. The extraordinary interest which he inspired in all his keepers won him, even in this stronghold of despair, unwonted privileges. Through the kindness of Lenoir, head of the police, he was permitted to correspond with his mistress, on condition that all letters should pass under the eyes of his confidential assistant, Boucher, and afterwards remain in his keeping. For three and a half years the lovers interchanged their passionate sympathies, their tender reminiscences, their griefs and their hopes. The version of these letters given to the world in 1792, through the unscrupulous greed of Manuel, procureur of the commune, is, according to M. Montigny, neither complete nor faithful; but how far the reckless prurience of the editor may have tampered with the originals, it is neither possible nor important now to determine. Of Mirabeau's other compositions during his confinement, the most important by far was his *Lettres de Cachet and State Prisons*, a work of immense labour, directed with vehement zeal towards a very noble end. His *Espion Dévalisé*, his *Collection of Tales*, his translations of Tibullus, of Boccaccio, and of the *Basia* of Johannes Secundus, are little worth. Of the *Biblion Eroticon* and *Conversion*, judging by report, the less that is said the better. Besides all these, were an elaborate treatise on *Inoculation*, drawn up for the benefit of his own and Sophie's child; translations of Horace, Ovid, Catullus, Propertius, and Tasso's *Aminta*; a general grammar; dramas; treatises on Mythology, on Religious Houses, on Standing Armies, &c.,—all which have been lost. Assuredly, whether well or ill employed, the prisoner was not idle. The idea of escape, save by legitimate means, seems never to have crossed his mind; and he perseveringly pleaded his cause, though without effect. He had been fifteen months in prison when the death of his son, "the last hope of our race," fell like a thunderbolt on the Friend of Men, who began to think himself "an especial object of Heaven's wrath,"—he, who had sounded his "conscience" every day, and "never did, nor wished to do, injury to a human being." In vain, however, was this occasion used to excite relentment. To his brother's timid remonstrances he answers in this truly Rhadamanthine style,—“I have rendered justice in my capacity of natural and domestic judge, and I could see, unmoved by remorse, the mother in the pillory and the son on the gallows tree! I should nevertheless carry my head erect and my bosom bare.” The good Bailli still persevered; and the gradual progress of the intercession, as revealed in their correspondence, is one of the most interesting parts of the adopted son's memoirs. His favourite daughter, Madame du Saillant, assiduously aided her uncle; and at length Rhadamanthus announced that, "for his own purpose, as well as ours, he should be liberated after trial." "Our purpose" was the perpetuation of the family: "If my grandson had lived, I should never have swerved from the word I gave to keep the father in prison." The happy day came at last; and on the 13th December 1780, after 42 months of duration, Mirabeau, with scarcely a rag to cover him, strode forth from his dungeon. At the hotel of his brother-in-law the grim portrait of the Marquis looked down on him from the wall; he burst into tears, uttering only the words, "My poor father!" Here is his first meeting with that father after an interval of nine years:—"I found myself face to face with him one day as I left Desjoubert's. His eye was piercing—his appearance strong and healthy. He cast down his eyes, drew to one side as far as he could, and I passed on."

Mirabeau's first work on regaining his liberty was the

Mirabeau.

Mirabeau. attempt to settle the long warfare of his parents; but the only result of his interference was an irrevocable alienation from his mother's love. She succeeded in her suit, and the report having spread that her defeat was to be the signal for the Marquis's reconciliation to his son, the old man determined to falsify it by receiving him at once. Boucher, the "good angel" of Vincennes, acted as mediator; and on the 20th May 1781, amid the tears of a friendly circle, the prodigal knelt at his father's feet. He spent the next eight months at Bignon, exerting himself to help and please his father, and so successfully, that the old man now found it necessary to defend himself and his prodigal from the mild sarcasms of the Bailli. "A son" he said, "cannot be amputated like an arm." Something told him, in spite of all outward appearances, that his son was "not more dangerous than a stuffed scarecrow; that the sternness with which he has contrived to invest his person, his reputation, and his mighty deeds, is nothing but smoke; and that at bottom there is no man in the kingdom less capable of committing a deliberate act of wickedness." During this period took place that last melancholy interview between Mirabeau and his long-lost Sophie. There had been jealousy and suspicion, now there were reproaches and recriminations; "the anger on both sides passed all reasonable bounds;" and so the lovers parted for ever.

And now Mirabeau girded himself to the great task of "replacing his head on his shoulders,"—getting the Pontarlier sentence reversed. The most able criminal lawyers pronounced the case frightfully complicated. His father and uncle, dismayed by the difficulties, scandal, and expense, proposed to solicit letters of abolition; in other words, to get the sentence quashed by a royal edict. But Mirabeau scorned a remedy which would absolve himself alone; and though Sophie generously urged him to yield, he was peremptory in his resolution to clear both or neither. "Since the days of the late Julius Cæsar," said the old man, "audacity and rashness have never existed in such strength." On the 2d February 1782 he left Bignon, accompanied by an able advocate named Desbirens, who soon, to his surprise and vexation, found his part in the business reduced to that of merely copying and examining documents for his client. Conciliation having been first attempted, with indifferent success, Mirabeau surrendered himself a prisoner at Joux, and a few days after obtained a provisional release. Against this the prosecutor appealed, and the prisoner was remanded. Mirabeau now opened his guns on the enemy, and continued firing till all France resounded with the "Case of the Count of Mirabeau." On the 5th March he appeared at the bar, and for ten hours was confronted with two of the principal witnesses, whom he succeeded in utterly demolishing, though "well crammed," and that touching things that had passed under their own eyes. The Marquis was in high dudgeon: he had "humiliated the witnesses, exasperated the judges, and insulted everybody." The Bailli took a calmer view of the whole business:—"Who, in that infamous Babylon, where everything scandalous in such an affair is soldered, cicatrized, and settled, is not, either by deed or will, guilty of all that is essentially blameable in the conduct of the *Infatigable*? It is true that he has given it more *éclat*; but the groundwork of the thing is the same,—adultery, rape, and seduction, supposing him to be guilty of all three, though he is guilty only of one, form the history of almost all men; in his case there is only a noisy publicity in addition." Here was the secret of all the terrible ill-fame of the Count of Mirabeau,—he had dared to break through the trammels of fashionable decorum, doing openly and bravely what it was "proper" to hush and veil under the polite forms of a corrupt society;

and that society, irritated and alarmed at the exposure, shuddered, not at the crime, but at the monstrous courage that justified it unabashedly in the face of day. Such a sin was, and ever has been, unpardonable.

Mirabeau's appeal for release was rejected; and three days after, he appealed the whole case to the Grand Chamber. His father sent his son-in-law, the Count du Saillant, to negotiate a compromise, but the undaunted prisoner would hear of none. He had reserved his heaviest artillery to the last, and now discharged his *Third Case* into the besieging camp. The prosecutor, Sombarde, who had throughout displayed the most indecent animosity, was within the prohibited degree of relationship to the accuser, and on this ground Mirabeau founded a most withering philippic. "If this," said he, with his sublime self-esteem, "be not eloquence unknown to these slavish times, I know not what that gift of heaven is, so seducing and so rare!" The enemy's fire was fairly silenced; and, after some delay and quarrelling, the matter was finally settled on the 14th August, Mirabeau getting his own terms, and satisfactorily proving his father's admission, that he was "in extreme cases very superior to a wise man." The Pontarlier sentence was reversed, the Marquis and Marchioness de Monnier separated, her dowry returned, and a conditional annuity of 12,000 francs a year settled on her. Having thus triumphantly replaced his head on his shoulders, the freed prisoner remained four days at Pontarlier, and exhibited himself in all public places for the benefit of his old friend Count St Mauris, or any other gentleman who might wish to speak with him, feeling, as he told his sister, "sadly in want of being run through the body."

The Friend of Men, while granting a qualified approbation to these proceedings, was as tough as ever on the subject of money; and in this melancholy predicament Mirabeau, having some MSS. to dispose of, retired for two or three months to Neufchâtel. Here, in spite of private woes, his public spirit found vent in a long and eloquent letter to the Count de Vergennes, showing the injuries inflicted on the Genevese republic by the intervention of France in favour of aristocracy. Meantime his sister pleaded for his return, and the Marquis requested the Bailli to receive him. He endeavoured to make the reception as ceremonious as possible, but quite failed; the cordiality of his nephew was too infectious, and the enthusiasm of the peasantry, "though he was in debt to some of them," passed all bounds. It was now time for Mirabeau to set about his second great task,—a reconciliation with his wife. The obstacles seemed insurmountable; she was passive in the hands of her exasperated father, and Mirabeau's letters were at first answered coldly, then with insults, and finally sent back unopened. The Bailli seconded his nephew's endeavours, while the Marquis held disdainfully aloof. He had no wish "to throw himself at the feet of that troop of play-actors¹ to beg for posterity;" it was time to stop that universal question, "Shall we never hear anything else but about that unruly race of the Mirabeaus?" All means of conciliation being exhausted, proceedings began in form, and on the 20th March 1783 the case came on for hearing at Aix. The court was crowded to excess; on the one side were the Marquis of Marignane, surrounded by a host of friends and advocates; on the other Mirabeau appeared with but three companions, and these three Englishmen, no Frenchman daring to stand by him. Two young advocates had lent him their assistance, but he pleaded his own cause. Restraining his usual vehemence as suited the line of defence, he spoke with great gentleness and moderation, with moving softness and dignity. Old Marignane at first sneered and tittered; as the speaker proceeded he bent his

¹ We are informed, on the Bailli's authority, that the Countess "acted plays and received the news of her husband's condemnation to death on a stage erected over the remains of her child."

Mirabeau's head, and at last he wept, as did half the audience. The pleading closed amid a tumult of enthusiasm, and Mirabeau's demand for a provisional reunion was sustained; but this temporary triumph only heightened the bitterness and activity of the enemy. The case came for final hearing before the Grand Chamber of Aix. On three several days Mirabeau pleaded before intensely excited audiences. On the final day the sensation reached its climax. Despite police and barricades, all doors and lobbies were stormed, and the very roofs of the neighbouring houses swarmed with human beings eager to catch even the distant hum of the pleader's voice.¹ So far as the public was concerned the triumph was complete; but one-half of the judge were relatives of Marignane! In proof of his kindness to his spouse, Mirabeau had quoted a letter dated May 28, 1774, proving his forgiveness in the case of a grave *faux pas*. This point was eagerly caught at by the public prosecutor as a ground for nullifying the husband's claim to cohabitation, and on it the whole case was made to turn. On the 5th July the chamber decreed a separation of body and goods, a sentence which was received with hisses by the angry public. The popular sympathy was some consolation to the defeated husband, and in due time bore fruit; he had made himself "the idol of the whole country." He resolved to appeal to the Court of Cassation at Paris; but the indefatigable intrigues of the enemy, and his own recklessness, defeated his efforts. A new *Case*, issued by him at Lyons, was suppressed by the keeper of the seals, whom he vainly attempted to enlighten on the subject of civil liberty; an appeal to the king was equally fruitless. As a parting shot, he republished his *Case* in Belgium, appending a sarcastic account of his interview with the seal-keeper; and, foreseeing troubles, made sail for England, accompanied by his fair friend Madame de Nehra.

His fortunes were now at their lowest ebb, and for the next five years his life was one of perpetual strait and struggle, of wandering and embarrassment, of hand-to-mouth expedients and reckless improvidence, of incessant and vehement activity, of headlong controversy, and of evil reputation—but a life still of high endurance, of patriotic zeal, of unconquerable independence. In England he resided eight months, of which some record is preserved in a collection of letters written during that period. He was, of course, an acute, and, for a foreigner, an unusually fair observer of the national peculiarities. In his wrappings with despotism he had often turned an eye of respect and longing towards Britain, and now he was able to see the practical working of that constitution which, in spite of defects and anomalies, seemed to him the best pattern for other nations to follow who had their own to rebuild. Among his most intimate friends were Romilly, Sir Gilbert Elliott (afterwards Lord Minto), and the Earl of Peterborough; and despite his formidable fame, he had access to "good society," in both senses of the term. As usual, he was full of great literary schemes; but the English publishers were not easily caught by flaming prospectuses. He wrote much, but published only *Considerations on the Order of Cincinnati*, a bulky volume, spun out from a thin pamphlet by an American, on a subject no longer interesting; and *Doubts on the Freedom of the Scheldt*—a defence of the Dutch monopoly against the designs of the Emperor Joseph II. At the end of seven months he sent out Madame de Nehra from the ark to spy the aspect of things abroad, and soon after followed her, reaching Paris on the 1st April 1785.

He now meditated a retirement to Provence for the composition of some great undefined work of history, but the illness of his (so-called) adopted son detained him in Paris, and his thoughts soon turned into a new channel. Intimacy with the Genevese exile Clavière, and his compatriot the banker Panchaud, directed his attention to the subject of finance, into the mazes of which he plunged with characteristic energy. The stock-jobbing fury was at this time at a climax in France, and Mirabeau determined to attack the hydra. At three of its principal heads were his thrusts directed,—the Bank of Discount, the Bank of St Charles, and the Paris Water Company. Between the months of May and December he issued five large pamphlets on these topics. His Genevese friends supplied the raw material; the arguments, the eloquence, the vituperation, were all his own. A rapid fall in the shares showed that his blows had told; and the rage and hostility excited were as the rousing of a nest of hornets. The new minister at first countenanced him, but having got into deep waters, soon found it expedient to shake off his fiery ally; and two of Mirabeau's pamphlets, one of which M. Calonne had himself revised, were successively suppressed. The attack on the Water Company was answered by the witty author of *Figaro* with a delicately cutting irony, to which Mirabeau, now in Brussels, replied with a vehemence of invective redeemed only by the utmost magnificence of style.

At the close of 1785 he left Brussels with a vague design of visiting the north of Europe, but once beyond the Rhine he felt strongly drawn towards Berlin, where the great Frederick, now scant of breath, but as fresh in head and fiery in temper as ever, was nearing the end of his long life-march. The king had ceased to receive foreigners; but to the general surprise, and the special chagrin of all the French residents, he twice gave audience to the doubtful stranger, whom his sharp eye had already noted as one fit to speak in the gate with kings. Mirabeau's first work on arriving was a long and bitter letter to M. Calonne, justifying himself against the minister; but his friends in Paris, to whom he sent it for revision, wisely refrained from publication. He worked incessantly at Berlin, but published only a pamphlet on Cagliostro and Lavater, castigating the impudent quackery of the one and the more honest but fanatical reveries of the other. About this time, also, he composed one of his best productions, published in the following year,—an Essay on Moses Mendelssohn and the Jews, in which he advocates principles of toleration not yet carried out towards the ancient people. At the end of four months he returned to Paris, and in a few weeks he was on his way back, commissioned as a secret agent to the Prussian court. On the day after the great Frederick's death he addressed his successor in a long and eloquent letter, replete with very noble counsel, delivered with such dignified frankness as rarely finds way to royal ears. His correspondence, and the accumulation of materials for a great work on the Prussian monarchy, occupied him constantly during six months. Two causes moved him to return to Paris: he had grown weary of his underhand employment, and wished a more honourable and acknowledged position. He had received the tidings, too, of the convocation of the Notables, and was in hopes of being appointed their secretary, having been the first to suggest the measure. In this hope he was disappointed; and, unsheathing his pen, within three weeks he wrote and published his *Denunciation of Stock-jobbing*. In this slashing pamphlet he commenced his assaults on Necker's financial measures, which he followed up with blow upon blow most perseveringly, most courageously, but also with most in-

¹ Here is the Marquis's version of the affair:—"My poor brother writes to me that his nephew spoke and pleaded from a quarter past 8 till 1 o'clock without spitting or blowing his nose. But I tell you that this posthumous Cicero is nothing more than an incorrigible clack-jaw and a fool." On the same severe authority we learn, that the opposite counsel, the celebrated Portalis, got such a dressing, that he was "borne fainting out of the Court," and kept his bed for days, a victory unparalleled in the annals of the long robe.

Mirabeau. temperate personality. The *Denunciation* had great success, and even the king acknowledged that Mirabeau had done the state good service. It was suppressed, nevertheless; and the denouncer received warning of a seventeenth *lettre de cachet* in readiness for him. He took refuge in Liège; and on the 24th May he set out towards Berlin for the purpose of completing his book. He remained three months at Brunswick with his friend and helper Major Mauvillon, encouraged in his labours by the Duke, through whom he obtained the King of Prussia's authority to consult state papers. The book appeared a year after in 8 vols. 8vo (and 4 vols. 4to). It was by far the most important and elaborate work he had yet produced, and greatly enhanced his reputation as a writer. His excellent coadjutor, to whom the credit of the composition was often attributed, has warmly disclaimed any right of paternity,—any merit save that of a most industrious and faithful Gibeonite.

At the close of September he returned to Paris, and was greatly shocked by the state of public affairs. The Parliament of Paris had just been banished to Troyes by Brienne, and things were daily looking worse. Advances were made to him by that crafty minister, but they were firmly declined. He was determined to preserve his independence till the fit hour came. While avowing his desire for active employment, he would remain in his obscurity "until there succeeds to the present confusion a regular order of things—until some great revolution, whether good or evil, command a good citizen, always accountable for his suffrage, and even for his talents, to raise his voice. That revolution cannot tarry long." The day after the refusal of the Parliament to register the enormous loan of 420 millions, he wrote to M. de Montmorin, showing in impassioned terms the fatal tendency of events, the wisdom of timely concessions, and the necessity of announcing the States General. But the curse of eyes that saw not, and ears that would not hear, had visited the rulers of France. They still hoped to do without the States General; and finding the Parliament obstructive, Mirabeau was strongly urged to write against it. The answer was noble from a man steeped to the lips in poverty, and with nothing to lose save the consciousness of independence: "Do not compromise a zealous servant who, when the time comes to devote himself to his country, will count the danger as nothing, but who, for all the thrones in the world, will never prostitute his name in support of an equivocal cause, where the end is uncertain, the principle doubtful, and the course dark and bodeful." In the summer of 1788, his friends Romilly and Dumont visited Paris. Mirabeau's character, the latter tells us, was "in the lowest possible state of degradation." Feared and suspected, the proud ruined aristocrat lived like an Ishmaelite—too well known but ignored, too honest to be bought, too poor to be courted. His old friends were afraid to compromise themselves by renewing the acquaintance, but they could not resist him; he took them by storm; and Dumont ere long was delighted and proud to hew wood and carry water for his gigantic friend.¹ Soon after this, doubtless under the pressure of sheer penury, he committed the grievous folly and wrong of publishing, under the title of *Secret History of the Cabinet of Berlin*, his confidential letters to the French ministry. This scandalous publication excited intense wrath against the author, and was ordered to be burned by the hands of the executioner.

At length the hour struck, long wished for, long delayed. On the 8th August 1788 De Brienne announced the convocation of the States General for the 1st of May 1789;

Mirabeau. and Mirabeau was up and doing. At length, out of the depths of darkness and humiliation, there broke upon him the light of day—the vision of a new and great arena, of victories and triumphs for his country and for himself. Now he would purge away the shame of the past in the glory of the future; France was to be saved, and saved by him! In January 1789 he took wing for Provence, launching, before his departure, another furious tirade against Necker, at that moment the idol of France. He presented himself for election to the nobility of Provence,—“the most ignorant, greedy, and insolent body of nobles” he had ever seen,—opposing them all single-handed in the discussions as to the mode of election, and drawing down upon himself their implacable hostility and rage. In reply to their attacks, he published a pamphlet literally blazing with indignant eloquence. “Generous friends of the peace!” he exclaims, “I do here appeal to your honour, and summon you to declare what expressions of mine are wanting in the respect due to the royal authority or to the nation's rights! Nobles of Provence, Europe is attentive; weigh well your reply! Priests of the living God, beware; God hears you! But if you maintain silence, if you entrench yourselves behind the vague declamations you have hurled at me, then suffer me to add one word:—In all countries, in all ages, the aristocrats have implacably persecuted the people's friends; and if, by some strange combination of fortune, such an one have arisen from among themselves, him above all have they struck at, eager to inspire terror by the choice of their victim. Thus perished the last of the Gracchi by the hand of the patricians; but struck with the mortal blow, he flung dust towards heaven, calling to witness the avenging deities, and from that dust sprang Marius—Marius, less great for having exterminated the Cimbri than for having overthrown in Rome the tyranny of the noblesse!” At the next meeting it was decreed that Mirabeau, having no fiefs of his own, had no right to sit in the Assembly; and the proud tribune, casting the dust from his feet, now threw himself into the arms of the Plebs. The story of his having, to win their favour, opened a clothiers shop at Marseilles, is too absurd for belief; had it even rested on good authority. Mirabeau needed no such devices to ingratiate himself with the enthusiastic Provençaux: he was already adored by them. His reception at Aix was triumphant beyond parallel. The whole country turned out; the air rang with *vivats*, with the thunder of cannon, and the pealing of bells; there were processions by day and illuminations at night. At Marseilles the enthusiasm was equal, and on the day of his departure he was escorted by “a hundred and twenty thousand” people and a retinue of three hundred carriages. At both cities famine, riot, and disorganization soon called for an exhibition of his magical faculty for subduing and pacifying the most formidable elements. Shortly after he was elected deputy both for Aix and Marseilles: on consideration he decided to sit for Aix.

At this point Mirabeau's history mingles with that of France. Into the remaining twenty-four months of his life were crowded events and labours fit for many years—labours that finally cut short the thread of a life in more senses than one too fast for human strength. Raised, as soon as prejudice had been conquered by his personal influence and the urgency of affairs, to indisputable supremacy in the Assembly, his aims throughout corresponded with his first professions. “*War with the privileged and with privileges*,” that was his motto: “*To crush the ministerial despotism and relieve the royal authority*,” that was

¹ This excellent man, whose *Recollections of Mirabeau* contain a good deal of striking truth and some very graphic pictures, with much confusion, vague reminiscence, and doubtful statements, amusingly describes his own feelings:—“When I worked for Mirabeau I seemed to feel the pleasure of an obscure individual who had changed his children at nurse, and introduced them into a great family: he would be obliged to respect them, although he was their father.”

Mirabeau. his aim. He soon found that the wreck of despotism was dragging with it the throne, that the blows which shook the one were undermining the other; and when he saw the very existence of the monarchy at stake he placed himself single-handed in the breach—too late, indeed, for his own fame and the good of his country. That he loved the breath of popular applause is true; that he scorned and braved the fierce *ardor civium*, when conscious of right, is not less so. His haughty soul may have inly spurned the many-headed monster which he had helped to loose. But let it not be denied him that he truly loved the People and battled for their rights, and as truly loved and battled for the Crown. How to reconcile these two—herein was his difficulty; a difficulty that might well have entangled and foiled a spirit less compassed with infirmity, an ambition more severely regulated than belonged to him. But that he basely pandered to the rage of a faction, and then sold himself in secret to the enemy with whom he professed to war—this is a view of his character that must be left to those whose special pleasure it is to lower our estimate of human nature, and who ever choose the worst hypothesis to account for what is dubious or abnormal in the conduct of men raised above their fellows.

On the 4th of May 1789 the national deputies marched in procession from Versailles to Nôtre Dame, amid the feverish expectation of all Paris and all France. Of the 600 members of the third estate, one alone attracted every eye. Among others who crowded the balconies of Versailles was Madame de Staël, who thus vividly pictures what she saw:—"You could not but look long on this man when once you had observed him. His immense black head of hair distinguished him among them all; you would have said his force depended on it like that of Samson; his face borrowed new expression from its very ugliness. His whole person gave you the idea of an irregular power, but a power such as you would figure in a tribune of the people." On his first appearance in the Assembly his name was greeted with murmurs; before many weeks had passed he swayed it at his will. He had already arranged for the publication of a *Journal of the States General*. Being free in its sarcasms, on Necker in particular, it was suppressed after the second number; but Mirabeau continued to enlighten the public in *Letters to his Constituents*, soon after converted into the *Courier of Provence*, under which name the journal went on long after he had ceased to have any concern in it. In this work he secured, with his usual marvellous power, the services of zealous coadjutors,—Dumont, Duroverai, Reybaz, and others. These assisted him also in the preparation of his speeches; and if Dumont speaks truly, he did not scruple to deliver orations wholly composed by other hands.¹ At first he spoke seldom, till he felt his way. He very soon discerned the dangerous and destructive temper of the Assembly; and while the question of the verification of powers was obstructing progress, he communicated his fears to the government through Malouet, a friend of Necker, urging them to be wise in time, and concluding with this offer:—"If they have a plan, and that plan be reasonable, I shall defend it." Unfortunately they had no reasonable plan. A meeting indeed took place between Mirabeau and Necker, but the severely respectable minister received the scandalous Count with chilling coldness and reserve. Mirabeau left him in indignation, saying, "I will go to him no more, but he shall hear of me!"

On the 23d of June occurred the memorable De Brézé scene, the turning-point of the Revolution. From that day Mirabeau was felt to be the foremost man, the

ruling spirit of the Assembly. He was greatly moved at not having been warned beforehand of the intentions of the court. "It is thus," he said, "that kings are led to the scaffold." On the 11th of July the old Marquis died at Argen-teuil, having lived to rejoice unstintedly in the triumphs of his son. Mirabeau, though urged by his friends to offer himself as a candidate for the mayoralty of Paris, with good prospect of success, hastened to attend to his father's obsequies, and for three days, days of terrible commotion, he mingled little in public business. Bertrand de Moleville, searching for the cause of this silence, attributes it to "profound intentions!" The truth is, that Mirabeau viewed with deep horror the frantic excesses of the populace, and in his letters to his constituents openly expressed his belief that "the continuance of popular dictation would expose the public liberty more than the plots of its enemies." "Too often," he added, "danger rallies absolute rule; and in the midst of anarchy a despot may even seem a saviour;" words prophetically true. On the 1st of September, in the face of fierce opposition and popular excitement, he spoke in favour of the King's absolute veto. On the 24th he defended the income tax of his enemy Necker, believing it necessary for the public salvation. "The force," says Dumont, "with which he presented so commonplace a subject was miraculous; he elevated it to sublimity. They who heard this speech will never forget it. From that day Mirabeau was considered as a being superior to other men: he had no rival. There were indeed other orators, but he alone was eloquent."

The suspicions of his complicity in the tumults of the 5th and 6th October, and of conspiring with the Duke of Orleans, have been utterly refuted by the testimony alike of friends and enemies. As has more than once been said, he never had any "party;" his only party was "his head." On the 6th November he opposed with all his energy the insidious motion against a deputy's being minister, or *vice versa*. His defeat on this occasion deeply wounded him; for the words "no deputy," he bitterly said, it might be as well to substitute "no deputy of the name of Mirabeau!"

Towards the close of the following spring appear to have begun his communications with the court, through the medium of his friend the Count de Lamarck. For a considerable time he had been comparatively silent, viewing the proceedings of the Assembly with a kind of sorrowful anger and disdain. In reply to the overtures made, he gave a full statement of his views in a letter dated May 10, 1790. He declares his invincible repugnance to enter on a new part, if he were not convinced that the restoration of the King's legitimate authority is the only means of saving France. He sees the nation daily drifting into anarchy, and he is "indignant at the bare idea of having contributed only to a vast demolition." He engages to serve the King with all his influence, but is as "utterly opposed to a counter-revolution" as he has been to the excesses already committed. He requires two months to collect his forces and arrange his plans; his conduct must not be judged by single speeches or acts; he promises finally to the King "loyalty, zeal, activity, courage,—everything but success." In conformity with this programme, he at once commenced operations, and established an agency throughout the kingdom for conveying intelligence and furthering his designs. That, in consideration of these services, in which Mirabeau really acted the part of an unrecognised prime minister, a few of his debts were paid from the civil list, and a monthly pension assigned him, which there is ground for supposing never to have been regularly drawn, are facts known to the world. How far they establish the charge of venality must be left to individual judgment; this at least is certain, that he in-

¹ Dumont, while doing his own best to strip Mirabeau of "his borrowed plumes," confesses that "Mirabeau had certainly a right to consider himself the parent of all these productions, because he presided at their birth, and without his indefatigable activity they would never have seen the light." He is speaking of other works, but the application holds good for all.

Mirabeau. curred large expenses in the interest of the King, and that he died insolvent. Those who incline to the more favourable view of his conduct will see some force in the saying ascribed to himself,—“A man like me might *accept* 100,000 crowns, but I am not to be *bought* for that sum.”¹ Be that as it may, from this time Mirabeau’s whole strength was bent on the salvation of the monarchy. On the 20th May he supported the King’s right to declare war or peace in a long and masterly oration. Great efforts were made to intimidate him; hawkers went bawling through the streets of Paris, “*Grande Trahison du Comte de Mirabeau !*” and the very tree was marked on which he was to hang. On the morning of the 22d the avenues leading to the Salle de Manège were thronged with angry crowds. His friends entreated him not to venture out, but his courage was of the kind that danger stimulates. “I know it well enough,” he said, “I must come hence to-day triumphant or piecemeal!” Triumphant he did come.

About the end of May took place his celebrated interview with the Queen. What had passed between them none ever knew, save that the Queen was delighted with Mirabeau, and he with her. But neither Queen nor court thoroughly or sincerely co-operated in the great schemes of Mirabeau; they had their own little schemes, ever varying with the feelings and changes of the hour. On the 30th December he addressed a long memorial to the Queen, expounding in detail his plans, and offering advices,—plans and advices far too wise and simple to be followed, though perseveringly urged up to the time of his death.

On the 1st Feb. 1791 he took his place as President of the Assembly, a distinction hitherto withheld through envy, and now yielded in the hope of lessening his influence by compelling him into silence. A foolish miscalculation; there, racked by internal pains, his neck swathed in linen to stanch the blood of leech-bites, administered between the sittings, his life consuming fiercely as it neared the close, the great tribune, never so great as now, sat and swayed the elements that raged around him. “Never,” says Dumont, “had this office been so well filled. He displayed in it a new kind of talent. He introduced a degree of order and clearness into the proceedings of which no member had previously the least conception. He simplified forms, could render the question clear by a single word, and also by a single word put down tumult.”

The end was approaching; for many weeks he had felt that his life-blood was being drained. Confident in his great strength, he had never slackened his pace, never stinted his labours or his indulgences. “Had I not lived with Mirabeau,” says Dumont, “I never should have known all that can be done in one day, or rather in an interval of twelve hours. A day to him was more than a week or a month to others. The mass of business he carried on simultaneously was prodigious; from the conception to the execution not a moment was lost.” And now, added to frightful anxiety, toil, and excitement, came fever, ophthalmia, rheumatic swellings, and fiery pains. “If I believed in slow poisons,” he said to Dumont, “I should think myself poisoned; for I feel that I am dying by inches—that I am being consumed in a slow fire.” But there was no rest for him: on the Sundays, indeed, he was down at

Argenteuil, among his flowers; on all other days “not an instant of rest from seven in the morning till ten or eleven at night; continual conversations, agitations of mind, and excitement of every passion; too high living,—in food only, for he was very moderate in drink.” On the 27th of March, though frightfully ill, he proceeded to the Assembly, where he spoke five times; he left it exhausted, and had a bath; thought he could sit out the Italian opera, but had to go homeward after a few minutes to bed, to rise no more. His friend and physician Cabanis found death written on his face. The sensation throughout Paris was indescribable; all day the Chaussée d’Antin was thronged with sad inquirers; bulletins were handed out every three hours to the eager multitudes, and messengers from the King came twice a day for tidings. All medicines were tried in vain, and Cabanis sat despondingly by the bed-side. “Thou art a great physician,” said his patient, gazing on him, “but the Maker of the wind that overthrows all things,—of the water that penetrates and fructifies,—of the fire that quickens or decomposes all things,—He is a greater physician than thou!” Even in the intervals of convulsive agony, with the sweat of death on his brow, and its shadows gathering around him, his supreme self-consciousness never forsook him; he was himself to the end. “He dramatized his death,” said Talleyrand. His friend Frochot supported his head. “Yes,” said the sick man, “support that head; would I could bequeath it thee!” At daybreak of the 2d April his windows were opened to let in the fresh breath of spring. He called Cabanis: “My friend,” he said, “I shall die to-day; there remains but one thing more to do; perfume me, crown me with flowers, environ me with music, so that I may enter sweetly on that sleep from which there is no awaking.” For three-quarters of an hour he discoursed with Lamarck and Cabanis on his own and the public affairs. “I carry in my heart,” he said, “the dirge of the monarchy; its remains will now be the spoil of the factious.” Towards night he was speechless, and in his dreadful pain he signed convulsively for drink; he waved the offered potions away, and hastily put down the words “*Dormir !*” He prayed for opium, but the doctor resisted; recovering utterance, he reproached his friend for hesitating to cut short his agony. For some time he lay silent, till the sound of distant guns broke upon his ear, and he asked—“Have we already the Achilles funeral?” A moment after, he had ceased to breathe.

So passed away, at the age of forty-two, the last Count of Mirabeau. Amid the tears of the French nation, with honours never before paid to any citizen, seldom to any king, his body was laid in the church of St Geneviève, the newly-consecrated Pantheon of France. Thence it was removed at the dead of night, in September 1794, to the churchyard of St Catherine, in the Faubourg St Marceau, the resting-place of criminals.

The memoirs of Mirabeau by his adopted son, M. Lucas Montigny (Paris, 1836, 8 tom. 8vo), are as yet, in spite of grievous defects, the most valuable source of information on the subject. Of innumerable briefer productions, there is but one demanding special notice,—the inimitable essay of Mr Carlyle. (A. N.)

¹ “I imagine,” Dumont shrewdly observes, “that in this kind of reputation Mirabeau has paid the usury of some offences to others. Exaggeration is the first penalty inflicted by the code of public opinion. He was so fully aware that if he had enjoyed personal consideration, all France would have been at his feet, that there were moments when he would have consented to pass ‘seven times through the heated furnace’ to purify the name of Mirabeau. I have seen him weep with grief, and heard him say, almost suffocated with sobs, ‘I am cruelly expiating the errors of my youth!’”

Mirabeau.

MIRABEAU, *Victor Riquetti, Marquis de*, the father of the great Mirabeau, and one of the most eminent teachers of the doctrines of the Economists in France, was born at Perthuis on the 5th of October 1715. He was the heir of an ancient Italian family of the name of Arrighetti, afterwards corrupted into Riquetti, who had been expelled from Florence during some civil broil in 1267, and had found a refuge and a home in Provence. His ancestors had bequeathed to him a lawless, stormy, and imperious temperament, that sought its proper element in some all-engrossing action or in the prosecution of some arduous project. This restless energy first found vent in the pursuit of war. He entered the army at an early age, fought bravely at the sieges of Kehl and Philipsburg, at the battles of Dettingen and Clusen; and won the Cross of St Louis in 1743. By this time his father had died, and had left him an independent fortune. The new Marquis now appeared in the character of a complete aristocrat, swelling with hereditary importance, stiff with haughty affectation, and enveloped in an atmosphere of contemptuous indifference, which was ever liable to be dispersed by storms of lurking passion. Quitting the army, he married the Marquise de Saulvebeuf, and taking up his abode in the old family castle of Mirabeau, on the banks of the Durance, he thought to lead on his tenantry to his ideal standard of improvement, to exact from them in return the most reverential respect, and to reign a despotic sovereign on his own estate. But all his ardent and benevolent exertions could not bend his stiff-necked peasantry into that pliability of submission upon which his imperious soul was so intent. He therefore abandoned his hereditary castle for ever, and settled in his newly-bought estate of Bignon, about 15 miles from Paris. Here his restless mind found a new crotchet in the political economy of Quesnay. Becoming a thorough-going disciple of that philosopher, he commenced to advocate his peculiar views in a work entitled *Ami des Hommes*, and in several other books and tracts. The only prominent result was, that he was lodged for some time in the Bastille. Nevertheless, on his release he continued pertinaciously to write on, indulging in strange and whimsical speculations, entangling his thoughts in hopelessly-complicated sentences, venting his pent-up passion in covert satire and bursts of eloquence, and sinning against all good taste by his egotisms, mannerisms, and forced metaphors. At the same time his whole parental authority was kept perpetually on the strain in endeavouring to mould his rising family into a conformity with his own educational theory. But the young Mirabeaus, rigid with the self-will of their race, could not be bent by the paternal efforts, persistent though they were. The result was an endless series of domestic broils, waxing hotter and hotter. The employment of confidential servants exasperated the turmoil, and the introduction into the household of an artful Swiss lady, Madame Pailly, brought it to a crisis. The wronged wife abandoned for ever the home in which she had lived for fifteen years. It was shortly after this that the Marquis directed the full torrent of his educational fury against his eldest surviving boy, Gabriel Honoré, and began that merciless system of tutorage which, however well meant, only resulted in bringing into play the wild irregularities of his great son's character. After the boarding-school and the army had failed to tame the fiery young spirit, the exasperated father did not hesitate to employ harsh imprisonment. Then his eye was ever on the watch to detect any attempts to escape from the imposed punishment, and his hand was always ready to thrust his culprit into severer bondage, if occasion required. He even thought upon banishment to the unhealthy climate of Surinam as an ultimate cure. At the same time the Marquis was instituting a series of law-suits against his wife, which made him the subject of the gossip and scandal of the entire country. He was also ruling the rest of his

children with a rod of iron, and was issuing against them numerous *lettres de cachet*. Once, it is said, he held his entire family under confinement, and sat alone by his household hearth in stubborn resignation, consoling himself with his political economy. Yet, like all his other projects, this project of subduing his family proved impracticable. The law-suits, after lasting for fifteen years, were decided against him to the almost utter ruin of his fortune. His son Gabriel Honoré turned out to be the most daring despiser of those very conventionalities which he had been so long forcing him to respect. The rest of his children went their own several ways in spite of him. These disappointments seem to have combined with advancing old age to soften down the asperities of the Marquis's character. His imperious temper became subdued into a perverse censoriousness. His philanthropy assumed the more definite form of a morality, grim, austere, and pompous, as became the nature of the man. He called his children together, was reconciled to them, and declared himself only fit now for sitting in the chimney-nook, and "patching his brains together again." Yet scarcely had he ceased from his lifelong and ineffectual struggles, when the aggrandizement of his family name,—that object at which he had so long aimed,—was suddenly achieved by a stroke of destiny. The French revolution opened up for his gifted son a path to the highest influence and renown. The hereditary pride of the old Marquis was at length gratified. He died on the 13th July 1789, when the name of Mirabeau had already become famous throughout Europe.

Miracles.

MIRACLES. A miracle is usually defined to be a suspension of the laws of nature, or a deviation from the uniform manner in which God exercises his power throughout the created world, or from the uniform method in which second causes operate and produce their effects. It follows that a miracle cannot be performed by human power. It is necessary, however, to distinguish between the *negative* and the *positive* element in miracles. A phenomenon is miraculous in the former sense when it is simply inexplicable by any known laws; but in the latter sense inexplicable events require to bear upon the interests of religion, as distinctive signs, in order to be considered miraculous. In the negative sense, a real deviation from ordinary phenomena may be admitted without necessitating an acquiescence in miracles in the positive and religious sense. Not a few phenomena in physical science are possessed of this negative element of miracles without being considered miraculous. They exhibit the character of a *prodigium*, or *τέρας*, without being what the religious miracle always is, a *σημείον*, or sign by which the Divine power is made known. It is in the latter sense that miracles are regarded here.

The person who professes to have received a revelation from God to be communicated to his fellow-men is bound to produce his credentials, in order that they may know that he is not either a deceiver or deceived. They have a right, and it is their duty, to demand sufficient evidence that his revelation is really from God before they place entire confidence in its truth and Divine authority. The working of a miracle will furnish incontestable proof that his statement is true. If an effect be produced which cannot be referred to the operation of natural laws, we at once recognise it as the act of Him who is the God of nature, and who alone can suspend its laws and produce effects in another way. If, therefore, a miracle be wrought by one who claims to be the bearer of a Divine revelation, we are warranted to conclude that his claims are well founded, and that God speaks by him. Man indeed is so constituted that he must draw this conclusion; for, "to try the theorem upon a simple case," after the example of Paley, if any man in the possession of his senses were to witness the performance of a miracle,—the restoration, for example, of sight to the blind, or the raising of the dead,—under circum-

Miracles. stances which satisfied him that there could be no deception or mistake, he would, without doubt, believe that he who wrought the miracle was the messenger of God, and spoke God's truth. The evidence of supernatural and Divine interposition in this way would be irresistible. Jesus himself has given his sanction to this reasoning, for He expressly suspends the authority of his doctrines, and his claims to man's belief, on the fact of his miracles: "The works that I do in my Father's name, they bear witness of me," &c. He repeated in the presence of the messengers of John the Baptist many of his most wonderful works: He healed the sick, cleansed the lepers, restored sight to the blind, raised the dead, and then dismissed them with this injunction,—"Go your way, and tell John what things ye have seen and heard." These miracles were proofs both of Divine power and of Divine goodness. They are works of a nature far superior to those which the uniform experience of mankind has taught us to consider as lying within the range of human power,—works, in short, which no man could do unless God were with him. At his word the storm was hushed into a calm, the deaf heard, the dumb spake, and the dead were raised to life; at his touch diseases fled, the blind saw, the lame walked, and the lepers were cleansed. His miracles were not only above the reach of human power, but they were benevolent in their motives and eminently useful in their effects. They tended in every instance to alleviate suffering and wretchedness, or to teach an important moral or doctrinal lesson. The benevolent tendency, therefore, of these miracles, as well as their wonderful character—the combination in them of might and mercy—proved that they were of God. They were performed by Christ for the express purpose of proving his claims to a Divine commission, and were constantly appealed to by Him as signs and seals of that commission,—as proofs of the truth of the system of doctrines and moral precepts which He taught. And it is obvious, that unless the doctrines which Jesus promulgated had received the Divine approbation, these miracles could not have been performed. Nicodemus gave expression to the instinctive feeling of human nature when he said to Jesus, "We know that thou art a teacher come from God, for no man can do those miracles that thou doest except God be with him" (John iii. 2).

A similar inference must of course be drawn from the miracles performed by the Apostles and Evangelists. Their works, like Christ's, were beyond the unassisted powers of man. Like Him, too, they appealed to these miraculous works as the credentials of their Divine commission. They affirmed "that the things which they taught, God had revealed to them by his Spirit."

But were these miracles actually performed? What evidence is there that these alleged miraculous works are not, as Strauss and his followers affirm, a collection of myths, or, as others say, mere illusions.¹ First of all, these miracles, if they were either illusions or frauds, were imposed alike on friend and foe, and triumphed over not only the strongest prejudices, but the deepest enmity. They were

Miracles. publicly performed in open day before multitudes of inveterate enemies, who had every motive to induce them keenly to scrutinize the evidence, and to detect and expose the deception, if the miracle was not genuine. We are expressly informed that the Pharisees narrowly examined into the reality of a miracle performed by Jesus on a man that was born blind; and we may be sure that they must have done so in the case of other miracles also. Prejudice, self-interest, and malignant hatred of Christ, must have made them eager to detect any falsehood or fraud in his conduct, if such had existed; and yet they were constrained to acknowledge with the Sanhedrim, in the case of the cure wrought by Peter and John on the lame man who sat at the gate of the temple, "that indeed a notable miracle had been done, and they could not deny it." Modern infidels deny the reality of the miracles related in the New Testament; but the ancient infidels who lived on the spot at the time, and were eye-witnesses of the events, were compelled to admit their miraculous character, though they ascribed them to the agency of evil demons. This acknowledgment by unbelieving Jews and pagans of the reality of the miracles of Christ and his apostles, shows that the evidence for them, after the strictest hostile scrutiny, was undeniable.²

Secondly, The miraculous facts of the gospel history are proved by the testimony of the Apostles and Evangelists, who have narrated what they saw and heard. They were not only competent, but also unprejudiced and disinterested witnesses; not only had they no prepossession to mislead their judgments and bias their minds in favour of the claims of Jesus of Nazareth, and no interest to serve by falsifying or misrepresenting what they had heard or seen, but they had many deep-rooted prejudices to overcome in embracing the religion of Christ, and many powerful motives to induce them to "resist even the evidence of their senses, and stifle the very firmest convictions of their mind." Like the rest of their countrymen, they entertained most erroneous notions respecting the character and office of the expected Messiah; and it was not till some time after the resurrection and ascension of Christ, that the pleasing dream of temporal grandeur which had captivated their minds was completely dispelled, and they became thoroughly convinced that their Master's kingdom "is not of this world." The witnesses of Christ's miracles, therefore, had none of the motives which usually influence human conduct to induce them to become his followers or to bear testimony in his behalf. On the contrary, they were solicited by the united ties of nature, of habit, of education, and of interest, to reject the claims of a religion which disappointed all their early associations and prejudices, all their favourite hopes and schemes. So that it is impossible to account for their conduct on any rational principle, except that they were fully convinced of the truth of what they declared, and "could not but speak the things which they had seen and heard."

Thirdly, the credit given to their testimony, and the

¹ The absurdities of the theory propounded by Paulus of Heidelberg, that the disciples of Christ mistook natural phenomena for supernatural occurrences, have been thus forcibly exposed by Quinet:—"The pen which wrote the *Provincial Letters* would be necessary to lay bare the strange consequences of this theology. According to its conclusion, the tree of good and evil was nothing but a venomous plant, probably a manchineel tree, under which our first parents fell asleep. The shining face of Moses on the heights of Mount Sinai was the natural result of electricity; the vision of Zechariah was effected by the smoke of the chandeliers in the temple; the Magian kings, with their offerings of myrrh, of gold, and of incense, were three wandering merchants who brought some glittering tinsel for the Child of Bethlehem; the star which went before them, a servant bearing a flambeau; the angels in the scene of the temptation, a caravan traversing the desert, laden with provisions; the two angels in the tomb, clothed in white linen, an illusion caused by a linen garment; the Transfiguration, a storm." (*Voice of the Churches*, by Dr Beard.)

² "But some people may say that the ancient Jews and pagans, who so readily believed in magical arts and the power of demons, must have been very weak and credulous men, and that therefore they may have given credit to tales of miracles without making any careful inquiry. Now there is, indeed, no doubt that they were weak and credulous; but this weakness and credulity would never have led them to believe what was against their early prejudices, and expectations, and wishes: quite the contrary. The more weak and credulous any man is, the harder it is to convince him of anything that is opposite to his habits of thought and inclination. He will readily receive without proof anything that falls in with his prejudices; and will be disposed to hold out against any evidence that goes against them." (*Whately's Introductory Lessons on Christian Evidences*.)

Miracles. consequent establishment and propagation of Christianity, can be accounted for only on the supposition that the miracles were really performed. Indeed, the Apostles, so far from commanding belief, would never have obtained even a hearing among the wealthy, refined, and proud inhabitants of the great Roman and Grecian cities, if they had not at the outset produced their credentials, and roused men's attention by the display of superhuman powers. The doctrines the Apostles preached were alike obnoxious to Jewish prejudices, destructive of Jewish hopes, and offensive to Grecian pride. To the one class they were "a stumbling-block," and to the other "foolishness." Their converts had to make a total revolution in their whole habits,—to incur the loss of all things, often of life itself,—to encounter foes in their own household,—to be separated from all they held dear in life,—to suffer ridicule, and contempt, and calumny, and violent persecution. And yet in a few years this mere handful of obscure and illiterate Jews induced vast multitudes of all ranks, and of different races and nations, to renounce the religion of their ancestors and to embrace the faith of Jesus of Nazareth. On the supposition that the miracles to which they appealed in confirmation of their statements were spurious, this is altogether unaccountable, and indeed incredible. The difficulty, therefore, as Whately remarks, of believing that the Christian religion was propagated by means of miracles, is nothing in comparison with the difficulty of believing that it could have been propagated without any. In the well-chosen words of Butler, "the miracles are a satisfactory account of the events of which no other satisfactory account can be given, nor any account at all, but what is imaginary merely and invented."

We are met, however, by the oft-repeated assertion, that a miracle is an impossibility, and therefore that no amount of evidence can prove that a miracle has been performed. This is the fundamental axiom of Strauss, who acknowledges that if it were not true, he would not think it worth while to attack the credibility of the Scripture history. "No just notion," he remarks, "of the true nature of history is possible without a perception of the inviolability of the chain of second causes, and of the impossibility of miracles." (Strauss's *Life of Jesus*, vol. i., Introduction, sect. 13.) The assumption that miracles are an impossibility is probably the most specious and widely-urged objection to Christianity in our day; and though enunciated with all the pretension of a new discovery, was one of the main arguments of the older infidels, as it is of their modern successors still. The main difference is, that the deists of a former day accounted for the miracles on the supposition of the grossest fraud acting on the grossest credulity; while Strauss and his disciples explain them by the theory of illusion or myth.¹ Strauss seems to regard the assertion as a self-evident truth, for he offers no argument whatever in its support. But it would not be difficult to show that the man who denies the possibility of miracles in any circumstances cannot consistently stop short of atheism. The atheist who repudiates

the notion of a distinct and independent Deity, and cannot founds Him with what is called Nature, may consistently deny the very possibility of a miraculous interposition; but he who believes in the existence of a God must admit that a miracle is at least not impossible. Surely the Being who created the universe can govern it as seems good in his own sight, and He who established what are called the laws of nature is not restrained by an invincible necessity from altering them as He sees fit, but may at his pleasure suspend their operation in any given instance, or introduce amongst them a new cause which will produce a new and different effect. Neander profoundly remarks on this subject:—"Although, from their very nature, miracles transcend the ordinary law of cause and effect, they do not contradict it, inasmuch as nature has been so ordered by Divine wisdom as to admit higher and creative agencies into her sphere, and it is perfectly natural that such powers, once admitted, should produce effects beyond the scope of ordinary causes. In the Divine plan of the universe (of whose fulfilment the connection of causes in the visible world manifest only *one side*), miracles stand in relations of reciprocal harmony to events occurring in accordance with natural laws. From the chain of causes involved in that great plan, indeed, no events, natural or supernatural, are excluded; both circles of phenomena belong to the realization of the Divine idea." (*Life of Christ*, b. iv., part 2.)

It is asserted by others, who do not venture to deny the possibility of miracles, that they are so improbable, that if they were wrought, no evidence could establish them. "Miracles are incredible," says Hume, "because they are contrary to experience." "But strictly speaking," as Paley remarks, "a miracle is only contrary to an experience when it is said to have been performed at a time and place, at which time and place, we being present and looking on, perceived no such event to have taken place; and this is a contrariety which no evidence can surmount." But it is preposterous to say that we are entitled to draw the same conclusion in the present instance, and to affirm that the miracles of Christ did not take place, merely because we have never witnessed a like event. Ten thousand of our Lord's Jewish contemporaries might have said that no such event as the raising of Lazarus from the dead ever occurred within their observation or experience, and their testimony might have been quite true; but it would in no way contradict the testimony of the Apostles, who declared that they were present and witnessed the resurrection of their Master's friend. In the same way, the testimony of all the men of the present day, that they have never seen the blind restored to sight or the dead raised to life, does not contradict or invalidate the evidence of those who say they did witness these miraculous interpositions. The truth of the one testimony does not disprove the truth of the other, for both may be true. They differ from, but do not contradict, each other. Experience teaches us that diseases are *generally* cured by the application of

Miracles.

¹ "Myths have been defined as fabulous narratives allegorically describing some physical or moral phenomena, philosophical principles, systems, &c., under the figure of actions performed by certain ideal personages; these allegories having been afterwards, through the mistake of the vulgar, believed as history." (*Historic Doubts*, p. 51.) On this mythical theory Dr Strauss explains the whole of the evangelical history, and affirms that the acts attributed to Christ are to be regarded, not as historic verities, but as allegorical fables, or at least as combining only a very slender portion of facts and truth with an immense mass of fiction and fable. He admits at the same time that strict historic investigations bring this collection of myths within thirty or forty years of the very time in which all the alleged wonders they relate are said to have occurred. According to this theory, Christianity is a system of mythology which originated in one of the most enlightened ages the world has ever seen, while all other mythologies have had their origin in an age of barbarism and of remote antiquity, before the commencement of authentic history. All other mythical systems have been of slow and gradual formation and reception, but the Christian "myths" sprung up at once within a single generation, and were received as historic facts by multitudes who must have been well aware of their recent origin. They originated among a people who expected a Messiah entirely different from Jesus of Nazareth, and were attached with the most intense bigotry to the faith which his gospel proposed to supersede. While other mythologies rarely, if ever, extend beyond the limits of the races which have originated them, Christianity was embraced by thousands of different races and nations, to whom it was most obnoxious on every ground—national, political, religious, and personal. And, finally, this accidental collection of fable and fiction, with a few facts interspersed, in a few years, though unaided by military power, or court authority, or philosophy, or science, triumphed over the prejudices of ignorance and superstition, and the vigilance of scepticism, the policy of government, and every other obstacle. The man who can believe this may believe anything. (*Eclipse of Faith*, 3d edition, pp. 209–212.)

Miracles.

medical remedies; the testimony of the Apostles affirms that they were *sometimes* removed at the mere word or touch of the Saviour; but these facts are not necessarily inconsistent or irreconcilable. "Each fact may arise from its own proper cause, each may exist independently of the other, and each is known by its own proper proof, be it of sense or testimony." (White's *Bampton Lecture*, p. 285.)

If, then, we are told that miracles are incredible because they are contrary to uniform experience, we ask the objector what he means by experience? Does he speak of his own experience and that of his friends and neighbours? Then, on this principle, the Indian prince of whom Hume speaks, who affirmed that there could be no such thing as ice, because it was contrary to his experience, was right in rejecting the possibility of such an occurrence. Does he mean the general experience of mankind? If so, his statement is true, but it is nothing to the purpose. Miracles are, from their nature, comparatively of rare occurrence, and being rare, are necessarily at variance with the experience of the greater part of mankind. If they were not, they would, as Paley remarks, be no miracles. Or does the objector mean that miracles are contrary to the uniform experience of all mankind in all ages? This were a mere begging of the question in dispute. He affirms that no one has ever witnessed a miracle, and when challenged to produce his evidence, he merely asserts in effect that nobody has ever witnessed one. Besides, how does the objector know that miracles are contrary to either the general or universal experience of mankind? Of course, by testimony and nothing else. So that, after all, it is on testimony which he derides, and not on experience, that the weight of Hume's argument depends. Farther, the experience of which Hume speaks extends to the mental and spiritual as well as to the physical and material part of nature—to the world of mind no less than to the world of matter. He expressly admits "that there is a uniformity in both the moral and physical world, and that nature does not transgress certain limits in either the one or the other." Again he says,—"We readily and universally acknowledge a uniformity in human motives and actions as well as in the operations of body." And he adduces an argument for the doctrine of "philosophical necessity," drawn entirely from the general uniformity observable in the course of nature with respect to the principles of human conduct, as well as those of the material universe, from which uniformity, he observes, it is that we are enabled in both cases to form our judgments by means of experience; "and if," he adds (*Essays*, p. 85, 8vo, 1817), "we would explode any forgery in history, we cannot make use of a more convincing argument than to prove that the actions ascribed to any person are directly contrary to the course of nature." It is admitted, then, by the objector to miracles that there are moral laws of nature as well as physical, and that the violation of the one, no less than of the other, beyond a certain point, is to be regarded as a miracle. Let us apply this admission to the present case. Here we have a considerable number of individuals declaring that in their presence certain works of wonder, of which they were competent to judge, were performed different from the usual manner in which the laws of nature operate, and which could not be accounted for according to those laws; that they saw the most inveterate diseases healed—the deaf, the blind, and the lame cured, and the dead raised by the mere word of Christ. In proof of their belief of these miracles, they renounced the religion in which they had been educated, and to which they had been previously attached with intense bigotry; they constantly adhered to this testimony, not only without any assignable motive, but in opposition to all the motives by which mankind are usually influenced; they persisted in affirming that these statements were true, in spite of ridicule and contempt, of

VOL. XV.

insult and wrong, of the scourge, the dungeon, the axe, the cross, and the stake. They had hundreds and thousands of associates of both sexes and of all ranks and ages, and yet not one of them was ever induced, either by the hope of reward or the fear of punishment, to betray their cause or to confess that it was an imposture. That this uniform and inflexible constancy should have been displayed in support of an unprofitable falsehood, by men who taught and preached the purest system of morality the world has ever heard of, is utterly at variance with all the principles of human nature, and would be a greater miracle than any work of wonder recorded in the Scripture history. If their testimony be false, the physical miracles must of course be false too; but then the moral miracle must be true. The denial of the one necessarily implies the belief of the other, and the falsehood of such testimony, in the circumstances of the case, would be more incredible far than the truth of the miraculous interpositions which it attests. (*Eclipse of Faith*, 3d edition, pp. 270–274.)

The argument of the sceptic has been most dexterously turned against himself in the masterly refutation of infidelity just referred to (p. 278). It is there shown that Strauss and Hume, and others who affirm that a miracle is impossible, would, if they saw what seemed a miracle, distrust their senses, and believe that they were deceived. The position, then, of those who deny and of those who assert miracles is exactly the reverse of Hume's statement. The man who believes "transubstantiation" distrusts his senses, and rather believes testimony; and in the same way, the man who believes that miracles are impossible, if he were to witness any event that has a miraculous appearance, must, on his principles, be prepared to deny the evidence of his senses, and to trust to testimony—to that general experience which comes to him, and can come to him only in that shape. It is the infidel, therefore, and not the Christian, who is affected by the argument of Hume.

The impossibility of a miracle—or at least the impossibility of proving a miracle—has been defended by Rousseau on an entirely different ground. A miracle he defines to be an exception to the laws of nature; and as we do not know, he says, what the laws of nature are, we cannot determine whether any given event be or be not a deviation from these laws; and therefore it is impossible to prove the reality of a miracle. It is true, we do not know universally what the laws of nature are; but there are certain events so different from their uniform results, that we may confidently affirm that they cannot have been produced by the operation of these laws. We do not know the full extent of the powers of medicine; but we do know that the cure of blindness, or deafness, or paralysis, by a word or a touch is at variance with all medical laws, and must therefore have been the result of another and totally different cause—the special interference of a superhuman power. The fertility of the earth varies in different countries and climates, and may probably hereafter, by the applications of science, be increased far beyond anything yet attained; but in no country, and by no possible application of science, could a few barley loaves and small fishes be instantaneously multiplied so vastly as to suffice for a meal to five thousand persons faint with hunger. We do not know fully the nature of fire or the utmost extent of its power; but this we do certainly know, that it is the nature of fire to burn; and therefore, when Daniel's three companions were thrown into the burning fiery furnace, and came out unhurt, this result was contrary to the nature or the laws of fire, and must therefore have been produced by a miraculous interposition.

Again, it has been said that no miracle can prove a moral truth, because there is no natural relation between the displays of physical power and any such truth. The performance of a miracle, therefore, it is alleged, is a mere evidence of extraordinary power, and is neither a proof of the veracity

Miracles.

Miracles. or Divine commission of the person by whom it is performed, nor of the Divine authority of the religion which he may teach. It is true that a miracle, considered by itself, proves merely that its author is endowed with superhuman power over the operations of nature; but the miracles of Christ do not stand alone—they form only one link of the chain of Christian evidences, and must be taken in connection with their circumstances and the purposes for which they were performed. Their character and tendency, as well as their miraculous nature, must be taken into account, together with the fact that they were constantly appealed to by our Lord as credentials of his mission. It is not from the miracles of Christ, considered merely as superhuman works, but from their benevolent character, which proves that they originated in a benevolent source,—the union in them of power and goodness, combined with the fact that they were performed in attestation of his claims to the office of Messiah, and in support of the system of doctrines and precepts which he taught,—that we draw a conclusive argument in favour of his Divine authority.

Lastly, it has been alleged, that whatever may have been the original strength of the evidence of the Scripture miracles, it has undergone a very serious diminution by being transmitted through a number of successive individuals and generations, and will in the end become extinct. "Suppose a fact to be transmitted," says Laplace, "through twenty persons,—the first communicating it to the second, the second to the third, &c.,—and let the probability of each testimony be expressed by nine-tenths (that is, suppose that of ten reports made by each witness, nine only are true), then at every time the story passes from one witness to another, the evidence is reduced to nine-tenths of what it was before. Thus after it has passed through the whole twenty, the evidence will be less than one-eighth." That is, the chances for the fact thus attested being true will be less than one in eight. "The diminution of evidence," he adds, "by this species of transmission may be compared to the extinction of light by the interposition of several pieces of glass. A small number of pieces will be sufficient to render an object entirely invisible which a single piece allowed to be seen very distinctly." (Laplace, *Essai Philosophique sur les Probabilités*.) Now it must be admitted that if any statement as to a matter of fact were to be transmitted successively through twenty persons, and we ourselves were to receive the account from the twentieth narrator alone, the credibility of the report would be very considerably diminished; in other words, the probability of error or mistake would be largely increased. But in the present instance we have not merely the testimony of the last, but of every preceding witness, to the truth of the gospel narrative. We can travel back step by step, in regular and unbroken order, through every link in the chain of testimony from the present time to the days of the Apostles, the eye-witnesses and original relaters of our Lord's miracles. We have not only the testimony of those who heard the Apostles tell their simple story, but of the Apostles themselves, who have declared what they heard and saw. In this way, to recur to the illustration of Laplace, we can remove one by one the interposing pieces of glass which intercepted the rays of the light of truth, until we are enabled to see the object presented to our view as clearly, and to judge of it as correctly, as the original spectators. (Benson's *Hulsean Lectures* for 1820, p. 80.)

The truth of the miracles recorded in the books of Moses can be established by similar arguments to those which have been adduced in proof of the reality of Christ's miracles. Both have all the marks which are necessary to prove them worthy of full credit. The four well-known rules laid down by Leslie as infallible tests of the genuineness of an alleged miracle, all meet in the works of wonder performed by Moses as well as by Christ; and they never have met, and

never can possibly meet, in any imposture or pretended miracle:—1. That the facts related be such as that men's outward senses—their eyes and ears—can be judges of them; 2. That those facts be done openly and publicly in the face of the world; 3. That not only public monuments, but outward institutions and actions, should be appointed and perpetually kept up in memory of them; 4. That these institutions should commence from the time the facts were done. The miracles of Moses,—the passage through the Red Sea, the miraculous supply of manna and of water from the rock in Horeb, and the passage over Jordan, &c.,—were all events regarding which the senses of the spectators could not be deceived. These miracles were performed in the most public manner, and in the presence of many witnesses; so that there was every opportunity to subject them to the most searching scrutiny. Not only were public monuments erected, but various institutions—such as the feast of the Passover—were appointed at the time to be observed in remembrance of these miraculous interpositions, and were observed by the Jewish nation in all succeeding ages,—institutions which, from their nature, it would have been impossible to induce any people to observe unless fully satisfied of their Divine authority. And the books in which these miracles are related are not only a history of the Jewish people, but their very statute-book, containing their municipal as well as civil and ecclesiastical laws, which, like the history, are inseparably connected with the miracles wrought by the legislator. (See Leslie's *Truth of Christianity Demonstrated*; and *Short and Easy Method with the Deists*.)

In comparing the evidence for the miracles recorded in Scripture with that which can be offered in support of any other miracle, it is proper, as Paley shows, to lay out of the case—

1. Such accounts of supernatural events as are written a long time after their alleged occurrence. On this principle we may at once set aside the miraculous story of Pythagoras, written 800 years after his death; the prodigies of Livy's history; the fables of the heroic ages; the whole of the Greek and Roman mythology; a great part of the accounts of Popish saints; the miracles of Apollonius Tyanæus, published more than 100 years after his death; and the miraculous powers ultimately claimed for Ignatius Loyola.

2. We may lay out of the case accounts published in one country of what passed in a distant country, without any proof that such accounts were received or known at home. The Gospels are not only a contemporary history, but they were first published, and the Christian church first planted, in the place where its Founder lived and performed his miracles, and died; while the accounts of the alleged miracles of Apollonius Tyanæus, of Francis Xavier, and others, were published at a great distance from the supposed scene of the wonders.

3. We ought to lay out of the case *transient* rumours. On the first publication of any story, unless we are personally acquainted with the facts of the case, we cannot know whether it is true or false. We look to the confirmation or contradiction of the account by its increasing notoriety or its dying away, and to its permanency or disappearance for the discrimination of truth from falsehood. Tried by this criterion, the miracles recorded in Scripture are presented to us in the most favourable light.

4. We lay out of the case what may be called *naked* history,—history found merely in a book, unattended with any evidence that the accounts given in the book were credited and acted upon at the time when the events are said to have occurred, and unsupported by any collateral or subsequent testimony, or by any important visible effect. This certainly is not the case with the history of the miracles of Christ. That history is to be combined with

Miracles.

Miramichi
||
Miranda.

the institutions of Christianity, with the time and place and circumstances of its origin and progress, as collected from other historical sources, with its prevalence to the present day, with the fact of our present books having been received by the advocates of Christianity from the first, with a great variety of subsequent books referring to the transactions recorded in the four Gospels, and containing accounts of the effects which flowed from the belief of those transactions,—those subsequent books having been written with very different views, “so disagreeing as to repel the suspicion of confederacy, and yet so agreeing as to show that they were founded in a common origin.”

5. A mark of historical truth, although only to a certain degree, is *particularity* in names, dates, places, circumstances, and in the order of events preceding or following the transaction. The gospel history, in this respect, affords extraordinary facilities for detecting its falsehood if it were an imposture, and it has stood the test most triumphantly.

6. We lay out of the case stories of supernatural events upon which nothing depends, and in which no interest is involved,—stories which require only an indolent assent, and which pass from one to another without examination.

7. We lay out of the case those miracles which were performed in confirmation of opinions already adopted. It is easy to account for the reception of those alleged miracles which go to support a system of religion already established; but Christianity is the only religion that was ever introduced—and introduced among enemies—by miraculous pretensions. (See Whately's *Introductory Lessons*.) The miracles recorded in the gospel history “were wrought in the midst of enemies, under a government, a priesthood, and a magistracy decidedly and vehemently adverse to them and to the pretensions which they supported. They were Protestant miracles in a Popish country; they were Popish miracles in the midst of Protestants.” They made converts among those who were most unwilling to credit these evidences, and who, in consequence of believing them, were required to abandon their most deeply-rooted opinions and inveterate prejudices.

8. We lay aside all those events which can be accounted for by a heated imagination, false perception, momentary insanity, or any other natural principle. But the miracles of Christ cannot be accounted for in any such way, or be resolved into the operation of the common powers of nature. When a person born blind was restored to sight, or the deaf and dumb to hearing and speech, or a man who had been dead four days was restored to life, we are sure that such events must be ascribed to a superhuman cause. (Paley's *Evidences of Christianity*; Douglas's *Criterion of Miracles*; Leland's *Deistical Writers*; Campbell *On Miracles*. (J. T.—R.)

MIRAMICHI, a river of North America, the second in size of those of New Brunswick, is formed by two branches, called the N.W. and the S.W. Miramichi respectively; and after a course of about 100 miles, falls into the Gulf of St. Lawrence, forming by its estuary the Bay of Miramichi. The banks of the river and the adjacent country are covered with pine forests; and timber is exported in large quantities from the river and bay. The mouth of the Miramichi is impeded by a sand-bar; but there is sufficient depth of water for vessels of 600 or 700 tons; and the river is navigable for a distance of 40 miles from its mouth. The most important towns on its banks are Newcastle and Chatham. The bay is about 20 miles wide at its mouth, and stretches inland for 21 miles. It contains several islands, the principal of which are Fox Island and Portage Island.

MIRANDA, DON FRANCISCO, the founder of the independence of Spanish America, was descended from a noble family, and was born at Caraccas, in South America, about the middle of the eighteenth century. He early began to meditate the liberation of his country. While holding the

commission of colonel in the Spanish service, he endeavoured to excite a revolution among the soldiers. His designs, however, were detected, and he was forced to flee into exile. After he had travelled through several European countries, acquiring their respective languages, liberalizing his opinions, and receiving encouragement in his patriotic aspirations from the leaders of the English opposition and others, he settled at St Petersburg. The Russian empress, Catherine II., patronized him, and pressed him to enter her service. But Miranda had for some time been observing in the French revolution the outburst of a freedom that might yet extend to his native country. He therefore repaired to Paris in 1790, was recommended by Pitt to Péthion, and was appointed a major-general by the Girondists. In this capacity he attended Dumouriez in his campaign against the Prussians. Yet in spite of his native sagacity, and his skill in strategy and engineering, he was foiled in his attempt to take Maestricht, and was defeated, along with his superior in command, at the battle of Neerwinden, in 1793. For the latter of these disasters, Miranda was blamed by Dumouriez, and was arraigned before the revolutionary tribunal. But after a trial of eleven days he was acquitted by the unanimous verdict of the jury. The fall of the Girondists, about the same time, left him exposed to the malice of the Mountain party. He was impeached before the Directory on the eighteenth Fructidor, and would have suffered transportation had he not opportunely contrived to escape into England. His return to France in 1803 was met by a verdict of banishment from the government of the First Consul. Miranda now began to use more direct measures for effecting the favourite project of his life. In 1806 he set sail from New York in a vessel manned by volunteers. After chartering two schooners at St Domingo, he was approaching the shore of his native country, when he was stripped of his late reinforcement by Spanish cruisers, and escaped with difficulty in his own vessel. On landing at Venezuela in the month of August, he was received with cold indifference by the inhabitants, and was forced to re-embark. A more successful attempt was made in 1810, and resulted in 1811 in the triumph of republican principles. But the friends of the Spanish monarchy gained the ascendancy in the following year, and obtained possession of General Miranda. In utter violation of the conditions on which he had surrendered himself, he was conveyed to Spain, and cast into the dungeons of the Inquisition, where he died in 1816.

MIRANDA, *Saa de*, an eminent Portuguese poet, was born of a noble family at Coimbra in 1495. Destined by his parents for the legal profession, he studied law, and was appointed professor of jurisprudence in his native city. But no sooner had his father died, than he threw up his appointment, and resigned himself to the far more congenial pursuit of poetry. A lengthened visit which he then paid to Spain and Italy was the cause of his introducing a new and striking feature into the literature of his country. On his return he began to publish eclogues in the Spanish language, and in the forms of the Italian poets Dante and Petrarch. He was thus the introducer of the Italian style into Portuguese poetry, and of the custom which led many of the subsequent poets of his native country to write in the language of Spain. Saa de Miranda was greatly esteemed and liberally patronized during his lifetime. He held an appointment at the court in Lisbon, until a quarrel with some nobleman forced him to resign it. With no great reluctance he repaired to his country seat near Ponte-de-Lima, in the hope of spending the rest of his days in rural amusements, domestic enjoyments, and the cultivation of his genius. For some time his expectation was not disappointed. From the fondness he manifests of introducing into his poetry rural pictures and rural allusions, we may imagine how pleasantly his days would glide past amid the sights and

Miranda.

Mirandola ||
Mirecourt ||
sounds of the country. But the death of his son in 1553 cast a shadow over this pleasant scene. The loss of his wife soon afterwards surrounded his existence with a settled gloom; and he died in 1558 of a broken heart. Besides eclogues, Saa de Miranda wrote two dramas in the style of Macchiavelli and Ariosto, and several lyrics and poetical epistles. As a writer of the language of Spain he occupies a high position among the authors of that country. His compositions in his native language also place him in the first rank of Portuguese poets. Of the many editions of his works, that of 1614 is the best.

MIRANDOLA, GIOVANNI PICO DELLA, Count and Prince of Concordia, one of the most brilliant scholars of his day, was the youngest son of Gianfrancesco della Mirandola, and was born in 1463. After receiving his elementary education from his mother, and astonishing every one by the precocity of his talents, he was placed at Bologna at the age of fourteen to study the canon law. In the course of two years, however, he abandoned this branch of knowledge in disgust, and turned with eager delight to philosophy and theology. The next seven years were spent by him in visiting the most celebrated universities of France and Italy, in sitting at the feet of eminent professors, in entering the lists against the most redoubtable controversialists, and in the most assiduous private study. His memory was now so tenacious that it retained every fact that was presented to it; his elocution was fluent and forcible; and his mind could unravel the most intricate problems with unflinching tact and rapidity. Thus equipped with his extensive acquirements and ready talents, Mirandola appeared at Rome in 1486 as a controversial champion. Propounding as the subjects of debate 900 theses on every possible branch of knowledge, he threw down the gauntlet to the whole learned world. At the same time he promised to defray the expenses of all those disputants who should come from a distance. No one responded to his challenge. His puerile vanity, however, was not suffered to enjoy this triumph long. Some dignified individuals, disgusted with the self-conceit, and envying the accomplishments of so young a scholar, accused him before the Pope of advocating heresies in 13 of his propositions. This was the beginning of a persecution which, though resulting in a full vindication of his orthodoxy, humbled his vanity and deepened his devotional feelings. He now renounced the study of profane literature, threw into the flames five books of amatory poems which he had composed in Italian, and devoted all his time to investigations into religion and the Platonic philosophy. To reconcile the tenets of Plato with those of Aristotle became his favourite attempt, and is the object of his treatise *De Ente et Uno*. The latter part of his life was spent at Florence in the midst of his books, in the enjoyment of a liberal fortune, and in daily intercourse with the most enlightened men of that time. He was cut off at the age of thirty-two in 1494. His collected works, published at Basel in 1601, contain treatises on the Lord's Prayer, the Kingdom of Christ, the 15th Psalm, the Rules of a Christian Life, &c. A Life was prefixed to his works by his nephew and pupil Gianfrancesco Pico Mirandola. More valuable, however, is the biography by the Rev. W. Parr Gresswell, 8vo, Manchester, 1805.

MIRECOURT, a town of France, in the department of Vosges, on the Madon, 17 miles N.W. of Epinal. It is irregular and ill built, but is pleasantly situated, and adorned by several fountains. It has a civil tribunal and one of commerce, and a library containing 7000 volumes. The principal manufacture is that of musical instruments, for which the town is somewhat noted. In the town and neighbourhood are about 20 establishments, giving employment to more than 6000 hands, and producing annually upwards of a million of violins, guitars, organs, and other musical instruments. Lacemaking, embroidery, and similar occupa-

tions are also extensively carried on, and afford employment to many females in the town and surrounding country. Mirecourt has a considerable trade in the produce of these manufactures, and in wines and cattle. Pop. (1851) 5443.

MIREPOIX, a town of France, department of Ariège, on the Lers, 14 miles E. of Pamiers. It is clean and well built, and contains several squares adorned with trees and fountains. It was formerly surrounded by ditches, but these have been filled up, and are now used as boulevards. The principal buildings are,—the parish church, a town-hall, a communal college; an hospital, with several schools attached to it; a handsome stone bridge of seven arches; and a square tower, all that remains of its ancient castle. Coarse woollen stuffs, linen, cotton, flannel, worsted, and soap are manufactured here; and there is a considerable trade in grain, and in the iron which is obtained in considerable quantities in the neighbourhood. Pop. 4476.

MIREVELT, MICHAEL JANSEN, an eminent portrait-painter, was the son of a goldsmith, and was born at Delft in 1568. While a pupil of Blocklandt, he made such rapid progress that he soon rivalled his master. His first works were altar-pieces for some of the churches in his native town. In a short time, however, he turned to the more lucrative vocation of painting portraits, and speedily rose into repute. He was often summoned from his settled residence at Delft to the Hague, to paint the princes of the House of Nassau. The Archduke Albert conferred upon him a considerable pension. In 1625 he was invited to England by Charles I., and would have complied with the request had not the plague been then raging in London. Meanwhile Mirevelt must have been amassing a fair fortune, since the very smallest of his numerous works was sold for no less than 150 florins. He died at Delft in 1641, after he had executed, according to Sandrart, nearly ten thousand portraits. "The portraits of Mirevelt," says Stanley in his *Dutch and Flemish Painters*, "are well drawn, full of expression, solidly coloured, and with a proper degree of finishing without the appearance of labour." Mirevelt's son Peter possessed some merit as a portrait-painter.

MIRGOROD, a town of Russia, in the government of Poltawa, situated on the Khorol, about 50 miles N.W. of the town of Poltawa. It contains three churches, and is the principal seat of the ecclesiastical dignitaries of the government. It has an extensive trade in earthenware and other articles; and five annual fairs are held here, which are of considerable importance. Pop. (1852) 8951.

MIRROR. See OPTICS, and BURNING-GLASSES.

MIRZAPORE, a town of Hindustan, and the principal place of the district of the same name. It is situated at the foot of a range of hills on the south bank of the River Ganges. The town consists of handsome European houses and native habitations, with clusters of Hindu temples crowding the banks of the Ganges, and making a lively appearance when seen from the river. It is one of the greatest inland trading towns in Hindustan, and the depôt of all the cotton from Agra and the Mahratta countries. It has also an extensive manufacture of carpets and some iron-works. Several opulent merchants and indigo planters, both native and European, reside in the town and its vicinity. The travelling distance from Benares is 30 miles. The East India Railway from Calcutta to Delhi passes by this town. E. Long. 82. 38., N. Lat. 25. 6.

The district of which this city is the capital has an area of 5235 square miles, with a population of 831,388, most of whom are Hindus, the Mohammedans being comparatively few. A portion of the tract was ceded to the East India Company by the Vizier of Oude in 1775, and the remainder in 1801.

MISENUM (*Capo di Miseno*), in ancient geography, a famous promontory on the coast of Campania, which formed the northern boundary of the *Sinus Cumanus* (Bay of

Mirepoix ||

||
Missions.

Naples). It is said to have derived its name from Misenus, who is represented by one legend as a companion of Ulysses, but by Virgil and others as the trumpeter of Æneas. Towards the close of the Republic its vicinity became a favourite site for the summer residences of the citizens of Rome. There, on the brow of a hill commanding an extensive seaward view, stood the villa of Marius, which afterwards, in the possession of Lucullus, attained to a more than regal magnificence. The promontory is mentioned by Cicero as a resort of the Cilician pirates. In the reign of Augustus its land-locked harbour became the permanent station of the fleet that was entrusted with the defence of the Lower Sea. A considerable town in consequence gradually rose around the port. Pliny the Elder was stationed here in command of the "Classis Misenensis," when he was induced, A.D. 79, to visit that eruption of Mount Vesuvius in which he perished.

MISHNA, a part of the Jewish Talmud, containing the text on which the Gemara is a commentary. (See TALMUD.)

MISKOLCZ, a market-town of Hungary, capital of the county of Borsod, is situated on the Sinwa, at the foot of the valley of Diós Gyor, 25 miles N.E. of Erlau. The town is well built, containing many fine houses and two squares, including a Roman Catholic church and convent, 1 Greek and 2 Protestant churches, a synagogue, several schools, and a county-hall. The inhabitants are chiefly Protestants, and are employed for the most part in agriculture. The town has a large trade in fruit, wine, and a peculiar sort of bread for which the place is famous. Iron of fine quality is extensively mined in the vicinity. Markets are held at Miskolcz weekly; and there are five annual fairs of considerable importance. Pop. (1846) 30,000.

MISSAL, the Roman Catholic book containing the several masses which are said on particular days. (See MASS.)

MISSIONS, RELIGIOUS. It is impossible within the limits of our article to give even a hasty sketch of those great religious movements which have exercised their influence at the dawn of every civilization on the face of the globe, and have done more to change the features of national life than the sword of kings or the scourge of conquerors. The civilization of Egypt can be traced upwards to sacerdotal colonies, slowly effecting a religious revolution, and prosecuting missionary work from centres of religious influence which at first were isolated and weak. From these religious schools swarms of colonists, chiefly priests, migrated into other lands and planted a sacerdotal civilization wherever they went. Not dissimilar in kind was the advance of the Brahmins over India, spreading by colonies and conquest a religious culture not indigenous to the country; and the progress of the Buddhists, who disseminated a foreign creed as far as Japan and Central Asia. In the traditions of many barbarous nations there is a floating recollection of religious change, and of a time when their present worship was adopted by their ancestors as an improvement, at the suggestion of teachers from some other clime. Unlike the forms of worship that rose and fell around it, Judaism seems to have made few converts in the days of its prosperity; and when its doctrines became known in the Western World by means of the dispersions, it was the internal tenacity of the system, and not its expansive power, that gave it a missionary character. The Jewish colonies, although they commanded respect from their heathen neighbours, served as little more than stepping-stones conveniently placed for the spreading of Christianity when it should be revealed. From the Greek tongue and the Greek race Christianity borrowed the great machinery of its speedy diffusion. Even in the East its chief seats were the Greek colonies, and from them "it spread into China and Tartary, and from its ancient success in these quarters kept in suspense the emperors who wielded the sceptre of Zengis, whether they should desolate the world with the sword in the one hand and the Koran or

Missions.

the Bible in the other." In apostolic times the choice long hung trembling in the balance whether the efforts of the first preachers were to be directed to the East or to the West; and to the operation of a few seemingly trivial causes we owe it that western Christianity is now carrying its gospel to the East, instead of missionary societies in Tartary sending their agents to convert the savages of Britain.

Under the supremacy of Rome much more might have been expected of the popes for the diffusion, if not of religion, at least of tenets that were favourable to their own interest and sovereignty, than was actually performed by them. Their attention was too much distracted by the quarrels of nominal Christendom, and the more tempting opportunities of increasing their power at home at the expense of Christian kings, to enable them to look steadily and far abroad, or to form any settled plan for extending their spiritual dominion over foreign nations. Another obstacle presented itself; the Papists were inferior in knowledge to the Moslem; the Greek church might boast of some superior civilization, but the Franks were despised by the Saracens for their ignorance and barbarity, as well as held in abomination for their gross idolatry. Their missions, therefore, were there chiefly confined to tribes of kindred and German origin, whose conversion was facilitated by the greater number of their own tongue and blood having already submitted to the papal sway.

But if the popes did little in comparison with their resources, individuals did much. The mission of St Patrick to Ireland may compare in zeal and in success with whatever had been undertaken for the spread of Christianity since the times of Constantine; and its effects were not confined to Ireland, but spread over Scotland and the north of England, and reached even to Germany. The popes, indeed, when aroused by the fear of a Tartar invasion, despatched an ill-contrived and hopeless mission to the sovereigns of Tartary, in order to avert the danger which threatened Europe, by converting them; but any real and disinterested zeal throughout the dark ages is chiefly to be found in individuals who, like the ingenious but fantastical Raymond Lully, were meditating plans for extending religion whilst the rest of the Christian world were careless and asleep.

The Reformation gave a revival to Popery itself; and as the Carthaginians sought to regain the resources which they had lost nearer home by founding a new empire in Spain, so the Roman Catholics endeavoured to counterbalance the loss of the third of Europe by extending the spiritual dominions of the church over the regions of the boundless and populous East. Of all religious revivals, the Reformation least abounded in missionary efforts, because in its origin and spread it was least of all dependent on the personal exertions of missionaries. It was the first great manifestation of the power of printing, and for a time so new and mighty an engine seemed to supersede all other exertions. It is true that so early as September 1556 fourteen Swiss missionaries took their departure from Geneva for Brazil, and the example was followed by many of the Reformed Churches; but not till the Reformed faith had suffered a long eclipse and been again restored to vigour, were any commensurate efforts made to carry the gospel to heathen territory. In modern times the scale of missionary effort has rapidly risen, until at the present moment there are few sects of Christians, however weak, who do not bestow some of their activity on this work. Instead of entering into particular details, which must be sought for in the lives of eminent missionaries given in this work, we prefer to begin our survey by a comprehensive table, containing a list of the principal missionary bodies, the sphere of their missions, the number of communicants reported as belonging to their churches, and of scholars attending their schools.
